33 **Abstract**

34 Tundra environments are experiencing elevated levels of wildfire, and the frequency is expected to keep
35 increasing due to accelerating climate change in the Arctic. Tundra wildfires can release globally significant
36 amounts of greenhouse gasses that influence the Earth's radiative balance. Here we develop a novel method for
37 estimating carbon loss and the resulting radiative forcings of gaseous and aerosol emissions from 2015 tundra
38 wildfires in the Yukon-Kuskokwim Delta (YKD), AK. We paired burn depth measurements using two vegetative
39 reference points that survived the fire event —*Sphagnum fuscum* and *Dicranum spp.*— with measurements of local
40 organic matter and soil carbon properties to estimate total ecosystem organic matter and carbon loss. We used
41 remotely-sensed data of fire severity from Landsat 8 to scale our measured losses to the entire fire-affected area,
42 with an estimated total loss of 2.04 Tg of organic matter and 0.91 Tg of carbon, and an average loss of 3.76 kg m⁻²
43 of organic matter and 1.68 kg m⁻² of carbon in the 2015 YKD wildfires. To demonstrate the impact of these fires on
44 Earth's radiation budget, we developed a simple but comprehensive framework to estimate the radiative forcing
45 from Arctic wildfires. We synthesized existing research on the lifetime and radiative forcings of gaseous and
46 aerosol emissions of CO₂, N₂O, CH₄, O₃ and its precursors, and fire aerosols. The model shows a net positive
47 cumulative mean radiative forcing of 3.67 W m⁻² using RCP 4.5 and 3.37 W m⁻² using RCP 8.5 at 80 years post-fire,
48 which was dominated by CO₂ emissions. Our results highlight the climate impact of tundra wildfires, which
49 positively reinforce climate warming and increased fire frequency through the radiative forcings of their gaseous
50 emissions.

51 **1 Introduction**

52 The Arctic region is characterized by permafrost soils with low rates of decomposition and high carbon
53 content from millennia of positive net ecosystem production (NEP; Lindgren et al., 2018). As a result, there is more
54 than twice as much carbon stored in permafrost soils as there is in the atmosphere, including roughly 1,035 ± 150 Pg
55 of carbon in the top three meters of soil (Schoor et al., 2015). Surface air temperatures in the Arctic have been
56 increasing more than twice as fast as the global average since the mid-20th century (Cohen et al., 2018) and are
57 expected to continue increasing with more variable precipitation (IPCC, 2021; Hu et al., 2015). Changing
58 environmental conditions will place some of this large carbon stock at risk for release into the atmosphere through
59 increased biological activity and wildfire (Natali et al., 2019, Natali et al., 2015, Rocha et al., 2011a, Hu et al.,
60 2010).

61 Fires are an increasingly important component of tundra carbon cycling. Fires are becoming more frequent
62 in Arctic systems due to increasing occurrences of hot and dry conditions coupled with more lightning ignitions
63 (Chen et al., 2021, Bieniek et al., 2020, Veraverbeke et al., 2017). For example, the 2007 Anaktuvuk River megafire
64 on the North slope of Alaska occurred during an especially hot and dry period and released an amount of carbon
65 similar in magnitude to annual sequestration across the entire tundra biome (Mack et al., 2011). Continued and
66 potentially accelerated rates of warming are expected to further increase the frequency of tundra wildfires, thereby
67 releasing significant amounts of carbon and altering the net carbon balance of the tundra biome (Hu et al., 2015).

68 A recent body of literature indicates the potential to estimate wildfire carbon emissions in boreal forests by
69 linking geospatial predictors, most prominently satellite-derived estimates of fire severity and extent, with *in situ*
70 measurements of carbon loss (e.g. Dieleman et al., 2020, Walker et al., 2018b, Veraverbeke et al., 2015, and Rogers
71 et al., 2014). Despite increasing incidence of tundra wildfires, these studies have primarily focused on boreal forests,
72 and few estimates are available for tundra (Mack et al., 2011). Whereas satellite-derived fire extent and severity is
73 widely available, representative *in situ* measurements of tundra wildfires are not. *In situ* measurements of fire
74 effects on tundra organic soils are challenging due to a lack of reference points (e.g., adventitious roots) that survive
75 the fire, which are used to estimate pre-fire organic matter depth and content (Walker et al., 2018a, Rogers et al.,
76 2014, Boby et al., 2010). Measurements of organic matter loss must also be region-specific because of differences
77 in vegetation and soil properties (Walker et al., 2020c, Mack et al., 2011).

78 Although carbon loss estimates from Arctic wildfires are important for understanding the impacts of
79 climate change on carbon budgets, radiative forcings from wildfire gaseous and aerosol emissions are needed to
80 properly gauge the impact on the Earth's atmosphere and climate (Huang et al., 2016, Ward et al., 2012, Randerson
81 et al., 2006). Radiative forcings from wildfires depend spatially on fire severity and atmospheric conditions and
82 temporally on changing atmospheric background concentrations in the months, years, and decades following the fire
83 (Huang et al., 2016, Joos et al., 2013). To date, radiative forcings from high-latitude wildfires have been estimated
84 for particular boreal forests (Huang et al., 2016, O'Halloran et al., 2012, Randerson et al., 2006) and within global
85 models (Ward et al., 2012), but not for tundra ecosystems.

86 Here we take a two-step approach to assess the impact of tundra wildfires on carbon budgets and climate.
87 We first developed a method for measuring carbon loss *in situ* in tundra ecosystems, particularly for the 2015 fire
88 season in the Yukon-Kuskokwim Delta, AK. We tested the agreement of multiple pre-fire reference points for

89 estimating burn depth in the field, and combined these estimates with laboratory-measured organic matter and
90 carbon fractions to estimate emissions. We then used 30 m remotely-sensed fire severity data (differenced
91 Normalized Burn Ratio, or dNBR) from Landsat 8 to scale our measurements to the entire fire area. Finally, we
92 estimated the long-term radiative forcings of the fire's gaseous and particulate emissions, including long-lived
93 greenhouse gasses, ozone, ozone precursors, and aerosols, using a variety of published algorithms and arctic-specific
94 parameters when available.

95 **2 Materials and Methods**

96 **2.1 Study Area**

97 Field measurements were collected in the summer of 2019 in a burn scar from the 2015 fire season in the
98 Yukon-Kuskokwim Delta, AK (YKD) (Fig. 1). Base camp was situated at 61.2632 °N, 163.2458 °W, approximately
99 95 kilometers northwest of Bethel, AK, accessible by float plane and helicopter. Sampling was done within about
100 an 11-kilometer radius of the base camp (Fig. 1c). Measurements from the field were scaled to all fire scars in the
101 YKD that burned in 2015 (Fig 1b).

102

103
104 **Figure 1.** (a) The location of the YKD within Alaska, (b) the areas of fires in 2015 within the YKD, and (c) the
105 locations of our vegetative reference point height transects in burned and unburned areas within about an 11 km
106 radius from base camp. Sources: Esri, DigitalGlobe, GeoEye, i-cubed, USDA FSA, USGS, AEX, Getmapping,
107 Aerogrid, IGN, IGP, swisstopo, and the GIS User Community.

108
109 The YKD contains tussock-sedge, dwarf-shrub, and lichen and moss tundra communities over ice-rich
110 permafrost peat plateaus (Raynolds et al., 2005). These peat plateaus were the primary land component burned in
111 the wildfires and were separated by fens, bogs, and open water. Within our sample area, lichen was the dominant
112 vegetation type (Frost et al., 2020), shrubs were interspersed across the landscape, and tussocks were rare. Soil is
113 predominantly organic (Jorgenson et al., 2000), which has accumulated over sand deposits from the Pleistocene
114 period (Shaw, 1998).

115 2.2 Vegetative marker height measurements

116 We measured the height of vegetative reference points above the surface in both unburned and burned
117 areas. Three main dominant surface vegetative reference points were available: *Sphagnum fuscum*, *Dicranum spp.*,
118 and *Eriophorum vaginatum* (tussocks; similar to the methods of Mack et al. (2011)). *S. fuscum* moss appeared in

119 large mats. *Dicranum* moss appeared in small dense patches. All vegetative reference points were particularly
120 conspicuous in burned areas as they were elevated above the burned surface (Fig. 2). In the burned area, we
121 measured the distance from the soil surface to top of the living parts of the vegetative reference points, which we
122 assumed to indicate full survival in the fire event. We did not measure dead remnants of vegetative reference points,
123 because we expect that these may not represent the actual pre-fire vegetation height.

124
125 **Figure 2.** An example burn depth measurement from the surviving top of a *Dicranum spp.* moss patch (red arrow;
126 pink string) to the top of the soil (blue arrow) in a burned transect. Transect tape was used to measure distance
127 between the moss patches.
128

129 We measured the average height along a transect between two like reference points. At the highest living
130 point on each moss patch, or to the top of the corms at the base of a tussock, we inserted a nail (red arrow, Fig. 2).
131 We ran a taut piece of string between the two nails (Fig. A1). In between the edges of the moss patch or tussock
132 pair (Fig. A1), we took height measurements vertically from the string to the ground, which was soil in the burned
133 areas (blue arrow, Fig. 2) or a dense vegetative surface in the unburned areas (Fig. A2). In between the starting and
134 ending point measurements on the transect we recorded height every 25 centimeters (Figs. A2 and A3). The starting
135 and ending points were never greater than 50 centimeters from the nail. Latitude and longitude were recorded at all
136 transects with an accuracy of three meters (Fig. 1) for ground-truthing remotely sensed burn severity categories.

137 One potential source of error is post-fire subsidence between the vegetative reference point pairs that may
138 bias the relative height of a vegetative marker above the surface (Jones et al., 2015). We minimized this potential
139 bias by maintaining transect lengths less than four meters, and predominantly one to two meters in burned areas.
140 We also visually assessed the area between each vegetative marker for signs of subsidence including cracked soil or
141 large elevation differences and chose not to sample these areas. Measuring from the top of one vegetative marker to
142 the top of another marker controlled for slopes and larger landscape elevation features because the string largely
143 mimicked the angle of the landscape.

144 We selected transects for height measurements opportunistically in the burned and unburned areas.
145 However, we tried to maximize spatial separation between transects and target visually identifiable areas of varying
146 burn severity. We corrected for spatial autocorrelation biases between transect averages in our statistical analyses
147 (see below). In unburned areas we maximized the number of transects measured for each vegetative reference point,
148 *Sphagnum* (n = 38), *Dicranum* (n = 40), and *Eriophorum* (n = 19).

149 Each burn depth measurement was associated with a dNBR value based on the 30 m pixel containing its
150 centroid. Burn depth measurements that came from the lowest third, middle third, and upper third of dNBR values
151 were considered to be in low, moderate, and high severity burned areas, respectively and a roughly even numbers of
152 transects were sampled in each burn severity category for *Sphagnum* (n = 56: high n = 20, med n = 17, low n = 19),
153 *Dicranum* (n = 54: high n = 18, med n = 17, low n = 19), and *Eriophorum* (n = 24: high n = 7, med n = 11, low n =
154 6).

155 **2.3 Organic matter and carbon pool measurements**

156 We calculated the total ecosystem organic matter and carbon pool sizes in unburned areas surrounding the
157 fire scar. We took vegetation and soil samples together in cores using a hand drill and hollow metal drill bit that was
158 30 centimeters in length and six centimeters in diameter. Cores were extracted at three points (start, middle, and
159 end) along transects between like vegetative reference points. We selected four sites of less than half a hectare
160 surrounding areas where we took our unburned vegetative reference point height measurements. These sites were
161 selected opportunistically to ensure the presence of an appropriate number of each of the three vegetative reference
162 points. In each site, we extracted cores from three transects per vegetative reference point pair, which totaled 27 soil
163 cores per site. In one site we found only two tussock pairs, so our total number of samples was 105. We maximized
164 physical separation of the unburned sites to control for heterogeneity in local soil and vegetation characteristics.

165 We measured the height of the live vegetation layer and fibric soil horizons for each core. Vegetation
166 layers and soil horizons were identified visually by soil density, texture, color, and identifiable plant parts. Each
167 core was separated into vegetation and fibric soil layers that were homogenized, weighed, and subsampled in the
168 field, and subsequently stored frozen until analyzed. In the lab, each vegetation sample and approximately 15 grams
169 of each fibric sample were dried for 48 hours at 60 °C and weighed to determine soil water content. We used the
170 proportion of dry mass to wet mass to estimate the dry weight of the field sample, which was used to determine bulk
171 density ($\text{g dry mass cm}^{-3}$). Soil samples were combusted for five hours at 450 °C to determine organic matter
172 content and analyzed for percent carbon using an Elementar Vario Max CN analyzer at the Woodwell Climate
173 Research Center, Falmouth, MA. We assumed the dry mass of the vegetation layer was fully organic matter. Using
174 the average across all herbaceous plant organs, we assumed the carbon content of the vegetation layer was 43.04%
175 from Ma et al. (2018). To calculate organic matter and carbon pools (kg m^{-2}) for each organic soil sample, we
176 multiplied bulk density by the height of the layer and percent organic matter or percent carbon, respectively. These
177 values were normalized for each sample to the average depth of the vegetation layer, which was seven centimeters,
178 and 10 centimeters in the fibric horizon.

179 **2.4 Fire severity**

180 We used a remotely sensed metric of fire severity from Landsat 8 Tier 1 surface reflectance imagery: the
181 Difference Normalized Burn Ratio (dNBR; Eq. 1; Key and Benson, 2006), which is based on the Normalized Burn
182 Ratio (NBR; Eq. 2). Clouds, cloud shadows and snow were masked from all images using the provided pixel quality
183 attributes generated from the CFMASK algorithm. Imagery for this index was acquired as the mean Landsat 8
184 composite between June 1st and August 31st for one year pre- and one year post-fire, and for all fire scars. All
185 remotely sensed variables were extracted in Google Earth Engine (Gorelick et al., 2017).

$$186 \quad dNBR = (NBR_{prefire} - NBR_{postfire}) \times 1000, \quad (1)$$

$$187 \quad NBR = \frac{(NIR - SWIR)}{(SWIR + NIR)}, \quad (2)$$

188 Where in Eq. (2) NIR is near-infrared (Band 5) and SWIR is shortwave infrared (Band 7).

189 **2.5 Calculating final estimates**

190 We calculated organic matter combustion and carbon loss across the fire area using burn depth derived
191 from the moss reference points (Fig. A4). We excluded estimates derived from tussock measurements because burn
192 depth estimates from tussocks correlated negatively with remotely sensed fire severity. Moreover, our sample size of

193 tussock-based measurements was substantially lower than the moss vegetative reference points due to their
194 infrequent occurrence in our study domain (Frost et al., 2020). Excluding tussock measurements required
195 reassigning dNBR values evenly as before across only *Dicranum* (n = 54: high n = 18, med n = 18, low n = 18) and
196 *Sphagnum* (n = 56: high n = 20, med n = 18, low n = 18) reference points. The highest dNBR values in the low and
197 moderate severity categories became the threshold values for low to moderate and moderate to high severity burn,
198 respectively. We split the fire area, based on these thresholds, into the three categories for burn severity. There
199 were 130.01 km² of low severity burn, 85.16 km² of moderate severity burn, and 326.37 km² of high severity burn,
200 which summed to 541.54 km² of total fire area (Fig. A5).

201 For final analysis of organic matter and carbon loss, we averaged the height of *Sphagnum* and *Dicranum*
202 reference points in the unburned areas to determine one height for each reference point, since their respective
203 heights were statistically different ($p < 0.001$). Burn depth was calculated at each transect in the burned areas by
204 subtracting the standard unburned height from the transect average height. We also averaged the dry organic matter
205 and carbon pool within the vegetative layer and fibric horizon separately across *Sphagnum* and *Dicranum* reference
206 points to determine one pool size for our sampling area.

207 Average organic matter or carbon loss (kg m⁻²) was estimated as the product of the organic matter or carbon
208 concentrations and depth of the vegetation and soil that burned at each burn depth transect. Average loss at each
209 transect was the sum of loss from each horizon. For our final calculation of total dry organic matter and carbon loss,
210 we averaged the organic matter and carbon lost across transects for *Sphagnum* and *Dicranum* reference points within
211 each fire severity category. Over the landscape, total carbon or organic matter released was calculated by
212 multiplying average carbon or organic matter loss for a given burn severity category by the total burned area for that
213 category. Total carbon or organic matter released was then calculated as the sum from all three burn severity
214 categories.

215 **2.6 Radiocarbon**

216 We used radiocarbon dating to confirm our burn depth measurements by comparing the radiocarbon age of
217 *Sphagnum* macrofossils on the burned soil surface with the radiocarbon age of *Sphagnum* macrofossils at different
218 depths of the unburned soil profile, similar to the methods of Mack et al. (2011). In the field we extracted one
219 unburned core and three burned cores of the same dimensions as our primary soil cores, described above. We
220 extracted a one-centimeter thick subsample of the cores every five centimeters in depth and froze the samples in a

221 sealed plastic bag until lab analysis. To construct an age profile, we analyzed unburned cores at depths of five to 20
222 centimeters for radiocarbon age. We assumed that a depth of zero centimeters had carbon from the time of harvest
223 in 2019. In the burned cores, we analyzed the zero-centimeter depth (i.e., surface) for radiocarbon.

224 In the lab, we visually identified *Sphagnum* branches in each of the subsamples being tested and rinsed
225 them with deionized water. The branches were then dried for 48 hours at 60 °C, and roughly five milligrams of dry
226 branch matter per sample was sent to the W.M. Keck Carbon Cycle Accelerator Mass Spectrometry Laboratory at
227 the University of California Irvine for the ¹⁴C content and δ¹³C. Results for ¹⁴C analysis are reported as the fraction
228 modern, which is defined as the ratio of the sample's carbon isotope ratio to that of a standard (Reimer, 2004).
229 Fraction modern values are calibrated to calendar years using OxCal online 4.4.1 (Ramsey, 2009), with the
230 appropriate modern era bomb curve taken from Hua et al. (2013). Due to the shape of the bomb curve, there are at
231 least two possible calendar years in which the carbon in the sample was fixed. However, we did not use the oldest
232 age for unburned samples with multiple calendar ages because the age of these samples must increase with depth
233 (Walker et al., 2019, Mack et al., 2011), which is not supported when considering the oldest calendar ages.
234 Furthermore, we were confident the burned samples were from the younger age because they were from visually
235 shallow burn depths. We compared the calendar age of carbon at the burned soil surface to age by depth profile
236 taken from the unburned core.

237 **2.7 Radiative forcings model**

238 We created a temporally-explicit model of radiative forcings for gaseous and aerosol emissions of tundra
239 wildfires and used it to compute the radiative forcings per unit burned area, similar to the framework employed in
240 Randerson et al. (2006) and Huang et al. (2016). These equations were derived using the average amount of organic
241 matter lost across fire-wide burn severity classes and vegetative reference points. Our model included the long-lived
242 greenhouse gas species CO₂, CH₄, and N₂O, as well as short-lived climate forcers, tropospheric O₃, O₃ precursors,
243 and aerosols. Ozone precursors include NO_x, nonmethanogenic volatile organic carbons (NMVOCs), and CO.

244 We first used emissions factors from Akagi et al. (2011) to calculate the mass of gaseous and aerosol
245 emissions from our estimated organic matter losses. Emission factors have not been previously defined for tundra
246 burning. Given that boreal forest, whose definition for emission factors includes organic soils, peat, and woody
247 vegetation, is likely the closest ecosystem type in terms of fuel properties to tundra in Akagi et al. (2011), we
248 employed these emission factors. However, we note a possible overestimate of relative contribution from woody

249 vegetation emissions in these numbers due to the relative lack of woody vegetation on the tundra landscape. We
250 converted the mass of each emission to a volume as the molar fraction of the emission to the atmosphere.

251 Once we estimated the mass of each gaseous emission, we calculated the concentration of the gas
252 remaining in the atmosphere and its radiative forcing each year after the fire by synthesizing existing models and
253 research on the lifetimes and radiative forcings of these gaseous emissions. Our calculations of radiative forcing
254 were dependent on the future ambient concentration of greenhouse gasses in the atmosphere. As a result, we
255 calculated the radiative forcings of gaseous emissions for three scenarios: historic, representative concentration
256 pathway (RCP) 4.5, and RCP 8.5. The historic scenario assumes the ambient concentration of greenhouse gasses
257 remains constant in the atmosphere after the fire. Future atmospheric concentrations for each RCP were taken from
258 Meinshausen et al. (2011). The radiative forcing for each gaseous emission per year was calculated separately and
259 then summed across forcing agent. Since O₃ precursors and aerosols had the most uncertain lifetimes and radiative
260 forcings (Bond et al., 2011, Quinn et al., 2008), we calculated the total radiative forcing of the emissions with and
261 without them. A flowchart of our general methodology for the entire radiative forcings calculation is presented in
262 the supplemental information (Fig. A6).

263 **2.8 Methane and Nitrous Oxide**

264 Our radiative forcing calculations for CH₄ and N₂O were based on Ward et al. (2012). For both gasses, we
265 assumed a pulse emission and calculated the concentration remaining in each year after the fire using a simple box
266 model with one outflow as shown in Eq. (3), where C₀ is the initial pulse mass of the gas, t is the number of years
267 after the fire, and L is the lifetime of the gas.

$$268 \quad C = C_0 e^{-\frac{t}{L}}, \quad (3)$$

$$269 \quad L = L_0 \left(\frac{E}{E_t} \right)^{-0.05}, \quad (4)$$

270
271 We used the atmospheric lifetimes for both gasses reported in Myhre et al. (2013). However, we calculated
272 a decreased lifetime of N₂O using Eq. (4) from Ward et al. (2012), as its ambient concentration changed in future
273 emissions scenarios, where L₀ is the initial lifetime of N₂O from Myhre et al. (2013), E is the ambient concentration
274 of N₂O in the year the fire burned, and E_t is the ambient concentration of N₂O at each year after the fire based on the
275 future emissions scenario (Meinshausen et al., 2011). We did not account for the effect of the changing atmospheric
276 concentration on the lifetime of N₂O due to the pulse emission itself.

277 We then calculated the perturbation concentrations of CH₄ and N₂O in the atmosphere each year after the
278 fire as the sum of the remaining pulse emissions and the ambient concentrations and used Eqs. (5) and (6) from
279 Ward et al. (2012) to estimate the radiative forcing of both gasses.

$$280 \quad RF = 0.036(\sqrt{M} - \sqrt{M_o}) - [f(M, N_o) - f(M_o, N_o)], \quad (5)$$
$$281 \quad f(M, N) = 0.47 \ln[1 + 2.01 \times 10^{-5}(MN)^{0.75} + 5.31 \times 10^{-15}M(MN)^{1.52}], \quad (6)$$

282
283 The radiative forcing of the gas at each year was RF, M was the perturbation concentration of the gas
284 whose radiative forcing was being calculated, and M_o and N_o were the ambient concentrations of both gasses
285 depending on which gas's radiative forcing was being calculated.

286 2.9 Carbon Dioxide

287 Carbon dioxide has a highly variable lifetime under different future emissions scenarios depending on the
288 strength of ocean and land sinks. To account for this variation, we used impulse response functions (IRFs) from
289 Joos et al. (2013), which represent the fraction of a pulse of CO₂ remaining in the atmosphere at each year after the
290 pulse for each scenario. For each year post-fire, we multiplied the relevant IRF function by the concentration of
291 CO₂ initially released to estimate the amount of CO₂ remaining in the atmosphere. The radiative forcing for CO₂
292 was calculated using Eq. (7) taken from Myhre et al. (1998), where C is the perturbation concentration and C_o is the
293 ambient concentration of the gas in each year.

$$294 \quad RF = 5.35 \ln \left(\frac{C_o + C}{C_o} \right), \quad (7)$$

295 2.10 Tropospheric Ozone

296 Tropospheric O₃ is created photochemically in the smoke plumes of wildfires by the combination of
297 sunlight and O₃ precursor gasses, and its creation can be expressed as a function of time and the amount of carbon
298 monoxide released (Jaffe and Wigder, 2012). We used data compiled in Jaffe and Wigder (2012), who provided a
299 synthesis of O₃ and its relationship with CO for fire plumes sampled in the Arctic at various times after a fire to
300 calculate a mean plume lifetime and derive a linear relation between plume age and the ratio of O₃ to CO. Because
301 the average plume age sampled was five days, we assumed O₃ was created for five days after the fire. The
302 concentration of O₃ on each of those five days was calculated by multiplying the initial concentration of CO released
303 from the fire (derived from Akagi et al., 2011) by the ratio of O₃ to CO we estimated for that day. After five days,
304 we assumed no more O₃ was created, and we calculated the remaining amount of O₃ after day five using the box
305 model approach from Eq. (3). The concentration of O₃ on day five was C_o, and L was the lifetime of O₃ taken from
306 Myhre et al. (2013).

307 We converted the concentration of O₃ to Dobson units (DUs) and converted from DUs to radiative forcing
308 using a conversion factor from Myhre et al. (2013) each day after the fire. The radiative forcing in each year was
309 the mean radiative forcing of all the days within that year, although the annual forcing was negligible after the first
310 year.

311 2.11 Ozone Precursors and Aerosols

312 We used a method based on global warming potential (GWP), similar to Huang et al. (2016), to calculate
313 the radiative forcing of the ozone precursors and the direct aerosol effect. GWP is defined as the ratio of the time-
314 integrated radiative forcing of a pulse emission of a gaseous species to the time-integrated radiative forcing of an
315 equivalent emission mass of CO₂ (Joos et al., 2013). GWP is typically calculated for 20- and 100-year time
316 horizons. Here, we use GWPs to determine the warming effect of the precursor and aerosol emissions relative to
317 CH₄ at the 20- and 100-year time horizons, as shown in Eq. (8). We derive the radiative forcings for ozone
318 precursors and aerosols based on CH₄ because the radiative forcing of ozone precursors is through their effect on
319 methane over the long-term (Collins et al., 2013). Furthermore, the radiative forcing of CH₄ has the simplest
320 derivation in our model, so we assume it is the strongest continuous radiative forcing from which to build our
321 continuous model using GWP's.

$$322 R_t = \frac{GWP_{t,x} \times EF_x}{GWP_{t,CH_4} \times EF_{CH_4}}, \quad (8)$$

323 The emissions factor (EF) and GWP are defined for gaseous species x, and the GWP is defined at the time
324 horizon t. For CO and NMVOCs, we interpolate this relative warming effect (R_t) between year one and year 20 by
325 assuming it remains constant. To interpolate this effect between years 20 and 100, we mirror the shape of methane's
326 cumulative radiative forcing curve over that time interval. From this curve we calculated the difference between
327 methane's cumulative radiative forcing at years 20 and 100. We then calculated the fractional decrease of this
328 difference each year between years 20 and 100. We multiplied those fractional decreases by the difference in R_t at
329 years 20 and 100 for CO and NMVOCs to derive a relative warming effect for the precursors. Finally, we
330 multiplied R_t by methane's cumulative radiative forcing curve to estimate the cumulative radiative forcing for each
331 precursor every year after the fire. We used the global GWPs for CO and NMVOCs from Myhre et al. (2013).

332 Since NO_x has a positive GWP at the 20-year time horizon and a negative GWP at the 100-year time
333 horizon, we chose not to mimic the shape of methane's radiative forcing curve when interpolating between the two
334 time points. Instead, we calculate an R_t value for NO_x at year one by scaling R₂₀ in proportion to the change of

335 methane's cumulative radiative forcing from years one to 20. Then we interpolated between the R_t values in years
336 one, 20, and 100 using an exponential decay function of the form $ae^{-bx} + C$, whose coefficients were calculated
337 using the `nls` function in R (R Core Team 2020). We multiplied the R_t value for NO_x at each year by the cumulative
338 radiative forcing of CH_4 in that year to obtain a cumulative radiative forcing curve for NO_x . We use the global
339 GWP for NO_x from Myhre et al. (2013).

340 To calculate the cumulative radiative forcing from black and organic carbon direct effects, we used R_{20} and
341 multiplied this value by the cumulative radiative forcing curve of CH_4 in that year. These were summed to report
342 the aerosol radiative forcing together. Our calculations assume this entire cumulative radiative forcing happens in
343 the year of the fire, as fire aerosols are typically removed from the atmosphere via wet and dry deposition within a
344 matter of weeks (Bond et al., 2011, Quinn et al., 2008). We used the GWPs for black and organic carbon estimated
345 for open biomass burning including the cryosphere effect from Bond et al. (2011). To estimate the indirect aerosol
346 effect, we multiplied the radiative forcing of the direct effect of aerosols each year by the ratio of indirect to all sky
347 direct effect radiative forcing from wildfires defined in Ward et al. (2012).

348 2.12 Statistical analyses

349 All statistical analyses were completed in R (R Core Team 2020) using the `nlme` package (Pinheiro et al.,
350 2020). For the vegetative reference point heights, we created a linear fit model using the `gls` function with average
351 burn depth and height above the dense vegetation layer along the transect as the response variable in the burned and
352 unburned areas respectively. Both models were corrected for spatial autocorrelation between transect locations. We
353 chose the model with the lowest Akaike information criterion (AIC) score across five correlation structures,
354 exponential, Gaussian, linear, rational quadratic, and spherical to be our final model. In burned areas, the model had
355 vegetative reference point nested within burn severity type, while in unburned areas, we only modeled the effect of
356 vegetative reference point type. The model with the lowest AIC score for both burned and unburned areas had a
357 rational quadratic correlation structure.

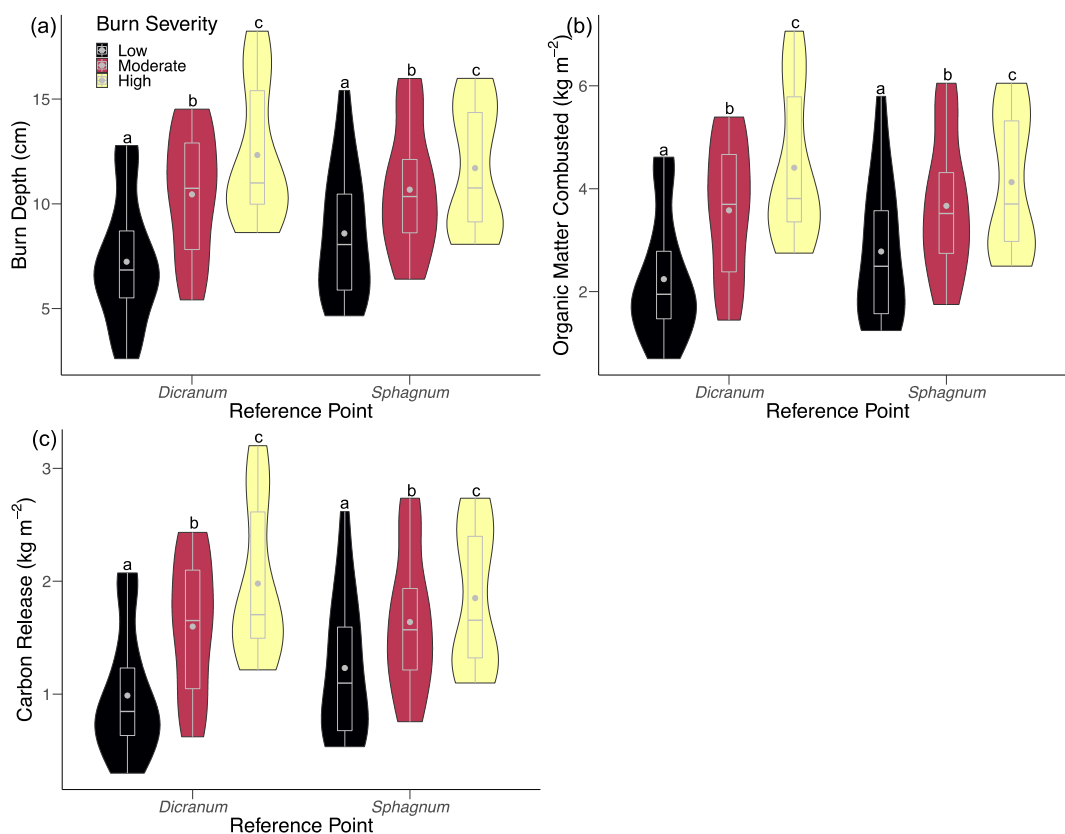

358 To analyze differences in organic matter and carbon pools, height, and bulk density of the vegetation and
359 fibric soil layers we created linear mixed effect models using the `lme` function. These models had the soil or
360 vegetation layer characteristic value for each core as their response variable, vegetative reference point type as a
361 fixed effect, and transect number nested in site as random effects.

362 Finally, we created linear fit models using the `gls` function with organic matter combusted and carbon lost
363 at each transect in the burned areas as response variables with the same structure as the burn depth model. These
364 models had the lowest AIC scores with a rational quadratic correlation structure. An analysis of variance (ANOVA)
365 was used to test for significant differences between groups for all of our models.

366 **3 Results**

367 We found that burn depth measurements were consistent with burn severity classification, and burn depth
368 increased with fire severity (Fig. 3). Based on a two-factor ANOVA with vegetative reference point nested within
369 burn severity, differences in average transect burn depth were significant ($p < 0.0001$) between burn severity
370 categories. The ranges of moderate severity burn depth measurements overlapped substantially with the high and
371 low severity measurements. Moderate severity groups also had the most evenly distributed probability densities
372 across burn depth. *Dicranum* measurements captured the shallowest and the deepest burn depths (Fig. 3).
373 Nevertheless, across both vegetative reference points, there was a clear stepwise increase in burn depth across burn
374 severity classifications.

375
376
377 **Figure 3.** Distributions of average (a) burn depth, (b) organic matter combusted and (c) carbon released per unit
378 burned area per transect within each reference point across burn severity levels. Boxes encompass the middle 50%
379 of data, whiskers are the upper and lower quartiles, horizontal lines intersecting boxes show the median, and gray
380 points are the mean. Letters indicate significantly different groups of data.
381

382 We found no significant differences between vegetative reference point types in terms of mean organic
383 matter pool size, carbon pool size, height, or bulk density for either the live vegetation layer or fibric soil horizon
384 extracted in our unburned cores ($0.3504 < p < 0.9558$).

385 In the unburned areas, the fibric soil horizon (17.9 ± 0.63 cm) was nearly three times thicker than the
386 vegetation layer (6.19 ± 0.60 cm) to the depth that our cores reached (~ 30 cm; Table 1), which is likely an
387 underestimate of the soil organic layer depth, given that our cores only occasionally reached the mineral soil layer.
388 However, there was larger variation in the vegetation layer ($1\sigma = 6.9$ cm) than fibric horizon ($1\sigma = 2.6$ cm) height.
389 In most cases, the fire burned through the vegetation layer, but never completely through the fibric horizon (Fig. 3,

390 Table 1). The fibric layer (to 24.1 cm average) had almost three times greater organic matter and carbon pool sizes
 391 compared to the vegetation layer because of its higher bulk density and height (Table 1).

392 **Table 1.** Bulk density, height, and carbon and organic matter percent and pool sizes of vegetation and fibric layers
 393 measured in unburned soils averaged across reference points. Carbon and organic matter pool measurements are the
 394 product of bulk density and their percent contents and are normalized to the height of the vegetation layer and 10
 395 centimeters in the fibric layer. Sample size is 72, which is equally attributable to the two reference points. Error is
 396 reported as SEM.

Layer	Bulk Density (kg m ⁻³)	Height (cm)	Percent Carbon (%)	Carbon Pool (kg m ⁻²)	Percent Organic Matter (%)	Organic Matter Pool (kg m ⁻²)
Vegetation	26.7 ± 1.4	6.19 ± 0.60	43.04*	0.712 ± 0.037	100*	1.65 ± 0.09
Fibric	54.6 ± 5.0	17.9 ± 0.63	39.41 ± 0.56	2.07 ± 0.16	88.12 ± 1.17	4.48 ± 0.30

397 *Based on assumption

398

399 Carbon and dry organic matter loss estimates similarly increased with burn severity (Fig. 3, Table 2).

400 Based on a two-factor ANOVA with vegetative reference point nested in burn severity, average organic matter and

401 carbon loss differed between burn severity categories (carbon loss: $p < 0.0001$; organic matter loss: $p < 0.0001$) (Fig.

402 3). Similar to burn depth distributions, the moderate severity range overlapped with the high and low severity burn

403 distributions (Fig. 3).

404 **Table 2.** Carbon and organic matter loss averaged within each burn severity category across reference point, and
 405 total carbon and organic mass loss over each burn severity category area. Total loss per burn severity category is
 406 summed to calculate total loss over the total fire area by burn severity classification. Error is reported as SEM,
 407 except for total loss over the fire area which is reported as the sum of errors.

408

Severity	Sample Size	Area (km ²)	Carbon Loss		Dry Organic Matter Loss	
			Average (kg m ⁻²)	Total (Tg)	Average (kg m ⁻²)	Total (Tg)
Low	36	130.01	1.11 ± 0.10	0.144 ± 0.013	2.51 ± 0.22	0.326 ± 0.029
Moderate	36	85.16	1.62 ± 0.10	0.138 ± 0.009	3.62 ± 0.22	0.309 ± 0.019
High	38	326.37	1.93 ± 0.12	0.629 ± 0.039	4.29 ± 0.23	1.40 ± 0.08
Total	158	541.54		0.911 ± 0.039 (Tg)		2.04 ± 0.09 (Tg)

409

410 The 2015 fires burned a total of 541.54 km² in the YKD. Most of the burned area (roughly 60%) was

411 classified as high severity, while moderate and low severity burns accounted for about 16% and 24%, respectively.

412 (Table 2). As a result, total organic matter and carbon loss within the high severity burn classification was over

413 three times greater than the other two burn severity categories. Although moderate severity occupied less fire area

414 than the low severity burn, it contained roughly equal total organic matter and carbon loss due to about 50% higher

415 organic matter and carbon losses per unit area on average. Summing carbon loss and dry organic matter loss over

416 the area of each burn severity category yielded a total loss of 2.04 ± 0.09 Tg of dry organic matter and 0.911 ± 0.039

417 Tg of carbon. This magnitude of total loss corresponded to an average 3.76 kg m⁻² of organic matter and 1.68 kg m⁻²

418 of carbon loss across the fire area.

419 The age of carbon increased by ~50 years from 5 to 20 cm in depth in the unburned area. Surface samples
420 from burned soils in a low severity area were dated to 2009, indicating a burn depth of about 5 cm or less, which is
421 within the range of our low severity burn depth measurements (Table 3). The rate of change in carbon age between
422 0 and 5 cm was 2.4 yr cm^{-1} ; for the 15 to 20 cm interval it was 3.6 yr cm^{-1} . Because none of our burn depth
423 measurements exceeded 20 cm, all carbon released from the fire was relatively new carbon, younger than 64 years
424 of age. Our average burn depth of 10.3 cm across burn severity and reference point indicated an average age of
425 about 23 years for carbon released.

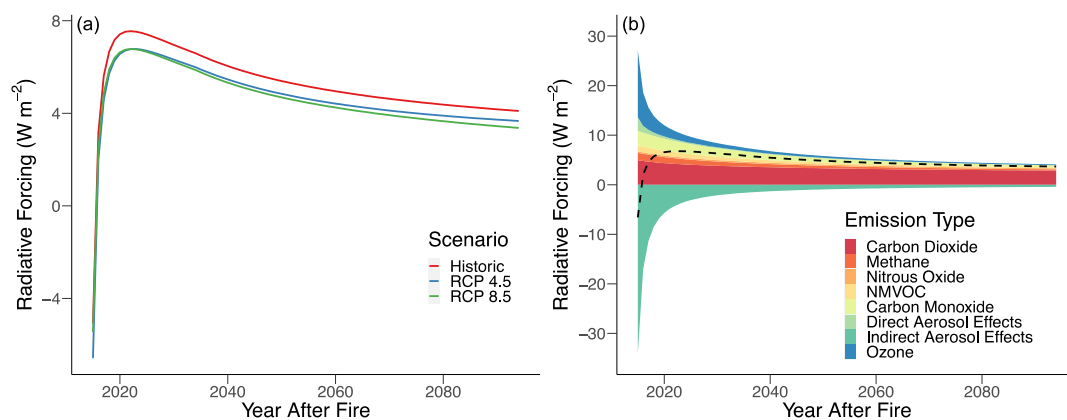

426 **Table 3.** The fraction of the modern standard and calibrated calendar age for each radiocarbon sample. Calendar
427 ages are the intercepts for the fraction modern value with the calibration curve. We do not consider the oldest
428 calendar ages.

Burn Status	Depth (cm)	Fraction Modern	Calendar Ages CE
Burned	0	1.0486 ± 0.0020	1957, 2009
Burned	0	1.0493 ± 0.0024	1957, 2009
Burned	0	1.0403 ± 0.0018	1957, 2008, 2009
Unburned	5	1.0625 ± 0.0020	1957, 2007, 2008, 2009
Unburned	10	1.1198 ± 0.0023	1958, 1996
Unburned	15	1.4603 ± 0.0024	1963, 1974
Unburned	20	1.0124 ± 0.0017	1956

429 The radiative forcing for gaseous and aerosol emissions from the 2015 fire season was positive for 80 years
430 post-fire according to our model, regardless of the future atmospheric gas concentration scenario (Fig. 4a).
431 However, the magnitude of the fire emissions' radiative forcings decreased with increasing ambient atmospheric gas
432 concentrations, with RCP 8.5 having the lowest radiative forcing at 80 years post-fire (Fig. 4a). Given the lack of
433 qualitative difference across future scenarios, below we present results for the RCP 4.5 scenario only (Table 4, Fig.
434 4b). Nitrogen oxides were the only gas with a negative radiative forcing at the 80-year cumulative mean. However,
435 they had a positive radiative forcing at the 20-year time horizon (Table 4). The only other negative radiative forcing
436 came from the indirect effect of aerosols that completely counterbalanced the positive radiative forcing from other
437 gaseous emissions in the first year, but the magnitude of this effect in terms of cumulative integrated forcing
438 diminished rapidly after the first decade (Fig. 4b). CO_2 produced the highest radiative forcing through 80 years
439 (Table 4, Fig. 4b). Nitrous oxide sustained its positive radiative forcing, however the radiative forcing was of
440 intermediate magnitude with respect to all gaseous emissions. In contrast, ozone and carbon monoxide exhibited
441 high radiative forcings, but the magnitude of these diminished rapidly with respect to carbon dioxide. Likewise, the
442 effect of the other ozone precursors, aerosols, and methane decreased relatively rapidly (Table 4). Overall, 20-years
443 post-fire, the effect of ozone precursors increased the total radiative forcing by roughly 11%. However, this percent
444

445 increase drops to 5% after 80 years, and the ozone precursors and aerosols show little effect on the percent reduction
 446 of the total radiative forcing between 20- and 80-years post fire. Therefore, the positive radiative forcing is
 447 sustained by long-lived gaseous emissions, especially carbon dioxide.

448
 449 **Figure 4.** (a) Total cumulative mean radiative forcing of gaseous emissions for three future atmospheric gas
 450 concentration scenarios, and (b) cumulative mean radiative forcing of different emissions (dashed line is net forcing)
 451 under the RCP 4.5 future scenario over 80 years post-fire from the YKD 2015 fire season.

452
 453 **Table 4.** Cumulative mean radiative forcing at 20- and 80- year time horizons post-fire for different greenhouse gas
 454 and aerosol emissions from the 2015 fire season under the RCP 4.5 future scenario. Percent reduction refers to the
 455 loss in radiative forcing when considering an 80-year time horizon compared to 20 years.

Time Horizon	Radiative Forcing ($w\ m^{-2}$)										
	CO ₂	CH ₄	N ₂ O	O ₃	NMVOC	CO	NO _x	Indirect Aerosol Effects	Direct Aerosol Effects	Total with Ozone Precursors and Aerosols	Total without Ozone Precursors and Aerosols
20 years	3.69	0.76	0.28	0.67	0.62	1.51	0.03	-1.71	0.14	5.99	5.41

456
 457 **4 Discussion**

458 Here we show that tundra wildfires release significant amounts of carbon and have a positive warming
 459 effect on the atmosphere due to their gaseous and aerosol emissions over an 80-year time horizon, representing an
 460 under-studied source of global greenhouse gasses under increasingly frequent tundra fire regimes. The 2015 fire
 461 season in the YKD represents a large efflux of carbon from a wetland tundra ecosystem, generally not considered to
 462 be highly vulnerable to fires. In total, we estimate that about 0.911 Tg of carbon was released from 541.54 km² of
 463 burned area in the YKD, which, proportional to size, is roughly equivalent to the 2.1 Tg of carbon released from the

464 1,039 km² of burned area in the 2007 Anaktuvuk River fire reported by Mack et al. (2011). While the current status
465 of tundra ecosystems as a sink or source of carbon remains uncertain, the 2015 YKD fire season alone released
466 about a tenth of the carbon sequestered annually from tundra sink estimates (Virkkala et al., 2021). If tundra
467 ecosystems become a source of carbon to the atmosphere under warming, emissions from tundra wildfires may
468 further exacerbate this positive feedback to warming due to a changing balance between respiration and productivity
469 (Natali et al., 2019, Belshe et al., 2013). Note that we did not account for post-fire effects on net ecosystem
470 exchange of CO₂, which tend to be sources to the atmosphere with greater fire severity due to continued soil
471 respiration until sufficient vegetation recovers (Rocha and Shaver 2011a).

472 On average, both the tundra fires in the YKD and at Anaktuvuk River lost roughly 1.7 to 2.0 kg m⁻² of
473 carbon (Mack et al., 2011). Carbon loss per area from tundra wildfires are within the range of total above- and
474 belowground carbon loss from boreal wildfires, approximately 0.5 to 4 kg m⁻² (Walker et al., 2020a; Walker et al.,
475 2018b; Rogers et al., 2014), and close in value to the median wildfire loss of carbon, 2.54 kg m⁻², across all land
476 cover types in Alaska between 2001 and 2012 (Veraverbeke et al., 2015). Despite the additional combustion of
477 overstory vegetation in forests, carbon loss in both tundra and boreal systems comes primarily from belowground
478 organic matter (Walker et al., 2020a; Walker et al., 2018b; Rogers et al., 2014). While carbon loss per area of
479 tundra wildfire is similar to boreal wildfires, information on carbon emissions from tundra wildfires is substantially
480 more limited than boreal forest studies (He et al., 2021; Veraverbeke et al., 2021).

481 Given a fire return interval in the YKD of over around 200 years (Sae-Lim, 2019), fires there likely do not
482 burn through all the carbon accumulated since the last fire. However, tundra fires may initiate post-fire successional
483 trajectories, such as increased shrub cover, that may promote shorter fire return intervals (Hu et al., 2015; Rocha et
484 al., 2012). Shorter fire return intervals, in turn, gradually deplete the available soil carbon stocks. For example, He
485 et al. (2021) showed current tundra areas with frequent fire have relatively shallow soil organic layers. Moreover,
486 our radiocarbon data show that as fires burn deeper into the tundra, they release older carbon more rapidly because
487 the density of carbon by age increases. Coupling these burn-prone successional trajectories with projected increases
488 in tundra wildfire occurrence over the next century due to more frequent hot and dry conditions (Hu et al., 2015;
489 Rocha et al., 2012; Joly et al., 2012; Hu et al., 2010), as well as increases in lightning (Chen et al., 2021; Bieniek et
490 al., 2020; Veraverbeke et al., 2017), tundra wildfires may begin to burn carbon of an older age than the historic fire

491 return interval and hence transition some tundra regions into fire-driven carbon sources, similar to what has been
492 observed in North American boreal forests (Walker et al., 2019).

493 Immediate combustion is not the only impact wildfires have on tundra carbon stocks, nor do measures of
494 carbon loss fully describe the effect of wildfire emissions on the climate. Fires drive higher soil temperatures and
495 deeper active layer depths that can persist over multiple decades after fire (He et al., 2021; Hu et al., 2015; Rocha et
496 al., 2012), which is caused by the loss of insulating vegetation and upper soil layers from combustion (Rocha and
497 Shaver, 2011b). Higher soil temperatures and deeper active layer depths may catalyze permafrost degradation and
498 thermokarst development (Jones et al., 2015) that accelerates the effects of climate warming on tundra ecosystems.
499 Tundra fires also emit multiple gaseous and aerosol species, which have a net positive radiative forcing for at least
500 80 years post-fire. Hence, even if all of the carbon lost from fire in a tundra ecosystem were to be sequestered again
501 over time through increased photosynthesis, the long-term radiative impact of gaseous and aerosol emissions would
502 still generate atmospheric warming and thus positive climate feedbacks, which are amplified by post-fire permafrost
503 thaw and degradation and not accounted for in this study.

504 This positive radiative forcing is driven by sustained radiative forcings from long-lived greenhouse gasses
505 (GHGs), as well as significant contributions from short-lived climate forcers (SCLFs) such as ozone, NMVOCs, and
506 CO. Carbon dioxide has the highest radiative forcing at both short and long time horizons because it is emitted in
507 the highest quantity (Akagi et al., 2011) and its concentration decreases relatively slowly over time, especially in the
508 RCPs 4.5 and 8.5 scenarios (Joos et al., 2013). Aerosols and NO_x are SCLFs with both positive and negative
509 radiative forcings due to distinct mechanisms for affecting the Earth's radiative balance. Aerosols exert a direct
510 radiative forcing by reflecting or absorbing sunlight in the atmosphere and when deposited on high-albedo surfaces,
511 mainly snow and ice (Bond et al., 2011). Although black carbon aerosols have a positive and organic carbon
512 aerosols have a negative direct radiative forcing, the magnitude of black carbon's radiative forcing far exceeds that
513 from organic carbon (Myhre et al., 2013) (note these are combined in our representation). Indirectly, aerosols serve
514 as the nuclei for cloud formation, which increases the Earth's albedo and exerts a negative radiative forcing (Ward et
515 al., 2012). Nitrogen oxides have a near-term positive radiative forcing because they act in concert with NMVOCs
516 and CO to increase ozone concentrations, yet they have a long-term negative radiative forcing because they decrease
517 the lifetime of CH₄ (Collins et al., 2013).

518 We include a total radiative forcing with and without aerosols and ozone precursors, CO, NMVOCs, and
519 NO_x. The radiative forcing of these ozone precursors and aerosols is uncertain within current literature, especially
520 when originating in the Arctic, because of their short atmospheric lifetimes and dependence on regional transport
521 patterns (Bond et al., 2011, Quinn et al., 2008). However, the long-term cumulative radiative effect of these gaseous
522 emissions is relatively minimal in comparison to the long-lived GHGs and ozone, and both estimates of total
523 radiative forcing are of the same order of magnitude as previous estimates of the radiative forcing of gaseous
524 emissions from boreal forest fires (Huang et al., 2016; O'Halloran et al., 2012).

525 We found that as the predicted concentration of future emissions increases across RCP scenarios
526 (Meinshausen et al., 2011), the net radiative forcing of gaseous and aerosol emissions from tundra fires decreases
527 slightly. Although counterintuitive, this result is due to the dependency of the radiative forcing equations for long-
528 lived GHGs, namely CO₂, CH₄, and N₂O, on the ambient concentration of a gas. In more extreme future climate
529 scenarios, the atmosphere generally has higher concentrations of these GHGs, meaning the additional quantity of gas
530 emitted by the fire has a more diluted effect. This effect is largely counter-balanced by the fact that land and ocean
531 CO₂ sink capacities are diminished in more extreme future climate scenarios, leading to longer atmospheric CO₂
532 lifetimes (Fig. A7). The net result is that tundra wildfires have a relatively similar positive radiative forcing under
533 all future emissions scenarios.

534 Although wildfires in tundra ecosystems and boreal forests have similar positive radiative forcings through
535 their gaseous emissions, boreal forests also have significant multi decadal post-fire albedo changes due
536 predominantly to the combustion of overstory trees that expose snow in the fall, winter, and spring (Lyons et al.,
537 2008). Randerson et al. (2006) and O'Halloran et al. (2012) show that the negative radiative forcing of these albedo
538 changes can exceed the positive radiative forcing of gaseous emissions and generate a net cooling effect for boreal
539 forest fires over long time horizons in specific locations. It should be noted, however, that (i) the net cooling or
540 warming is heavily dependent on combustion levels, pre-fire canopy composition, and time horizon; (ii) fire-induced
541 albedo forcings predominantly impact the regional climate (Rogers et al., 2013), as opposed to globally-mixed
542 GHGs; and (iii) this cooling impact is expected to diminish with future climate change due to decreases in spring
543 snow cover (Potter et al., 2020).

544 In contrast, tundra ecosystems lack an overstory, and hence fires generate relatively short-lived decreases in
545 albedo (Rocha et al., 2012, French et al., 2016). These albedo changes are only caused by char and the exposed soil

546 surface in the summer because tundra vegetation rarely exists above the snow layer (Mack et al., 2011). As a result,
547 within four years after the Anaktuvuk River fire, low post-fire surface albedo recovered to its pre-fire reflectance as
548 the vegetation grew over the charred soil surface (French et al., 2016; Rocha and Shaver, 2011b). The decreased
549 surface reflectance contributes to increases in soil temperature and thaw depth after fire (Rocha and Shaver 2011b).
550 Therefore, the positive radiative forcing caused by tundra wildfire gaseous and aerosol emissions is not offset by
551 post-fire albedo changes as seen in boreal forest fires.

552 For the purpose of calculating the radiative forcing of wildfires in future research, we make our
553 computational code available on Github (see Code and Data Availability section). Our workflow is applicable to
554 wildfires in other arctic-boreal ecosystems, and could be applied to any ecosystem globally with the adjustment of
555 emissions factors of the specific material burning (Akagi et al., 2011) and global warming potentials for SCLFs
556 based on the geographic region of the wildfire (Myhre et al., 2013). As a result, our method of calculating the
557 radiative forcing of wildfires can be used for studies across multiple regions with the appropriate parameters, which
558 can advance a more complete understanding of the effects of wildfires on the climate.

559 Future work could clarify some of the uncertainties that were not explicitly analyzed in our final estimates
560 of carbon loss and radiative forcing. Regarding our estimates of carbon loss from the YKD fires, we did not account
561 for combustion of aboveground tall woody vegetation, predominantly confined to peat plateau edges. Although this
562 biomass was sparse on the tundra landscape, it represents an additional source of carbon from combustion (for
563 boreal forest fires, see Walker et al., 2020c). Despite the lack of difference we found between soil and vegetation
564 matter characteristics across vegetative reference point groups, there could have been variation in these
565 characteristics outside of the primarily peat plateau areas that we sampled. Furthermore, the fact that *Dicranum*
566 accounted for a larger range of burn depths, though not significantly different from *Sphagnum*, could indicate more
567 variable burn dynamics around *Dicranum* or better efficacy of *Dicranum* for measuring extreme burn depths, which
568 highlights the potential bias introduced by choosing specific combustion markers. Likewise, we eliminated tussock
569 measurements from our final analysis because they were relatively scarce on the landscape and yielded inconsistent
570 results, perhaps due to burn dynamics around tussocks that remain obscure using our combustion measurement
571 method. Another robust analysis of carbon loss would seek to minimize potential bias and find combustion markers
572 and soil characteristics for different land cover types at a higher resolution within a fire, similar to how different
573 combustion markers are used regionally (Walker et al., 2020c; Mack et al., 2011; Boby et al., 2010).

574 Regarding spatial scaling of fire emissions, our assignment of low, moderate, and high severity was based
575 on our particular collection of field measurements and therefore may not translate well to other fire complexes. We
576 also used a relatively simple method for extrapolating emissions based on fire severity. More involved techniques
577 such as relating mechanism-based geospatial predictors to field plots using statistical techniques and machine
578 learning, which has been employed for boreal forests in Alaska and Canada (Dieleman et al., 2020; Walker et al.,
579 2018b; Veraverbeke et al., 2015; Rogers et al., 2014), would likely yield more robust estimates for regional
580 emissions. In this context, we strongly recommend increasing the number of tundra fire carbon emission
581 observations in different regions to facilitate synthesis and biome-wide modeling, as has been done for boreal forests
582 (Walker et al., 2020a,b,c).

583 Our radiative forcings model uses data and algorithms from multiple previous studies, including for
584 emissions factors (Akagi et al., 2011), RCP scenarios (Meinshausen et al., 2011), GWPs (Myhre et al., 2013), ozone
585 and CO concentration ratios (Jaffe and Widger, 2012), and aerosol direct and indirect effects (Ward et al., 2012), all
586 of which may not be geographically, biologically, or temporally specific to the YKD fires. These factors are also
587 known to be variable depending on fuel types, fire severity and lifetime, and atmospheric dynamics at the time of
588 and following fire (e.g., Wiggins et al., 2016; Jaffe and Widger, 2012; Chen et al., 2009). Furthermore, our model
589 does not include the potential mitigating or exacerbating effects of post-fire ecosystem changes on gas
590 concentrations, such as changes in post-fire vegetation (Frost et al., 2020; Zhou et al., 2019; Barrett et al., 2012),
591 increased soil respiration (Rocha and Shaver, 2011a), and increased active layer depths and permafrost degradation
592 (Holloway et al., 2020; Jafarov et al., 2013; Rocha et al., 2012). With reparameterizations specific to individual
593 fires, our model could be made more accurate for future work.

594 **5 Conclusions**

595 To our knowledge, our study is the first to account for both carbon loss and radiative forcing from tundra
596 wildfires. We develop a method that pairs *in situ* measurements of combustion levels from local pre-fire reference
597 points with remotely sensed burn severity data to scale organic matter and carbon loss to the entire fire area. Our
598 estimate of the radiative forcing of gaseous and aerosol emissions from the fire event suggests that tundra wildfires
599 positively reinforce climate warming; however, the role of post-fire vegetative regeneration in mitigating these
600 carbon emissions remains unknown. Our results stress the importance of considering tundra wildfires in assessing

601 climate feedbacks and the need for future research that more explicitly discerns the warming effect of fires across

602 the tundra biome.

Figure A7. The radiative forcing of CO₂ emitted from the 2015 YKD fire season for RCP 4.5 (a) and 8.5 (b) when (i) holding the emission constant (red lines) so that no emitted CO₂ is sequestered, (ii) holding the background atmospheric concentration constant (green lines), and (iii) the combination of these, resulting in our main CO₂ radiative forcing equation (blue lines; Eq. 7). In the case of (i, red lines), increasing atmospheric CO₂ concentrations dampen the radiative impact of fire-emitted CO₂. In the case of (ii, green lines), the only time-varying impact on CO₂ radiative forcing is ocean and land sinks, which become less effective and even reverse with more extreme climate change according to model results presented in Joos et al. (2013). These lines are similar to the impulse response function of CO₂ for their respective scenarios in Joos et al. (2013).

668 **Code and Data Availability**

669 The radiative forcings calculation code is available on GitHub and Zenodo via DOI: 10.5281/zenodo.6617455
670 (Moubarak, 2022). All field and lab raw data used in this study, including vegetative reference point height
671 measurements and soil and vegetation core metrics, and combustion data products derived from our calculations are
672 publicly available in the NSF Arctic Data Center via DOI:10.18739/A2PR7MV5P (Moubarak et al., 2020).

673 **Author Contributions**

674 MM, BR, SS, and SN were involved with conceptualization, funding acquisition, and methodology. SP completed
675 investigation of burn severity data and jointly completed visualization with MM. MM, SS, and BR did investigation
676 of burn depth measurements and soil and vegetation characteristics. MM analyzed data and developed the radiative
677 forcings model. SS and SN did project administration for the field sampling. MM curated data and wrote the
678 original manuscript draft. MM, BR, SS, SP, and SN reviewed and edited the final published work.

679 **Competing Interests**

680 The authors declare that they have no conflict of interest.

681 **Acknowledgements**

682 This work was funded by the National Science Foundation (NSF-1915307 to SMN, NSF-1915307 to SS),
683 Casstevens Family Fund (to MM), and the National Aeronautics and Space Administration (NASA) Arctic-Boreal
684 Vulnerability Experiment (ABOVE; NNX15AU56A to BR) and the Gordon and Betty Moore Foundation (8414 to
685 SMN and BR). The authors would like to thank Dr. William Pfitsch for his helpful mentorship in the synthesis of
686 this project and creation of the written work. Also, the authors would like to thank Dr. Catherine Beck for offering
687 her knowledge about radiocarbon sample preparation and analysis.
