15 **Abstract.** Biocrusts are a worldwide phenomenon, contributing substantially to ecosystem functioning. Their growth and
16 survival depend on multiple environmental factors, including climatic ones, and the relations of these factors to physiological
17 processes. Responses of biocrusts to individual environmental factors have been examined in a large number of field and
18 laboratory experiments. These observational data, however, rarely have been assembled into a comprehensive, consistent
19 framework that allows quantitative exploration of the roles of multiple environmental factors and physiological properties for
20 the performance of biocrusts, in particular across climatic regions. Here we used a data-driven mechanistic modeling
21 framework to simulate the carbon balance of biocrusts, a key measure of their growth and survival. We thereby assessed the
22 relative importance of physiological and environmental factors for the carbon balance at six study sites that differ in climatic
23 conditions. Moreover, we examined the role of seasonal acclimation of physiological properties using our framework, since
24 the effects of this process on the carbon balance of biocrusts are poorly constrained so far. We found substantial effects of air
25 temperature, CO₂ concentration, and physiological parameters that are related to respiration on biocrust carbon balance, which
26 differ, however, in their patterns across regions. The ambient CO₂ concentration is the most important factor for biocrusts from
27 drylands while air temperature has the strongest impact at alpine and temperate sites. Metabolic respiration cost plays a more
28 important role than optimum temperature for gross photosynthesis at the alpine site; this is not the case, however, in drylands
29 and temperate regions. Moreover, we estimated a small annual carbon gain of 1.5 g m⁻² yr⁻¹ by lichen-dominated biocrust and
30 1.9 g m⁻² yr⁻¹ by moss-dominated biocrust at a dryland site, while the biocrusts lost a large amount of carbon at some of the
31 temperate sites (e.g., -92.1 for lichen- and -74.7 g m⁻² yr⁻¹ for moss-dominated biocrust). These strongly negative values
32 contradict the observed survival of the organisms at the sites and may be caused by the uncertainty in environmental conditions
33 and physiological parameters, which we assessed in a sensitivity analysis. Another potential explanation for this result may be

34 the lack of acclimation in the modeling approach since the carbon balance can increase substantially when testing for seasonally
35 varying parameters in the sensitivity analysis. We conclude that the uncertainties in air temperature, CO₂ concentration,
36 respiration-related physiological parameters, and the absence of seasonal acclimation in the model for humid temperate and
37 alpine regions may be a relevant source of error and should be taken into account in future approaches that aim at estimating
38 the long-term biocrust carbon balance based on ecophysiological data.

39 **1 Introduction**

40 Non-vascular photoautotrophs, such as lichens, mosses, eukaryotic algae and cyanobacteria, together with heterotrophic
41 microorganisms, form biological soil crusts (biocrusts) which occur in various environments across the globe and provide a
42 wide range of important ecosystem functions, such as build-up of soil organic carbon and nutrients (Belnap et al., 2016;
43 Chamizo et al., 2012; Dümig et al., 2014; Ferrenberg et al., 2018). Due to the importance of biocrusts in ecosystem functioning,
44 their growth and survival have been extensively studied, through different methodological approaches (e.g. Ladrón de Guevara
45 et al., 2018; Lange et al., 2006; Porada et al., 2019). An established measure to quantify the growth of biocrusts is their long-
46 term carbon balance (hereafter, C balance), which corresponds to the (accumulated) net carbon flux across the system
47 boundaries including all relevant carbon gains and losses.

48 In order to ensure survival, any species needs to achieve a positive C balance in the long-term, while negative values may
49 occur for short periods. Acknowledging the importance of C balance, an increasing number of studies have investigated the
50 long-term C balance of individual non-vascular organisms as well as biocrust communities, and their environmental drivers.
51 An annual carbon budget of 21.49 g C m⁻² based on measured field data was reported in the study of Lange (2003b) on the
52 crustose lichen *Lecanora muralis* growing on a rock surface in a temperate climate of southern Germany. Furthermore,
53 Büdel et al. (2018) estimated an annual C balance of 1.7 g C m⁻² based on measurements on cyanobacteria-dominated
54 biocrust in an Australian dry savannah ecosystem. Several other studies obtained long-term, large-scale values of the C
55 balance by scaling up short-term, local measurements of CO₂ exchange rate under natural field conditions (Lange et al.,
56 1994; Zotz et al., 2003). For an estimation of the global C balance of cryptogamic covers, which include biocrusts,
57 conversion factors based on the maximum photosynthesis rate have been suggested as a best-guess solution (Elbert et al.,
58 2012). However, there are some drawbacks to these approaches for acquiring a C balance at both organism and community
59 scale. First, the measurement of the long-term continuous CO₂ exchange rate of an individual organism or biocrust
60 community has technical limitations and is highly time- and resource-consuming. Second, upscaling via extrapolation may
61 result in bias in annual C balance estimation if the length and the frequency of sampling cannot capture the full variability of
62 CO₂ exchange throughout the year (Bader et al., 2010). Moreover, using empirical approaches alone, it is difficult to
63 understand the underlying mechanisms of how climatic conditions affect individual physiological processes, and
64 consequently which role these processes play in the observed changes in C balance and growth at the individual as well as

65 community level. Such approaches are thus subject to large uncertainty when used for projections of C balance under climate
66 change.

67 Most studies on the relationships between C balance and environmental factors for biocrusts are based on laboratory
68 experiments (e.g. Coe et al., 2012b; Cowan et al., 1992; Lange et al., 1998) or direct field measurements in situ over short
69 periods of time (e.g. Brostoff et al., 2005; Lange et al., 1994). From this work cited above, it has been recognized that the C
70 balance of biocrusts is strongly influenced by factors such as water supply, temperature, radiation, and CO₂ concentration and
71 the complex relations of these factors to physiological processes such as photosynthesis and respiration. While the highest
72 values of productivity under field conditions are achieved when the environmental factors are in the range that is optimal for
73 the specific biocrust, it has been found that biocrusts are also able to achieve metabolic activity and thus, potential productivity,
74 under sub-optimal conditions of temperature and light (Colesie et al., 2016; Raggio et al., 2017, 2014). It is largely unknown,
75 however, which relative importance each of these environmental factors and physiological parameters has for the long-term C
76 balance of biocrusts under natural field conditions, and if the importance of factors/parameters shows a spatial and temporal
77 pattern. In addition, seasonal acclimation of photosynthetic and respiratory properties of species to intra-annually varying
78 climate factors found by several studies (e.g. Gauslaa et al., 2006; Lange and Green, 2005; Wagner et al., 2014) may
79 substantially affect biocrust C balance, thus leading to further complexity in the spatio-temporal relations between C balance
80 and environmental factors/physiological parameters. One of the few experimental studies investigating biocrust acclimation
81 potential to changing temperatures has found threshold temperatures for the survival of lichen species (Colesie et al., 2018)
82 but the overall extent of the impact is poorly understood.

83 Here, we applied a mechanistic data-driven model to (a) complement empirical estimates of the annual C balance of biocrusts
84 and (b) to address the knowledge gaps concerning the relative importance of different environmental factors and physiological
85 parameters for the C balance in contrasting climates, thereby accounting for the role of seasonal acclimation. The advantage
86 of this modeling approach is that it can predict at high temporal resolution the dynamic C balance of biocrust organisms for
87 given locations by simulating the physiological processes driven by environmental factors. The model allows for a deeper
88 mechanistic understanding of the C balance of biocrusts through factorial experiments and sensitivity analyses regarding
89 physiological parameters and individual environmental factors, which would be impractical to realize in field or laboratory
90 experiments. To complement our analyses using the data-driven model, a process-based dynamic non-vascular vegetation
91 model, called LiBry, was employed as an supporting tool (Porada et al., 2013).

92 **2 Material and Methods**

93 We simulated the C balance of biocrusts from six climatically different study sites in a semi-empirical way using a data-driven
94 model. The model simulates photosynthetic rate based on the Farquhar photosynthesis model developed by Farquhar and von
95 Caemmerer (1982) and respiration rate based on a Q10 relationship. The C balance is computed as the difference of
96 photosynthesis and respiration accumulated over a given time period. In the model, both photosynthesis and respiration depend

97 on surface temperature, relative water saturation, and the activity of the biocrust, which are all simulated in a coupled way via
98 the surface energy balance as a function of climate input data. Photosynthesis additionally depends on ambient CO₂
99 concentration.

100 To calibrate the model, we first determined soil and land surface properties that are required for the coupled energy and water
101 balance in the model through fitting simulated to measured surface temperature patterns. Then, we parameterized the
102 physiological properties of the organisms using measured relationships between net photosynthesis and light intensity, water
103 content, and temperature. Finally, we validated the model with regard to the water content or activity patterns of biocrusts and
104 compared the modelled CO₂ assimilation rate to measured values. The data sets used for calibration and validation of the model
105 as well as basic climate conditions of each site are described in Table 1. Sites were listed in ascending order of total annual
106 precipitation based on measured data.

107 **2.1 Study sites**

108 In our study we considered six sites, namely two dryland sites at Almeria (Spain) and Soebatsfontein (South Africa; hereafter
109 D1 and D2); three temperate sites at Gössenheim (Germany), Öland (Sweden), and Linde (Germany; Hereafter T1, T2, and
110 T3); and one alpine site at Hochtorn (Austria; Hereafter A1) (Table 1). These sites were chosen based on data availability for C
111 balance estimation, and because they cover a broad range of climatic conditions. The field and laboratory measurements
112 conducted at all sites were following a similar protocol, which allows comparing the simulation results among sites. The
113 necessary empirical data for C balance estimation regarding climatic conditions, species physiological characteristics, and
114 status especially in terms of moisture such as water content or activity, have been monitored in a relatively small number of
115 experiments, so far, and the six study sites chosen here to provide a good opportunity to utilize these data for an extended
116 modeling approach. In this context, activity measurements are more suitable than soil moisture records since they are direct,
117 non-invasive and they do not show deviations in the temporal patterns at high resolution, which may occur with soil moisture
118 time series.

119 Sites D1 and D2 are characterized by an arid climate with mean annual precipitation of less than 250 mm, but a wet winter
120 season (Büdel et al., 2014; Haarmeyer et al., 2010). Sites T1, T2, and T3 have a temperate climate. The mean precipitation in
121 these three sites is around 550 mm (Büdel et al., 2014; Diez et al., 2019). Site A1 is located in a humid alpine region with a
122 mean annual precipitation between 1750 and 2000 mm, of which more than 70% are snowfall; the A1 site is covered by snow
123 for at least 200 days per year (Büdel et al., 2014). More detailed site descriptions are provided in the corresponding studies
124 cited above.

125 **2.2 Observational Data**

126 **2.2.1 Climatic variables**

127 The proposed data-driven model for estimating the annual C balance of dominant biocrust types at each site was forced by

128 hourly microclimatic variables. The forcing data sets of the data-driven model include photosynthetically active radiation
129 (PAR), long-wave radiation (near-infrared), relative air humidity, air temperature, wind speed, rainfall, and snowfall. All the
130 microclimatic variables were measured on-site by climate stations with a temporal resolution of 10 min (5 min in A1 and D1;
131 data available at <http://www.biota-africa.org>; Raggio et al., 2017; M. Veste, unpublished data), except for long-wave radiation
132 and snowfall, which were taken from ERA5 dataset (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>).
133 Although directly measured surface temperature data are available for all sites, we use ERA5-based down-welling long-wave
134 radiation instead to simulate surface temperature on biocrusts. This is necessary since, in our model, calculations of
135 photosynthesis and respiration require not only surface temperature, but also depend on water saturation of biocrusts (affecting
136 activity). However, we do not have water saturation data available at most sites. Therefore, we instead simulate the dynamic
137 water saturation of biocrusts based on climate, via processes such as evaporation, rainfall, and dew. The calculation of
138 evaporation and dew automatically includes the computation of a surface temperature that emerges from solving the surface
139 energy balance, thereby including down-welling long-wave radiation. Since the simulated surface temperature that is
140 connected to simulated water saturation slightly deviates from the observed surface temperature (see Fig. 1 and S1), we do not
141 directly use the observed surface temperature as input in the modeling approach, to avoid inconsistencies. Then all these
142 microclimate data were aggregated to data with hourly temporal resolution.

143 **2.2.2 Dynamic biocrust variables**

144 Besides the surface temperature, biocrust activity was either monitored directly (binary: active or not active) using a continuous
145 chlorophyll fluorescence monitoring system (Raggio et al., 2014, 2017), or indirectly via the electrical conductivity of the
146 substrate (BWP, Umweltanalytische Produkte GmbH, Cottbus, Germany; Weber et al., 2016; M. Veste, unpublished data).
147 For site D2, the biocrust water content was calculated instead of activity based on electrical conductivity. Due to snow covering
148 the measuring instruments, data of site A1 only covers the time from August to October. Samples from both lichen- and also
149 moss-dominated biocrusts were measured at all sites, except for site T3 where four BWPs were mostly located in moss-
150 dominated biocrusts. At site D2, additionally cyanolichen- and cyanobacteria-dominated biocrusts were monitored. The
151 measured surface temperature, water content, and activity data at all sites were then aggregated to data with a temporal
152 resolution of one hour.

153 As explained in Sect. 2.2.1, we did not directly use the observed surface temperature and activity (or water content) as forcing
154 data for the model, but estimated the time-series of surface temperature and water saturation data at all sites based on a
155 simulation of the energy and water balance. The activity of the organisms was then approximated via the empirical equations
156 describing the link between water saturation and metabolic activity (see Porada et al., 2013). Furthermore, ambient CO₂
157 concentration was assumed to be constant at 400 ppm. The CO₂ concentration at the soil surface may be higher than 400 ppm
158 due to the flux of respired CO₂ from the soil. Since our study sites are on open ground, we do not assume substantial
159 accumulation of CO₂ in the near-surface boundary layer. We discuss the effect of uncertainties in CO₂ concentration below in
160 Sect. 4.2.

161 For validation of C balance, we used data of the on-site CO₂-exchange rate of different biocrust types (lichen- and moss- and
 162 also cyano-dominated biocrusts removed from surplus soil; the latter composed of cyanolichen and cyanobacteria) that were
 163 measured by a portable gas exchange system at several time intervals from November 4th to 8th at site D2 (Tamm et al., 2018).
 164 For the other sites, additional field measurements of CO₂-exchange were not available.

165 2.2.3 Photosynthesis response and water storage

166 For all sites, CO₂ exchange measurements under controlled conditions in the laboratory or in the field (site T3) were conducted
 167 using a mobile gas exchange system GFS 3000 (Walz GmbH, Effeltrich, Germany) with an infrared-gas analyzer to explore
 168 the physiological characteristics of samples of different biocrust types (same as those measured for validation; main species
 169 see Table 1; Diez et al., 2019; Raggio et al., 2018; Tamm et al., 2018). Before measurements, the soil underneath these biocrust
 170 samples was removed up to the amount necessary to preserve the physical structure of the biocrusts. And the samples were
 171 subjected to reactivation for at least two days (D2) or three days (T1, T2, D1, A1). At T1, T2, A1 and D1, for instance, samples
 172 were kept at 12°C under 12 h dark and 12 h light (100 μmol m⁻² s⁻¹) conditions for three days and wetted once a day. Net
 173 photosynthesis was measured at different ranges of light intensity, water content, and temperature. Light response curves, for
 174 instance, were determined at optimum water saturation and 15 °C, water response curves were measured at 400 μmol m⁻² s⁻¹
 175 and 15 °C at sites D1, T1, T2, and A1 (Raggio et al., 2018). Moreover, the maximum water storage capacity (MWC) of the
 176 samples was quantified in the laboratory for samples from sites D1, T1, T2, and A1 (Raggio et al., 2018), whereas the MWC
 177 at site D2 was approximated as the maximum value when measuring water response curves (Tamm et al., 2018; Weber et al.,
 178 2012). MWC at site T3 was estimated as the value of the same genus measured in Hamburg, Germany (*Cladonia portentosa*
 179 and *Polytrichum formosum*, Petersen et al., in prep.). MWC was acquired since it is one of the essential parameters of the
 180 model to convert the specific water content in mm to relative water saturation required by the model used here.

181 **Table 1:** Properties of the study sites and data which are available (+ sign) for calibration and validation of the data-driven
 182 model.

Site	Almeria, Spain	Soebatsfontein, South Africa	Gössenheim, Bavaria, Germany	Öland, Sweden	Linde, Brandenburg, Germany	Hochtor, Austria

183 **2.3 Parameterization of the data-driven model**

184 **2.3.1 Abiotic surface properties**

185 Several abiotic parameters of the data-driven model describing soil and land surface properties, such as roughness length or
 186 soil thermal conductivity, were required to simulate the energy and water balance. These parameters were obtained by fitting
 187 the daily and diurnal surface temperature patterns of lichen-dominated biocrust at all sites except for site T3. At site T3, we
 188 compared the surface temperature patterns of simulated moss-dominated biocrusts to data collected by sensors in four
 189 locations.

190 The set of parameters that corresponded to minimum differences between simulated and measured values (visual assessment)
 191 was used in the data-driven model. The calibration results of surface temperature and the photosynthesis response curves at
 192 site T2 are shown in Fig. 1 and Fig. 2, respectively. The results of dominant species at other sites are shown in Fig. S1 and S2.
 193 The daily surface temperature was simulated accurately (the maximum value of root mean square error (RMSE) at all sites is
 194 3.78) except for site T3 where the temperature during cold seasons was underestimated, and at site D1 the peak temperature
 195 within a day in hot seasons was underestimated (Fig. S1). The peak in surface temperature occurred too early by around 1-2
 196 hours at site D1, A1, T1 and T2, but the magnitude of the peak corresponded well to the measured data (Fig. 1 and S1).
 197 Therefore, in general, the fitting of the surface temperature patterns was satisfactory. The mismatches may result from the
 198 measured climate variables such as PAR or air temperature at 2 m being inconsistent with the measured surface temperature
 199 (detailed descriptions are in Appendix) and bias in the calibrated soil properties such as soil thermal conductivity since it may
 200 affect the surface temperature difference between morning and evening. A sensitivity analysis of soil thermal conductivity to
 201 C balance is shown in the Appendix.

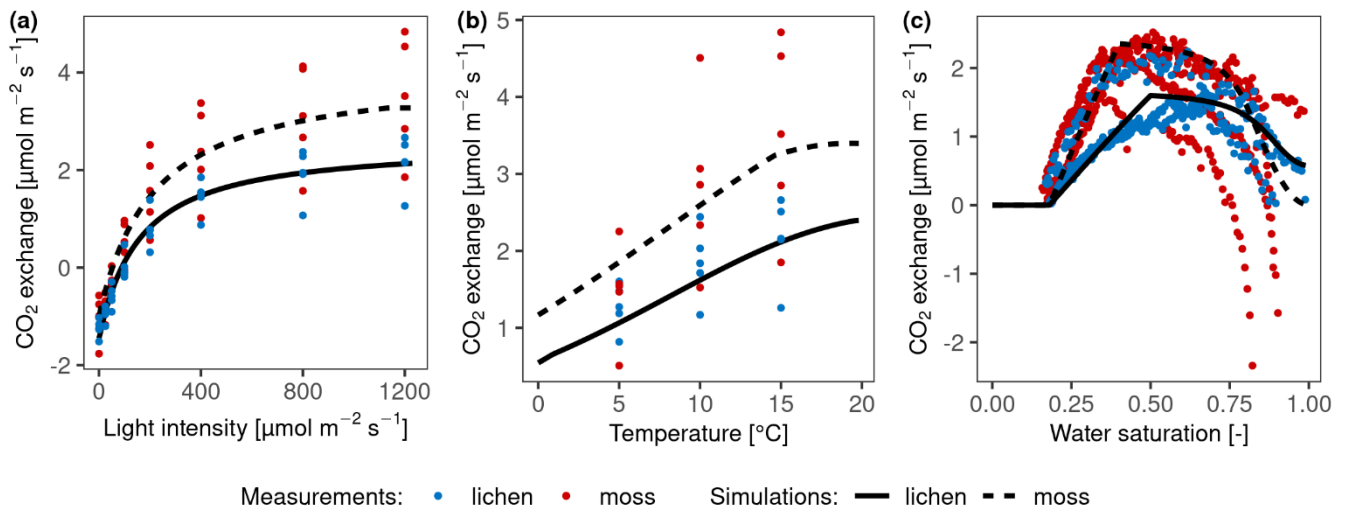

202

203 **Figure 1:** Calibration results of abiotic parameters of the data-driven model by fitting the daily (a) and diurnal (b-e) patterns
 204 of surface temperature of lichen-dominated biocrusts at site T2. (b) to (e) represent the patterns of average hourly surface
 205 temperature from January to March (JFM), April to June (AMJ), July to September (JAS), and October to December (OND),
 206 respectively.

207 **2.3.2 Biocrust physiological properties**

208 Furthermore, several parameters required by the Farquhar photosynthesis scheme and the respiration scheme were directly
 209 measured or calculated from gas exchange data sets, such as MWC of the thallus, optimum water content, the optimum
 210 temperature for gross photosynthesis, metabolic respiration cost, and the Q10 value of respiration. Since the ambient
 211 temperature range that was applied in the laboratory for samples from all sites except D2 was too small to capture the optimum
 212 temperature of photosynthesis reliably, we approximated the optimum temperature from the measured data set as the average
 213 surface temperature during active periods. In addition, the optimum temperature was also constrained by fitting the Farquhar
 214 equations to photosynthesis curves, as related to environmental factors light, water content, and temperature. Such fitting
 215 method was also used to obtain some other photosynthesis-related parameters of organisms, such as molar carboxylation and
 216 oxygenation rate of RuBisCO (V_{cmax} , V_{omax}), respiration cost of RuBisCO enzyme (Rub_ratio), and minimum saturation
 217 for activation (Sat_act0).

218

219 **Figure 2:** Calibration of photosynthesis parameters of the model by fitting photosynthesis response curves of moss- and lichen-
 220 dominated biocrust samples to measurements at site T2. (a): net photosynthesis rate in response to light at optimum water
 221 content and 15 °C. (b): net photosynthesis rate in response to temperature at 1200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light and optimal water content.
 222 (c): net photosynthesis rate in response to relative water saturation at 400 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light and 15 °C.

223 Since the measured values between replicates showed large variation, in particular the water and temperature-dependent data,
 224 as illustrated by the coloured points in Fig. 2, we fitted the curves to the average values of all replicates. The calibration results
 225 showed that visually and overall, the photosynthetic curves could be parameterized to fit the measurements well, given that
 226 different samples were used for measuring responses to different driving factors, and considering the methodological
 227 differences between light and water response curve measurements. However, the water responses were least well-fitted,
 228 especially at high water contents. The measured net photosynthesis response rate was negative in some cases at high water

229 saturation, but it is not possible to reproduce this negative net photosynthesis rates with our adapted Farquhar photosynthetic
230 model for the light and CO₂ conditions of the laboratory setup. Under these conditions, gross photosynthesis is larger than
231 respiration and thus CO₂ is required to diffuse from the atmosphere into the thallus, not out of it. Even under low diffusivity,
232 caused by high water saturation, there will be no net diffusion of CO₂ from the thallus into the ambient air assuming that
233 inward and outward flows of CO₂ share the same pathway and that diffusion of CO₂ between atmosphere and thallus is in
234 steady-state with the flux (respiration minus gross photosynthesis). For details please see Appendix. Furthermore, matching
235 the simulated temperature-response of net photosynthesis to the measured data under cool conditions turned out to be difficult
236 for samples from site T1 and A1 (Fig. S2). There were too few data points in the measured temperature response data set to
237 constrain the optimum temperature and temperature relation (see Fig. 2), but the fitting turned out well because the simulated
238 optimum temperature for net photosynthesis at site T1 was coincidentally close to the value of 17 °C reported by Colesie et al.
239 for this site. (2014; see Fig. S2).

240 **2.4 Validation of the data-driven model**

241 The water saturation and activity estimated by the data-driven model were validated by comparing with the daily and diurnal
242 patterns of measured activity (5 sites, not at site D2) and water content data (only at D2). Furthermore, the C balance estimated
243 by the data-driven model was validated by comparison to the in situ measured net CO₂ exchange rate of moss, lichen, and
244 cyanocrust-dominated biocrusts. These data were sampled at site D2 by removing the soil respiration rate, predicted by means
245 of a fitted regression (Weber et al., 2012). Since data on water saturation were available, measured PAR, surface temperature,
246 and water content were used to simulate the C balance using the data-driven model, in contrast to the setup described above.
247 The activity, however, was calculated in the same way as described in the setup. Moreover, the parameters of the model were
248 the same as the calibrated ones of the corresponding biocrust types.

249 **2.5 Sensitivity analysis**

250 To investigate the role of environmental factors, physiological properties, and also seasonal acclimation for the simulated
251 annual C balance of biocrusts, we conducted three sensitivity analyses using our data-driven model. With this setup, we intend
252 to put into context the effects of environmental conditions and the uncertainty associated with the physiological properties that
253 were used to parameterize the model. We additionally explore the impact of seasonally acclimatized physiological properties
254 on carbon assimilation at site T1, since variation between seasons represents additional uncertainty in the estimation of the C
255 balance.

256 **2.5.1 Effects of environmental factors**

257 To investigate the role that environmental factors, namely air temperature (T_{air}), light intensity (Light), ambient CO₂
258 concentration (CO₂), and different types of water sources play in regulating the C balance of biocrusts, sensitivity analyses
259 were conducted for lichen-dominated biocrusts from all study sites. The different types of water sources include rainfall (Rain)

260 and non-rainfall water inputs such as dew and water vapor, which are determined by relative air humidity (R_hum). All the
261 environmental factors were reduced and increased by half (+/- 50%), except for T_air and R_hum. The T_air differences varied
262 by 5 K and R_hum by 20%. Moreover, relative humidity was constrained between 0 and 100% when the varied relative
263 humidity exceeded this range.

264 The annual C balance for each modified environmental factors was then normalized following Eq. (1), and normalized again
265 among different environmental factors within each climatic zone for comparing the relative importance of environmental
266 factors:

$$267 \text{ Normalized } C \text{ balance} = \frac{C_{ij} - C_j}{|C_j|}, \quad (1)$$

268 where C_{ij} is the C balance of factor j under operation i , and C_j is the original C balance of factor j .

269 A positive normalized C balance demonstrates an increase in annual C balance when certain environmental factors change,
270 and a larger magnitude of the normalized C balance number demonstrates a larger effect of this environmental factor compared
271 to a factor with a smaller value.

272 **2.5.2 Effect of physiological parameters**

273 The sensitivity analysis of physiological parameters was conducted for lichen-dominated biocrust at all study sites. The original
274 parameter values were obtained by calibration to measured net photosynthesis response curves. We then varied the values of
275 the following physiological parameters by a consistent range for all sites: metabolic respiration cost per surface area
276 (Resp_main), Q10 value of respiration (q10), the optimum temperature for gross photosynthesis (Topt), respiration cost of
277 RuBisCO enzyme (Rub_ratio), and light absorption fraction in cells (ExtL), minimum saturation for activation (Sat_act0), and
278 minimum saturation for full activation (Sat_act1). Specifically, we increased or decreased Resp_main, ExtL, q10, Sat_act0 by
279 30%, Rub_ratio and Sat_act1 by 20%, and Topt by 5 K. These parameters are chosen since they are closely related to the
280 response of photosynthesis and respiration to water, light, and temperature. These ranges of different parameters were
281 determined based on the observed bounds of the photosynthetic response curves of all replicates (see calibration results with
282 varied parameters at all sites in Fig. S5-S10), which have large deviations between each other at most sites as shown in Fig. 2
283 and Fig. S2. The effects of the varied physiological parameters on the C balance were then normalized using the same
284 normalization method as for the environmental factors (in Sect. 2.5.1) for comparison among parameters and climatic zones.

285 **2.5.3 Effect of seasonal acclimation**

286 Another sensitivity analysis was performed for site T1 to investigate the impact of seasonally acclimatized physiological
287 properties on the C balance. We analysed the lichen- and moss-dominated biocrusts at site T1 as an example, because the
288 measured time-series of activity showed that in temperate sites such as T1, the organisms were active most of the time, and
289 thus the C balance would be more sensitive to seasonally varying properties.

290 In the analysis, rather than keeping all calibrated parameters fixed throughout the simulation period of the data-driven model,
291 the physiological parameters metabolic respiration cost per surface area (Resp_main), light absorption fraction in cells (ExtL),
292 and the ratio of Jmax to Vcmax (jvratio) were set to another set of values in the winter months in order to adapt to the climatic
293 conditions, since biocrusts at sites T1 were collected in summer months. These new, “dynamic” parameters were applied in an
294 additional simulation and the resulting C balance was compared to the original simulation based on the “fixed” parameters.
295 The dynamic parameters were chosen and varied based on the literature: Respiration of lichens was found to acclimate to
296 seasonal changes in temperature (Lange and Green, 2005). Moreover, under low light, organisms showed shade-adapted
297 physiological characteristics with low PAR compensation and saturation points (LCP and LSP; Green and Lange, 1991). These
298 properties can be expressed by certain parameters of the data-driven model. For instance, the respiration rate is determined by
299 the parameter Resp_main; LCP and LSP can be affected by changing the slope of the photosynthesis-light relations through
300 the parameter ExtL; LCP and LSP can also be modified via the parameter jvratio as it influences the value of light use efficiency
301 at unsaturated light.

302 Accordingly, in an hourly simulation during September and December, January, and February, the parameter Resp_main was
303 reduced to half to lighten the respiratory cost for the samples collected at site T1. The size of ExtL was doubled to increase the
304 slope of photosynthesis-light relations. In addition, the parameter jvratio was doubled as well to enhance the light use
305 efficiency.

306 **2.6 LiBry Model**

307 LiBry is a process-based dynamic global vegetation model (DGVM) specific to non-vascular vegetation. The model mimics
308 environmental filtering in the real world by simulating many different functional strategies and selecting those which maintain
309 a positive C balance under the respective climatic conditions. The strategies are characterized by a combination of 11
310 physiological and morphological parameters. More information about the model is briefly described in the Appendix, and a
311 full detailed description can be found in Porada et al. (2013, 2019).

312 For this study, the LiBry model was run for 300 years with repeated microclimate forcing data of one year from the six study
313 sites, calibrated abiotic parameters same as the data-driven model, and initially generated 1000 strategies. C balance and
314 dynamics of the surface cover of the strategies were simulated until a steady state was reached, so that the final successful
315 strategies were those where long-term biomass values were positive. Moreover, at the end of the simulation, the average values
316 of functional traits were estimated by weighting all surviving strategies based on their relative cover. The (hypothetical)
317 strategy characterized by these average values is called average strategy. The strategy with the largest cover area is called
318 dominant strategy.

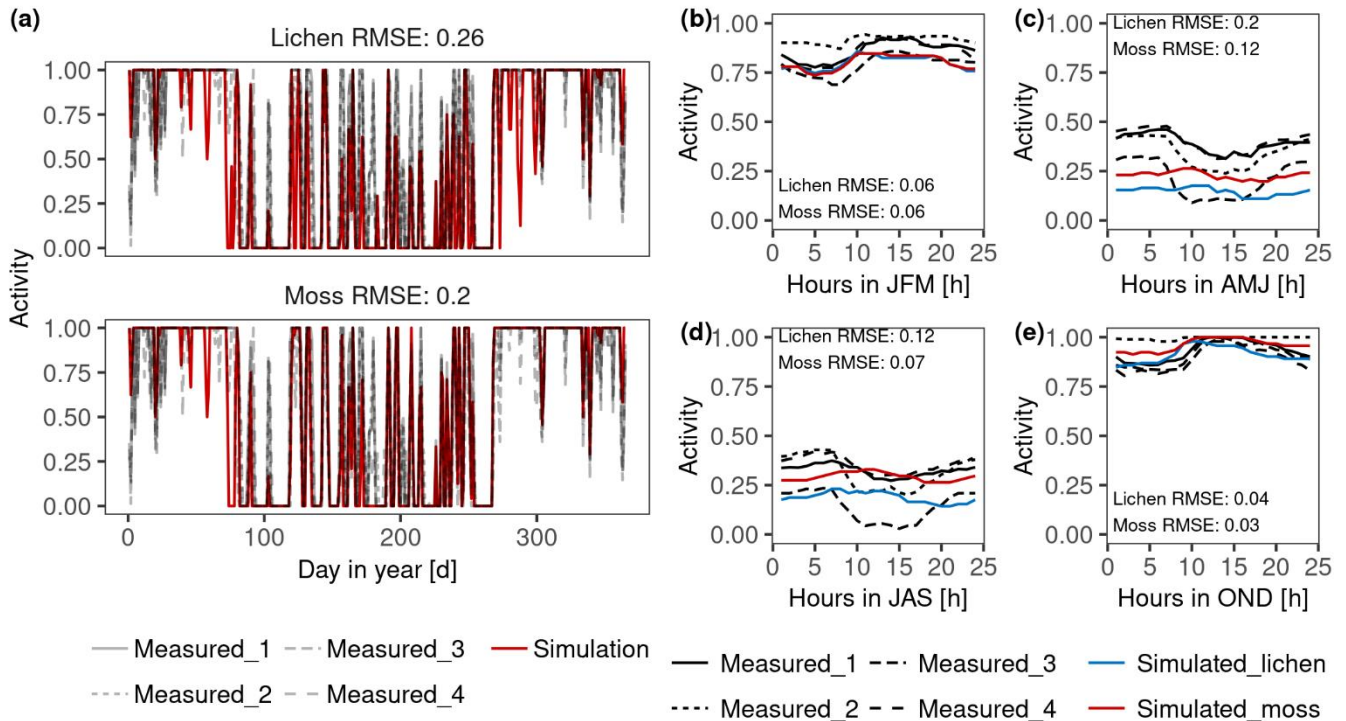

319 Furthermore, we compared the physiological parameters of the average strategy and the selected dominant strategies to the
320 ones of organisms in the field by means of their respective photosynthesis response curves. This comparison can verify the C
321 balance estimated by the data-driven model from a reversed perspective as LiBry model is based on the same processes as the

322 data-driven model, but the strategies were freely selected by the LiBry model based on their C balance, without prescribing
 323 values based on site level observations.

324 3 Results

325 3.1 Data-driven model

326 3.1.1 Validation of the data-driven model

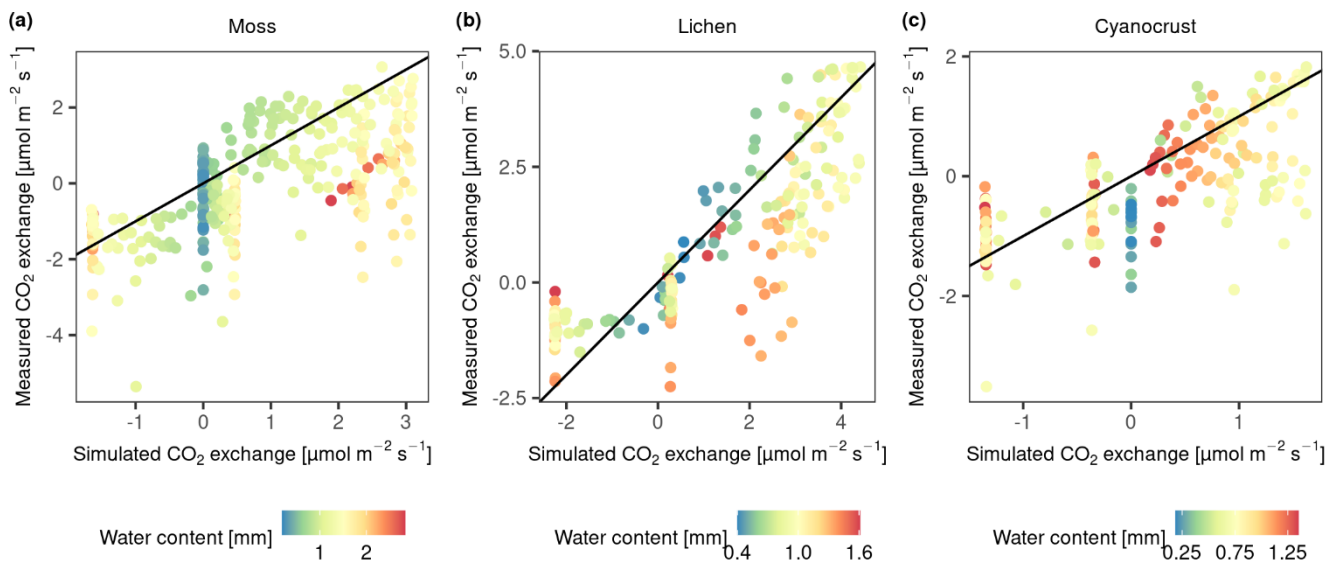

327

328 **Figure 3:** Validation of the estimated daily (a) and diurnal (b-e) patterns of activity of lichen- and moss-dominated biocrusts
 329 at site T3. The simulated patterns of activity were compared to measured data by four sensors at different locations. (b) to (e)
 330 represent the patterns of average hourly activity from January to March (JFM), April to June (AMJ), July to September (JAS),
 331 and October to December (OND), respectively.

332 In general, the simulated daily and diurnal patterns of activity (water content at site D2) fit the measurements reasonably well
 333 in magnitude (Fig. 3 and Fig. S3). However, our fitting resulted in a more dampened diurnal activity pattern simulated by the
 334 model, and the activity at night and in the morning was underestimated during several seasons at sites D1, T1, T2 and A1. In
 335 addition, both the daily and diurnal activity during April and June at site T1 were underestimated. Furthermore, water content
 336 was overestimated for moss-dominated biocrust, especially when there was a large amount of water input at D2, although the

337 patterns corresponded well to the measured data for all three biocrust types (Fig. S3). This overestimation may have resulted
 338 from the bias in measured MWC of samples used for constraining the water content in the model.
 339 The comparison of simulated and on-site measured CO₂ exchange rates of three biocrust types (moss, lichen, and cyanocrust
 340 composed of cyanolichens and cyanobacteria) at site D2 showed mismatches, especially when water saturation was at both
 341 ends of the gradient (Fig. 4). The CO₂ exchange rate at high water content was overestimated compared to the measurements.
 342 Moreover, there were large variations in measurements of respiration and CO₂ exchange rate as water content was low and
 343 thus simulated CO₂ exchange rate was zero. Excluding the values at both ends of water content (0.58 and 1.74 mm for moss;
 344 0.22 and 0.68 mm for lichen; 0.65 and 1.24 mm for cyanocrust), the accuracy of the model predictions was improved (root
 345 mean square error (RMSE) decreased from 1.44 to 1.36 for moss, 1.27 to 0.65 for lichen, and 0.79 to 0.77 for cyanocrust).
 346 Furthermore, the simulations were similar to measurements in magnitude. Therefore, despite the large variation, we are
 347 confident about the general validity of the model.

348
 349 **Figure 4:** Validation of the photosynthesis and respiration scheme of the data-driven model through comparison of modelled
 350 and measured CO₂ exchange rate of moss, lichen, and cyanocrust given the measured water content, surface temperature, PAR,
 351 and calculated activity. Observational data were collected in November in 2013 at site D2. The 1:1 line is shown in black.

352 3.1.2 Estimated C balance by data-driven model

353 The simulated annual C balance of each collected biocrust type at each site is listed in Table. 2. The annual C balance of lichen-
 354 and moss-dominated biocrusts at dryland D1 showed a small positive value. Moreover, the moss-dominated biocrust at dryland
 355 D2 gained small amount of carbon while lichen-dominated biocrust and a cyanocrust additionally measured at site D2 showed
 356 a small net release of carbon in the model.

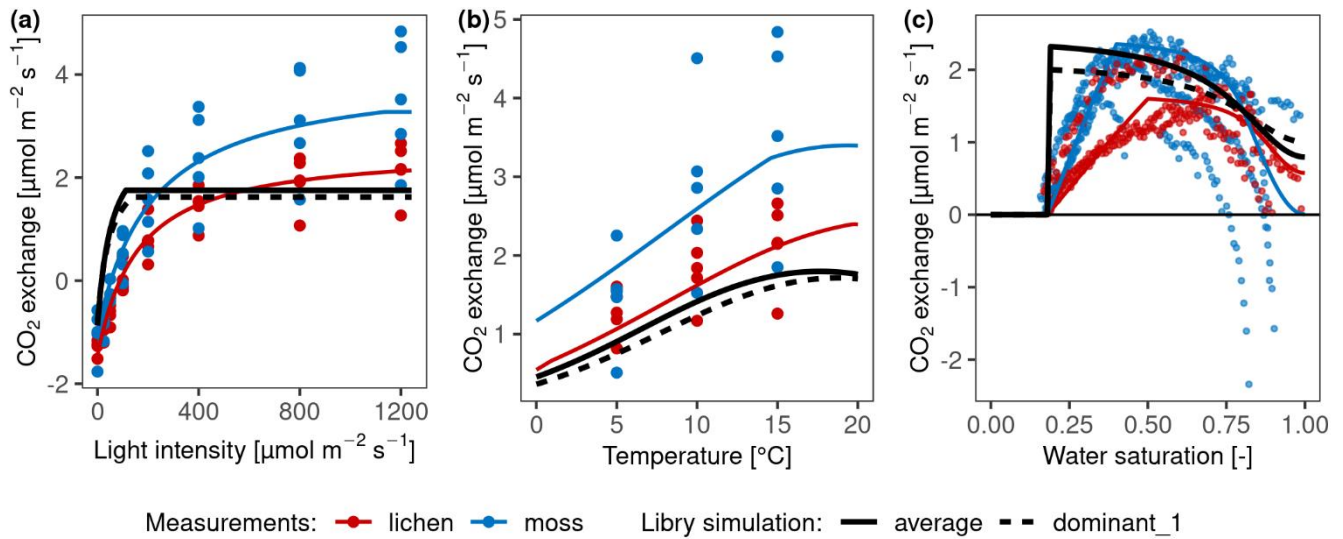

357 **Table 2:** Simulated annual carbon budgets of each biocrust type at all sites.

	Lichen	Moss	Cyanocrust
	g C m ⁻² yr ⁻¹	g C m ⁻² yr ⁻¹	g C m ⁻² yr ⁻¹
D1 (Almería)	1.5	1.9	
D2 (Soebatsfontein)	-1.7	3.1	-8.3
T1 (Gössenheim)	-42.8	-39.4	
T2 (Öland)	-92.1	-74.7	
T3 (Linde)	9.4	18.7	
A1 (Hochtor)	-17.9	-6.8	

358 Furthermore, according to these data-driven model simulations, despite the C balance of two biocrust types being positive at
359 site T3, a large amount of carbon was lost at the sites T1 and T2 in temperate humid regions. These results imply that according
360 to the data-driven model, the biocrusts would not survive in the long-term at most of the temperate humid research sites. At
361 the alpine site A1, both lichen- and moss-dominated biocrust lost carbon in a year with long periods of ice cover.

362 **3.2 Dominant strategies selected by the LiBry Model**

363 In general, the photosynthesis response curves of dominant and average strategies selected by the LiBry model did not fit well
364 to the measurements, especially at temperate site T2 (Fig. 5; the results for the other sites with negative C balance are shown
365 in Fig. S4). Specifically, the selected physiological traits which determine water and light acquisition of the dominant and
366 average strategies in LiBry differed from those of the collected samples at all sites. Compared to the measured samples, the
367 LiBry strategies showed markedly higher efficiency at low light intensity and faster activation. By design, the LiBry model
368 selected strategies with a positive C balance in the long-term run, and thus the mismatches are consistent with the fact that the
369 data-driven model simulated negative C balances.

370

371 **Figure 5:** Comparison of net photosynthesis response of measured samples with simulated selected dominant and average
 372 strategies of LiBry at site T2. (a): light response curve; (b): temperature response curve; (c): water response relation. The
 373 colored points represent the measured CO₂ exchange rates of moss and lichen, and the coloured lines correspond to the data-
 374 driven model. The black lines show the photosynthesis response of the dominant strategy selected by the LiBry model (dashed)
 375 and the average strategy (solid). The parameter values of the average strategy correspond to the average of all surviving
 376 strategies.

377 3.3 Driving factors of variation of the C balance

378 3.3.1 Environmental factors

379 The environmental factors light intensity, CO₂ concentration, air temperature, and various water sources, had different effects
 380 on the C balance of lichens in different climate zones (Fig. 6). For all sites within a given climate zone, the effects of different
 381 environmental factors on C balance were overall similar but showed an apparent larger variation at the temperate site T3 in
 382 contrast to the other two temperate sites, and at site D2 compared to D1 (Fig. 6a). This may be due to physiological differences
 383 of the investigated biocrust species between these sites and consequently variations in the responses of net photosynthesis rate
 384 to temperature, water, and light between them (Fig. 2 and S2).

385 Furthermore, the spatial patterns of the relative importance of different environmental factors show that the factors which have
 386 the strongest effects differ between climatic regions (Fig. 6b).

388 **Figure 6:** (a) The effects of environmental factors - CO₂ concentration (CO₂), relative air humidity (R_hum), rainfall amount
389 (Rain), air temperature (T_air) and light intensity (Light) on the annual C balance of lichens in different climate regions. The
390 altered annual C balance resulting from increasing or decreasing environmental factors is normalized by the C balance under
391 original environmental conditions. The colored columns indicate the average value of the normalized C balance at sites with
392 similar climate conditions. Various styles of black points indicate different sites. Positive normalized C balance implies that
393 the annual C balance increases with varying environmental factors and more carbon was accumulated in a year at the site, and
394 vice versa. A larger normalized C balance reflects that the C balance is more sensitive to the altering environmental factor,
395 and thus the environmental factor has a larger effect on C balance. (b) Relative importance of each environmental factor
396 compared to other factors across the climatic regions. Larger relative importance implies a more important effect the factor
397 has on the C balance compared to other factors in the given climatic region, and vice versa.

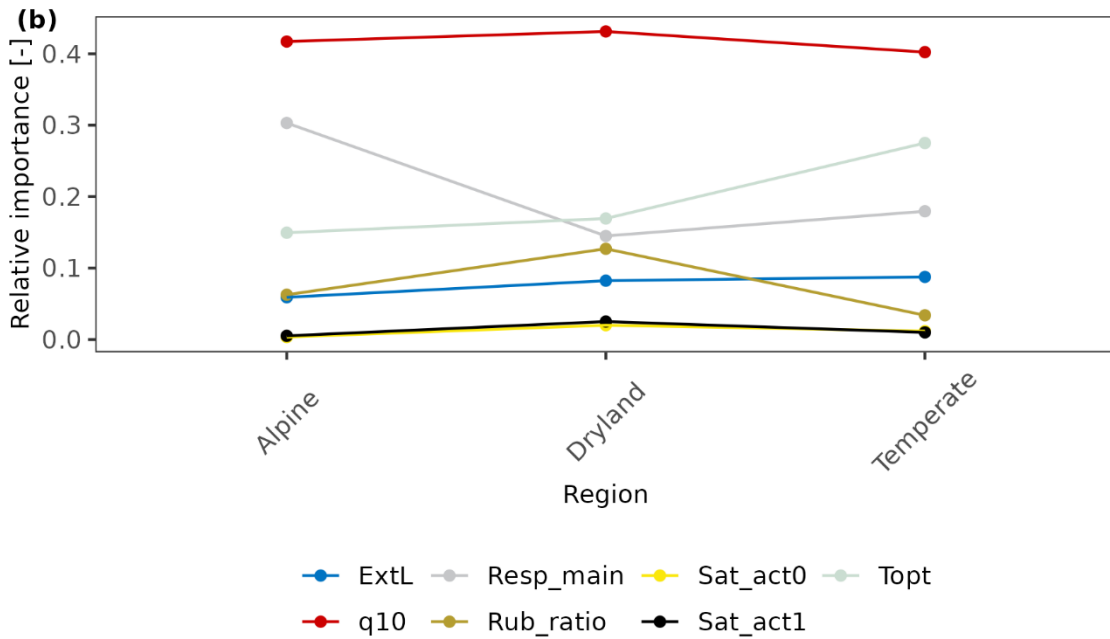

398 In general, air temperature and CO₂ concentration were the most important drivers for C balance of biocrust organisms between
399 climate zones. Light intensity and relative humidity played a relevant role in impacting the C balance as well. Rainfall amount
400 had lower relative importance at all sites except dryland D2, where the effect of rainfall on C balance was similar to other
401 factors (Fig. 6a). Therefore, rainfall amount showed a maximum in relative importance in drylands, compared to other regions.
402 In general, the effect of the other water source, relative air humidity, was moderate but notable at all climate zones, and is
403 slightly larger in temperate region in comparison to other climate zones. Furthermore, the humidity had a slightly larger impact
404 on C balance in comparison to rainfall amount at all temperate and alpine sites (e.g., change amplitude was 0.007 for rainfall
405 and 0.021 for humidity at T1). In drylands, however, the impacts of water sources on C balance varied between sites. The
406 results showed that relative humidity had a slightly larger impact than rainfall amount at D1 while smaller at D2 (the change
407 in amplitude at D2 was 0.108 for humidity and 0.137 for rainfall).

408 The ambient CO₂ concentration was an essential factor for the C balance at all sites especially in drylands, resulting in positive
409 effects on C balance with increasing CO₂. Furthermore, light intensity had a marked impact on the C budget at all sites, and it
410 was relatively more important in drylands and temperate regions than the alpine site. At all sites, the normalized C balance
411 increased with enhanced light intensity and vice versa (e.g. normalized C balance at T2 are -0.013 and 0.008 for half and
412 doubled light intensity). Air temperature had a large impact on C balance at all sites. Especially at the alpine site A1, C balance
413 decreased strongly as air temperature raised by 5 K (normalized C balance of -0.735), and at all sites, the direction of the effect
414 remained constant, namely, warming decreased the C balance and vice versa.

415 **3.3.2 Physiological parameters**

416 We found that physiology plays an important role in all regions. In particular, the respiration-related parameters such as q₁₀,
417 Resp_{main}, and T_{opt} have a notably higher impact on C balance estimation (Fig. 7). Furthermore, the relative importance of
418 several physiological parameters showed similar patterns across climatic zones: in all regions, q₁₀ is the most essential
419 parameter, Sat_{act0} and Sat_{act1} play little roles in affecting C balance. Other parameters showed slightly different patterns

420 among regions. Metabolic respiration cost (Resp_main), for instance, plays a more important role than optimum temperature
421 for gross photosynthesis (Topt) at the alpine site, while the optimum temperature is more essential in drylands and temperate
422 regions (Fig. 7b).

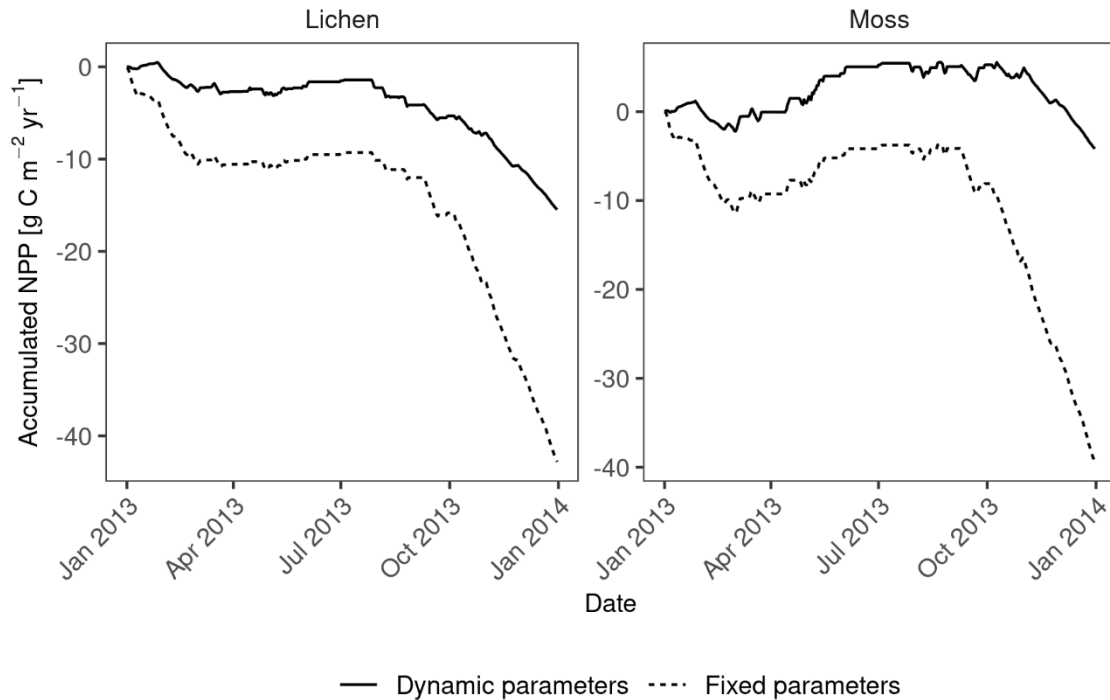

424 Figure 7: (a) The effects of physiological parameters – metabolic respiration cost per surface area (Resp_main), Q10 value of
425 respiration (q10), the optimum temperature for gross photosynthesis (Topt), respiration cost of RuBisCO enzyme (Rub_ratio),
426 and light absorption fraction in cells (ExtL), minimum saturation for activation (Sat_act0), and minimum saturation for full
427 activation (Sat_act1) – on the annual C balance of lichen-dominated biocrusts in different climate regions. The parameters
428 decreased or increased by a consistent range for all sites based on the measured deviation in photosynthesis response curves
429 of replicates. The altered annual C balance resulting from increasing or decreasing parameters is normalized by the original C
430 balance. The coloured columns indicate the average value of the normalized C balance at sites with similar climate conditions.
431 Various styles of black points indicate different sites. (b) Relative importance of each physiological parameter compared to
432 other parameters across the climatic regions. Larger relative importance implies a more important effect the parameter has on
433 the C balance compared to other parameters in the given climatic region, and vice versa.

434 However, even though physiology parameters play an important role in all regions, the C balance at T1, T2 and A1 did not
435 become positive when the physiological parameters were varied reasonably, that is the parameters were varied to relatively
436 cover the deviation of response curves of replicates. Furthermore, the change in C balance value is much smaller in drylands
437 compared to other regions (as shown in Fig. S11 in Appendix).

438 **3.3.3 Acclimation of physiological properties**

439 The sensitivity analysis for acclimation showed a marked increase in annual productivity of lichen- and moss-dominated
440 biocrusts at site T1 (Fig. 8) when the seasonal acclimation of several physiological parameters was included in the model (from
441 -42.8 to -15.5 g C m⁻² yr⁻¹ and from -39.4 to -4.2 g C m⁻² yr⁻¹).

442

443 **Figure 8:** Comparison of accumulated annual C balance between two simulations in the sensitivity analysis of seasonal
 444 acclimation of physiological properties. In the simulation “fixed parameters”, all parameters that have been calibrated or
 445 measured remained constant throughout the simulation year. For the simulation “dynamic parameters” at site T1,, parameter
 446 metabolic respiration cost per surface area (Resp_main) was reduced by half, light absorption fraction in cells (ExtL) was
 447 doubled but restricted to one, the ratio of Jmax to Vcmax (jvratio) was increased by two times from September to February to
 448 adapt to the winter climates. For the other months, the “fixed” values were used.

449 **4 Discussion**

450 **4.1 Simulated C balance of data-driven model**

451 The data-driven model aims to provide observation-based estimates of the carbon fluxes of non-vascular photoautotrophs
 452 which may serve as approximation for the C balance of vegetation in biocrust-dominated ecosystems. At the two dryland sites,
 453 the moss-dominated biocrusts were estimated to be carbon sinks on an annual basis, and lichen-dominated biocrust can also
 454 be a carbon sink at one of the dryland sites. As shown in the results, mosses accumulated 1.9 and 3.1 g C m⁻² yr⁻¹ at site D1
 455 and D2, respectively, and lichens accumulated 1.5 g C m⁻² yr⁻¹ at site D1.

456 The estimated C balance at the two dryland sites is consistent with the magnitude of the annual C balance of different biocrust
 457 types reported by various studies in arid habitats. Feng et al. (2014) recorded that the biocrusts composed of lichens, mosses,

458 and cyanobacteria of the Mu Us Desert in China took up 3.46 to 6.05 g C m⁻² yr⁻¹. Brostoff et al. (2005) estimated a larger
459 carbon gain by lichen biocrust of 11.7 g C m⁻² yr⁻¹ in the Mojave Desert, USA. For cyanobacteria, an annual carbon uptake of
460 0.02 to 2.3 g C m⁻² was reported for deserts (Jeffries et al., 1993). The estimated C balance values in drylands fluctuate
461 relatively largely, but the magnitude is consistent with the simulated results by the data-driven model at D1 and D2.
462 For biocrust lichens growing on rock surface without soil attached underneath in a temperate grassland, Lange (2003b)
463 measured an annual carbon gain of 21.49 g C m⁻². Additionally, several studies estimated the carbon budget in humid tundra
464 habitats. An amount of ~12–70 g C m⁻² yr⁻¹ carbon was fixed by moss-dominated biocrust, for instance (Schuur et al., 2007).
465 The magnitude of these values corresponds to the estimation of the C balance at T3. However, the estimated annual carbon
466 losses of lichens and mosses by the data-driven model in temperate regions T1 and T2 should actually lead to the death of
467 these organisms, which is not consistent with their dominant abundance in the field and is much lower than published by
468 previous studies.
469 The mismatches of trait values between strategies predicted via selection by the LiBry model for the sites and the collected
470 species with regard to their net photosynthesis response curves indicate that the physiological parameter values that would be
471 necessary to maintain a positive C balance in LiBry are not compatible with those of the sampled biocrusts. This is in line with
472 the results of the data-driven model, which also simulates a negative C balance and is based on the same physiological
473 processes as LiBry. This also applies to the lack of seasonal acclimation in both modeling approaches, since the strategies in
474 LiBry are assumed to have constant functional properties throughout the simulation.

475 **4.2 Uncertainties of long-term C balance simulated by the data-driven model.**

476 The data-driven model simulated relatively reasonable C balance values in drylands but unrealistic, negative values at
477 temperate sites T1 and T2. Since the same or similar gas exchange methodology has been used for all sites, differences in the
478 simulated C balance among these regions likely result from variation in the species-specific interactions between climate and
479 physiological processes, including seasonal variation in physiological properties due to acclimation.
480 As the results (Fig. 6) show, CO₂ concentration is an essential factor for the annual C balance of biocrusts, especially at dryland
481 and some temperate sites. Therefore, uncertainty in the CO₂-value prescribed in the model may be a source of error. The CO₂
482 concentration at the surface boundary might exceed the value of 400 ppm that was prescribed in the model because of CO₂
483 diffusion from the soil, which may lead to an underestimated C balance (Fig. 6a). However, with enhanced CO₂ concentration
484 in the sensitivity analysis (600 ppm) at site T1, for instance, the estimated C balance increased only slightly, and is still strongly
485 negative (-37.0 g C m⁻² yr⁻¹ for lichen and -30.2 g C m⁻² yr⁻¹ for moss). Hence, the lower CO₂ concentration can partially
486 contribute to the strongly negative C balance at T1 and T2, but is not a major factor.
487 Furthermore, the negative C balance at temperate and alpine sites may result from the uncertainties in physiology, which were
488 also observed between replicates (see Fig. 2 and Fig. S2). An overestimation of dark respiration rates of the photoautotrophs
489 in the biocrust may result from including a small amount of heterotrophic respiration. The overestimated respiration rate then
490 leads to an overestimation of the parameter metabolic respiration cost per surface area (Resp_main) and might also cause an

491 underestimated Q10 value (q_{10}) calculated from the respiration rates. The uncertainties of these two parameters reduce the
492 estimated C balance largely (Fig. 7). Additionally, the optimum temperature (T_{opt}), which is also the reference temperature
493 for calculating the respiration rate, cannot be well constrained by the limited measured temperature response data set. Thus,
494 T_{opt} may be underestimated. The larger difference in surface temperature to T_{opt} results in a larger respiration rate, and lower
495 gross photosynthesis, which leads to a lower C balance.

496 Although the uncertainty in individual physiological parameters may not lead to the markedly negative C balance estimates,
497 as indicated by still negative values upon variation of these parameters (Fig. S11), additive effects of all parameters combined
498 with long-term unfavourable environmental conditions may cause a large amount of carbon lost over a year. The optimal
499 conditions are rare within a year, which was also described by Lange (2003b). Thus, the overestimated respiration rate leads
500 to a lower carbon gain during the relatively optimal conditions, which may not be sufficient to compensate for exaggerated C
501 losses under long-term harsh conditions, such as autumn and winter at site T1, for instance. For this reason, the simulated C
502 balance of mosses and lichens in temperate humid regions was mostly negative.

503 In addition to the uncertainty in the values of physiological parameters, seasonal acclimation of these physiological traits to
504 the current climatic conditions may play an important role in regulating the C balance at humid sites where the organisms are
505 active throughout the year, such as site T1 (Fig. 8). It was observed, for instance, that the respiration of lichens shows
506 acclimation to seasonal changes in temperature, and the maximum CO_2 exchange rate of the organisms remains steady
507 throughout the year (Lange and Green, 2005). Gauslaa (2006) found a higher chlorophyll a/b ratio in forest lichens with
508 increasing light. Moreover, depression in quantum efficiency in summer under extremely dry conditions has been observed
509 (Vivas et al., 2017). These varied physiological properties of organisms within a year may result in different photosynthesis
510 and respiration rates, and thus different C balances in comparison to the ones that cannot acclimate to the seasonal climate.
511 The missing seasonal acclimation of physiological traits may explain why the data-driven model estimated a negative C
512 balance for biocrusts in humid regions.

513 Another limitation of the modeling approach may be the lack of separate responses of respiration and photosynthesis to
514 metabolic activity. Both photosynthetic activity and respiration reach their maximum in the model once the water saturation
515 reaches the optimum value for net photosynthesis (W_{opt_np}). In some cases, however, respiration rate may reach the maximum
516 value only at a higher saturation than W_{opt_np} (Lange, 1980), indicating that the model may overestimate respiration in the
517 long-term.

518 In comparison to the unrealistic C balance numbers at T1 and T2, we estimated more reasonable values in drylands and at T3.
519 However, we do not make a definitive statement about whether or not the model predicts an accurate C balance in drylands.
520 since the measured climate data and photosynthesis response curves that were used for calibrating land surface properties and
521 various physiological parameters represent only samples of the large physiological and climatic variation. A higher accuracy
522 would be more likely to be expected in drylands as these regions have a more uniform climate throughout the year than
523 temperate regions that show substantial seasonality. Additionally, variation in light conditions is slightly more relevant for the
524 simulated C balance than variation in moisture (see Fig. 6) because the organisms are able to become inactive, meaning that

525 the dry season in drylands does not have a decisive effect on the C balance, while low light in winter in temperate climate does
526 since organisms have to be active then. Furthermore, the longer total inactive period in drylands could reduce the bias in the
527 magnitude of the simulated C balance caused by incorrectly estimated physiological parameter values. We estimated a smaller
528 absolute change in annual C balance in drylands with varied physiological parameters in the sensitivity analysis (for instance,
529 the C balance of lichens changed by 34.6 g C m⁻² yr⁻¹ for parameter T_{opt} at T1, while it changed only by 1.5 g C m⁻² yr⁻¹ at
530 D1).

531 Furthermore, the estimated C balance may be inaccurate due to the potential bias in estimated relative water saturation, which
532 partly depends on prescribed MWC obtained by measurements. However, the outcome of the sensitivity analysis of MWC at
533 T1 revealed that the annual carbon estimation is robust to the uncertainties with regard to the prescribed MWC (details in
534 Appendix). Another factor that potentially affects the accuracy of C balance estimates is interannual climatic variability. While
535 the model estimated unrealistic C balance values of lichen-dominated biocrusts at T1 and T2 for current conditions, the C
536 balance may have been different in other years. Therefore, the simulation of annual C balance based on multi-year climate
537 data is worthy of future study to understand the long-term C balance better. Moreover, the estimated negative C balance of
538 certain lichen and moss species may not be generalizable and representative for the overall situation in the field due to the
539 large variation in physiological adaptation strategies to climate. There could be other organisms that form cryptogamic covers,
540 for instance, that show a different degree of depression in net photosynthesis at high water content (Lange et al., 1995), and
541 thus have more reasonable C balance values.

542 **4.3 Potential factors influencing the C balance**

543 Despite diverse climatic conditions, we found similarities regarding the dominant environmental factors and physiological
544 parameters controlling the C balance. Thereby, CO₂ and air temperature were the two most important environmental factors at
545 all sites. Relative air humidity, partly precipitation, and light intensity were also relevant for the estimation of the C balance.
546 In terms of physiological parameters, the respiration-related parameters were the most important drivers, while parameters that
547 affect V_{cmax} and thus the light-independent CO₂ assimilation rate were relevant, too.

548 The relative importance of these factors/parameters varied slightly among climatic regions. Regarding the comparison between
549 environmental factors, we cannot rule out that the magnitudes of changes in environmental factors that we applied in the
550 sensitivity analysis were not balanced, which may have led to an overestimation of the relative importance of certain factors,
551 such as air temperature, for instance, compared to the others. The spatial patterns across climate regions of a given
552 environmental factor, however, are not affected by this, which means that differences between climatic regions for a given
553 factor are most likely robust. Hence, air temperature is more relevant at the alpine site and relative air humidity has a higher
554 impact in temperate than in other regions, rainfall and CO₂ are likely to have the largest effect on C balance in drylands. Even
555 though the data-driven model failed to estimate reasonable C balance at some sites, the comparison of the relative importance
556 of the environmental factors across climatic regions may be valid since the measurement procedure is consistent. Moreover,
557 the patterns of relative importance remain similar when excluding the sites with strongly negative C balance (T1, T2, and A1;

558 as shown in the Fig. S12 in Appendix). Nevertheless, we only studied the sensitivity of the C balance of biocrusts dominated
559 by the lichen *Psora decipiens* and *Cladonia furcata* (at T3), and there are variations between lichens of different growth forms
560 and between biocrust types. For example, cyanolichens increase in abundance with increasing rainfall, but trebouxoid lichens
561 have their physiological optimum in drier conditions (Phinney et al., 2021). Moreover, the impact of precipitation on isidiate
562 lichens is weaker than that of temperature (Phinney et al., 2021).

563 4.3.1 Environmental factors

564 Our results suggest that warming can result in a large amount of carbon loss at all sites, with a particular large effect in the
565 alpine region. The consistent effects of warming on C balance of biocrusts are found in various field studies (e.g., Darrouzet-
566 Nardi et al., 2015; Ladrón de Guevara et al., 2014; Li et al., 2021; Maestre et al., 2013). This can be explained by the overall
567 less optimal water and temperature conditions associated with warming. The simulated increasing respiratory costs with
568 warming overcompensate gains in gross photosynthesis.

569 Ambient CO₂ concentration affects the gross photosynthesis rate to a large extent in the model. Although the intra-annual
570 change in air CO₂ concentration may be small in the field compared to other environmental factors, the increase of CO₂ in the
571 atmosphere in recent decades (IPCC 2021) may alter the long-term C balance substantially. However, this beneficial effect of
572 elevated CO₂ on photosynthesis and C balance may be reduced in reality due to future limitation of growth by nitrogen (Coe
573 et al., 2012a), which is not considered in the model, or also due to shortened activity periods resulting from warmer and drier
574 future climatic conditions.

575 Light intensity has the third largest effect on C balance, slightly larger than moisture. Light is one of the essential factors for
576 photosynthesis as simulated by our model, and it is a limiting factor of photosynthetic carbon assimilation, in particular in
577 winter at temperate and alpine sites (the mean value of radiation maxima in January is 244 $\mu\text{mol m}^{-2} \text{s}^{-1}$ at T1 and 245 μmol
578 $\text{m}^{-2} \text{s}^{-1}$ at the alpine site). Hence, increasing light intensity can promote carbon accumulation.

579 Factors that determine water supply are rainfall and non-rainfall inputs such as dew and water vapor that are related to relative
580 humidity. The relative importance of different moisture factors in mediating C balance varies in the model. Relative humidity
581 plays a more important role in mediating the C balance than rainfall amount. This may be due to the timing of dew or water
582 vapor uptake, which is greatest before sunrise (Chamizo et al., 2021; Ouyang et al., 2017) and prolongs the activated periods
583 in the early morning when the organisms start assimilating carbon (Veste and Littmann, 2006). This may result in a markedly
584 increased annual C balance in the model. Rainfall amount was not a key factor affecting the simulated biocrust performance
585 at one of the arid sites, which is consistent with another study (Baldauf et al., 2021). At the other dryland site (D2), however,
586 this was not the case. Moreover, we found that the effect of the amount of rainfall is small in humid temperate and alpine
587 regions as well. The differing effects of rainfall on the C balance depend on the change in relative water saturation that follows
588 from rainfall event sizes and patterns throughout the year (Reed et al., 2012). In some cases, decreased rainfall leading to lower
589 water saturation of biocrusts may facilitate photosynthetic carbon gain via increasing the CO₂ diffusivity from the atmosphere
590 into the chloroplast (Lange et al., 1997). Nevertheless, reducing water saturation below a certain value can cause a decline in

591 the duration of activity (Proctor, 2001; Veste et al., 2008) which thus reduces carbon accumulation. Thus, there may be a rain
592 threshold below which decreasing rain may start having a negative effect on biocrust C balances. The threshold is likely
593 species-specific as it is associated with the water-holding capacity of the organism. Our simulation results thus highlight the
594 need for the combined application of field experiments and data-driven modeling to improve our understanding of differential
595 responses to variation in precipitation.

596 **4.3.2 Physiological parameters**

597 The parameter q_{10} is a key parameter that substantially affects respiration. $Resp_{main}$ is the dark respiration rate at a reference
598 temperature that is linked in the model to V_{cmax} , the maximum rate of carboxylation of RuBisCO in the Calvin Cycle of
599 photosynthesis (Walker et al., 2014). $Topt$ is a parameter that controls gross photosynthesis as well as respiration as it is also
600 the reference temperature for calculating respiration rates. Rub_{ratio} can affect V_{cmax} and hence the maximum CO_2
601 assimilation rate, while $ExtL$ regulates the light using efficiency under limited light conditions. Sat_{act0} and Sat_{act1} are two
602 parameters that determine the range of water saturation for initial activation and full metabolic activity. They have the smallest
603 effects on the C balance of lichen-dominated biocrusts at all sites.

604 Our modeling results give insights into the relative effects of individual physiological parameters on annual C balance across
605 different climatic zones. However, the impacts of physiology on biocrust C balance are complex since they always arise from
606 combinations of these physiological parameters. Thereby, different parameter combinations that correspond to different
607 relative impacts on the C balance may lead to the same response curves. Hence, we cannot directly link individual physiological
608 parameters to the underlying mechanisms since we do not have enough data to distinguish multiple possible parameter
609 combinations from each other, in case they produce the same response curves.

610 **4.4 Validation of the data-driven model**

611 The validation results of the model showed an overall good fit of daily and diurnal patterns of water content and activity (Fig.
612 3 and S3), and C balance at D2 (shown in Fig. 4) given the uncertainties in the data used to parameterize and evaluate the
613 model. This indicates that the data-driven model may be a reliable tool for C balance estimation, provided that a sufficient
614 amount of suitable forcing data is available.

615 A potential explanation for the general underestimation of activity at night and morning during several periods in a year is the
616 larger prescribed MWC and Sat_{act0} of organisms in the model compared to those of the samples from the activity
617 measurements. Consequently, simulated saturation was lower, but minimal saturation for being active was higher than the
618 samples. Thus, the activity may have been underestimated at small water inputs such as dew and water vapor, which occur
619 mainly during the night and in the morning hours (Fig. S13). Moreover, underestimated activity in April and June at site T1
620 (Fig. S3 F(b)) may have resulted from a gap in rainfall measurements during this period. Not only rainfall amount but also
621 timing and frequency of rainfall events are essential for the physiological responses of biocrust communities (Belnap et al.,
622 2004; Coe et al., 2012b; Reed et al., 2012). Therefore, although the measured annual total amount of rainfall is reasonable (424

623 mm at site T1), the missing rainfall during a series of days in summer at site T1 would lead us to incorrectly predict that the
624 biocrusts remain inactive on these days.

625 Moreover, the mismatch between modelled and observed CO₂ assimilation rates at low or high water contents at site D2 (Fig.
626 4) may have partly resulted from the calibration procedure. In the calibration the simulated CO₂ exchange rates were higher
627 than measurements when the saturation exceeded the optimum saturation and hardly showed any negative values at high
628 saturation (Fig. S2 f). In turn, the simulated CO₂ exchange rates of biocrusts with an extremely low water content were zero
629 while the measurements showed negative values (see Fig. S2 f), pointing at a certain degree of metabolic activity in natural
630 conditions. Furthermore, the samples used for validation were different from the ones for calibration, which can also lead to
631 inaccuracies.

632 Additionally, the ability of the model to capture seasonality variations of C balance, which have been shown by other studies
633 (Büdel et al., 2018; Lange, 2003a; Zhao et al., 2016), could not be evaluated here since the monitoring of C balance in the field
634 and collection of samples used for photosynthesis performance measurements were conducted only during October and early
635 November.

636 **5 Conclusions**

637 Our data-driven model provides possibilities to predict the long-term C balance of biocrusts in the field across various climate
638 zones, and it enables us to analyse mechanisms that drive the C balance, despite marked uncertainties in the parametrization.
639 We simulated reasonable C balance values in drylands but unrealistic ones at temperate sites with substantial seasonality.
640 Uncertainties in environmental factors and respiration rate are likely to be the source of error for the C balance estimation
641 since (1) all environmental factors that were examined in our study may act as relevant drivers for the C balance of biocrusts
642 and (2) respiration-related parameters had the largest impacts compared to other physiological parameters, such as water
643 relations or parameters solely related to V_cmax. CO₂ and air temperature showed the strongest effects among environmental
644 factors and at the alpine site, the air temperature was most relevant. Compared to environmental factors, the relative impacts
645 of physiological parameters are rather equal across climate regions. The optimum temperature may be slightly more relevant
646 in temperate regions, while metabolic respiration cost is most important at the alpine site. Due to the importance of respiration-
647 related physiological parameters, more studies to improve their accuracy are warranted in the future application of C balance
648 modeling approaches.

649 Our study suggests that a better, more detailed understanding of the seasonal variation of physiological traits is necessary, as
650 the more realistic estimations in drylands compared to temperate sites could be due to the weaker climate seasonality. The
651 model needs to be calibrated with a larger number of samples collected and measured in various seasons to take the acclimation
652 of physiological properties into account. Additionally, the integration of acclimation of physiological traits in process-based
653 models may improve their accuracy in C balance estimation.

654 *Code and Data Availability Statement.* Source code of the data-driven model, LiBry modelling results, R-scripts to run the
655 analysis in this manuscript are available in Zenodo repository at <https://doi.org/10.5281/zenodo.7756960>. Field and
656 laboratory data are available in the corresponding publications cited in the manuscript and also from the corresponding
657 author upon request.

658 *Author Contributions.* YM and PP designed the study, BW, AK, MV and JR provided the observational data. YM did the
659 data processing, ran the model, YM, PP, CC, BW and MB did the data analysis and interpretation, YM wrote the manuscript,
660 and all authors revised it.

661 *Conflict of Interest.* The authors have no conflict of interest to declare.

662 *Acknowledgments.* This research is supported by the University of Hamburg. The research in Linde is funded by
663 Zwillenberg-Tietz Stiftung by a grant to MV. Research in South Africa was funded by the Federal Ministry of Education and
664 Research (BMBF), Germany, through its BIOTA project (promotion number: 01 LC 0024A), the German Research
665 Foundation (Project numbers WE 2393/2-1, WE 2393/2-2) and the Max Planck Society. The research was conducted with
666 Northern Cape research permits (No. 22/2008 and 38/2009) and the appendant export permits and lab facilities were
667 provided by Burkhard Büdel at the University of Kaiserslautern and Ulrich Pöschl at the Max Planck Institute for Chemistry
668 in Mainz. JR acknowledges the Research Projects SCIN (PRI-PIMBDV-2011-0874) and POLAR ROCKS (PID2019-
669 105469RB-C21), both funded by the Spanish Ministry of Science, the possibility of obtaining part of the data and analyzing
670 them respectively in the frame of this research. CC acknowledges funding support provided by a NERC Standard Grant
671 (NE/V000764/1) and the Feodor Lynen Research fellowship from the Alexander von Humboldt foundation.
