23 **Abstract**

24

25 The trace metal iron (Fe) is an essential micronutrient that controls phytoplankton productivity,  
26 which subsequently affects organic matter cycling with feedback on the cycling of macronutrients.  
27 Along the continental margin of the U.S. West Coast, high benthic Fe release has been  
28 documented, in particular from deep anoxic basins in the Southern California Borderland.  
29 However, the influence of this Fe release on surface primary production remains poorly  
30 understood. In the present study from the Santa Barbara Basin, in-situ benthic Fe fluxes were  
31 determined along a transect from shallow to deep sites in the basin. Fluxes ranged between 0.23  
32 and 4.9 mmol m<sup>-2</sup> d<sup>-1</sup>, representing some of the highest benthic Fe fluxes reported to date. To  
33 investigate the influence of benthic Fe release from the oxygen-deficient deep basin on surface  
34 phytoplankton production, we combined benthic flux measurements with numerical simulations  
35 using the Regional Ocean Model System coupled to the Biogeochemical Elemental Cycling model  
36 (ROMS-BEC). For this purpose, we updated the model Fe flux parameterization to include the  
37 new benthic flux measurements from the Santa Barbara Basin. Our simulations suggest that  
38 benthic Fe fluxes enhance surface primary production, supporting a positive feedback on benthic  
39 Fe release by decreasing oxygen in bottom waters. However, a reduction of phytoplankton Fe  
40 limitation by enhanced benthic fluxes near the coast may be partially compensated by increased  
41 nitrogen limitation further offshore, limiting the efficacy of this positive feedback.

42

## 43 **1. Introduction**

44 The California Current System (CCS), located off the coasts of Washington, Oregon, and  
45 California, is a typical Eastern Boundary Upwelling System, where seasonal upwelling supports a  
46 highly diverse and productive marine ecosystem (Chavez and Messié, 2009; Carr and Kearns,  
47 2003). The CCS can be split into three main parts: the main equatorward California Current  
48 offshore, a subsurface poleward undercurrent fringing the continental shelf, and a recirculation  
49 pattern known as the Southern California Eddy in the Southern California Bight.

50 In the CCS, both upwelling and large-scale circulation provide essential nutrients to the euphotic  
51 zone, where they fuel high rates of net primary production (NPP). While seasonal upwelling  
52 dominates north of Point Conception, advection by the CCS provides a major route for nutrient  
53 supply to the Santa Barbara Channel in the Southern California Bight (Bray et al., 1999). Following  
54 phytoplankton blooms, sinking and degradation of organic matter lead to oxygen consumption and  
55 widespread oxygen loss in subsurface waters (Brander et al., 2017; Chavez and Messié, 2009).  
56 Along the southern California coast, this oxygen depletion is exacerbated by regional circulation  
57 patterns that include transport of low-oxygen waters of tropical origin along the poleward  
58 undercurrent (Evans et al., 2020; Pozo Buil and Di Lorenzo, 2017). Oxygen decline is particularly  
59 apparent in deep, isolated basins such as those found in the Southern California continental  
60 borderland, where the presence of shallow sills limits ventilation of deep waters, and anoxic  
61 conditions are often encountered near the bottom (Reimers et al., 1990; Goericke et al., 2015;  
62 White et al., 2019).

63 In the CCS, the trace metal iron (Fe) has been identified as a limiting factor for the growth of  
64 phytoplankton (Hogle et al., 2018). Fe is an essential micronutrient that has also a considerable  
65 influence on the dynamics of phosphorus and nitrogen in the euphotic zone (Tagliabue et al., 2017).  
66 Similar to other nutrients, Fe is transported to the surface by upwelling and circulation. However,  
67 Fe supply is generally low in oxygenated environments relative to other macronutrients, reflecting  
68 rapid scavenging of insoluble iron-oxide minerals by sinking particles that eventually accumulate  
69 in the sediment (Bruland et al., 2001, 2014; Firme et al., 2003; Till et al., 2019). While early studies  
70 suggested that Fe inputs to the CCS are dominated by rivers and aeolian deposition (Biller and  
71 Bruland, 2013; Johnson et al., 2003), more recent work highlights a combination of sources,

72 including benthic fluxes (Severmann et al., 2010; Noffke et al., 2012; Tagliabue et al., 2017;  
73 Wallmann et al., 2022) and ocean currents, which help redistributing Fe in coastal waters (Bray et  
74 al., 1999; Boiteau et al., 2019; García-Reyes and Largier, 2010).

75 Benthic release of Fe(II), the reduced and soluble form of Fe, has been recognized as a potential  
76 source of Fe to the surface ocean along the continental shelf and slope of the CCS, including the  
77 deep basins of the California borderland (John et al., 2012; Severmann et al., 2010). Under hypoxic  
78 or anoxic bottom waters, Fe(II) produced in the sediment during microbial organic matter  
79 degradation coupled to Fe (III) reduction diffuses across the sediment-water interface and  
80 accumulates in the water column (Furrer and Wehrli, 1993; Dale et al., 2015; Severmann et al.,  
81 2010; Wallmann et al., 2022). In the CCS, this benthic Fe flux is likely to exceed atmospheric  
82 deposition (Deutsch et al., 2021), and may ultimately make its way to the surface by upwelling  
83 and vertical mixing, supporting high rates of photosynthesis.

84 The interaction between low bottom water oxygen, Fe(II) release, and transport by the ocean  
85 circulation is particularly important in the Santa Barbara Basin (SBB), an oxygen-deficient basin  
86 located between the Channel Islands and mainland California in the Southern California Bight.  
87 The SBB frequently experiences seasonal anoxia in the bottom water in fall, with irregular oxygen  
88 flushing of dense, hypoxic water below the western sill depth (470 m) during winter and spring  
89 (Goericke et al., 2015; Sholkovitz and Soutar, 1975; White et al., 2019; Qin et al., 2022). This  
90 seasonal flushing reflects either changes in upwelling strength and frequency, or changes in  
91 stratification at the sill depth, although the exact cause of the flushing is still unclear (Goericke et  
92 al., 2015; Sholkovitz and Gieskes, 1971; White et al., 2019). Lack of oxygen in the deeper parts  
93 of the basin supports anaerobic microbial processes in the bottom water and sediment (White et  
94 al., 2019), including benthic Fe reduction (Goericke et al., 2015), causing the release of Fe(II) into  
95 the water column (Severmann et al., 2010). Ventilation events that re-oxygenate the deep basin, as  
96 well as mixing by the vigorous submesoscale circulation (Kessouri et al., 2020), could allow  
97 upwelling of this Fe above the sill depth and ultimately to the surface, providing a linkage between  
98 benthic processes and upper water-column biogeochemistry. Increased surface primary production  
99 supported by this Fe source would in turn drive higher remineralization and oxygen loss in deep  
100 waters, thus providing a positive feedback to benthic Fe release. However, with a dearth of benthic  
101 Fe flux measurements in the SBB, gaps remain in our understanding of the dynamics and impact

102 of benthic Fe flux in the Southern California Borderland, particularly with respect to its magnitude,  
103 dependence on bottom water oxygen, and ability to reach the euphotic zone and influence primary  
104 production.

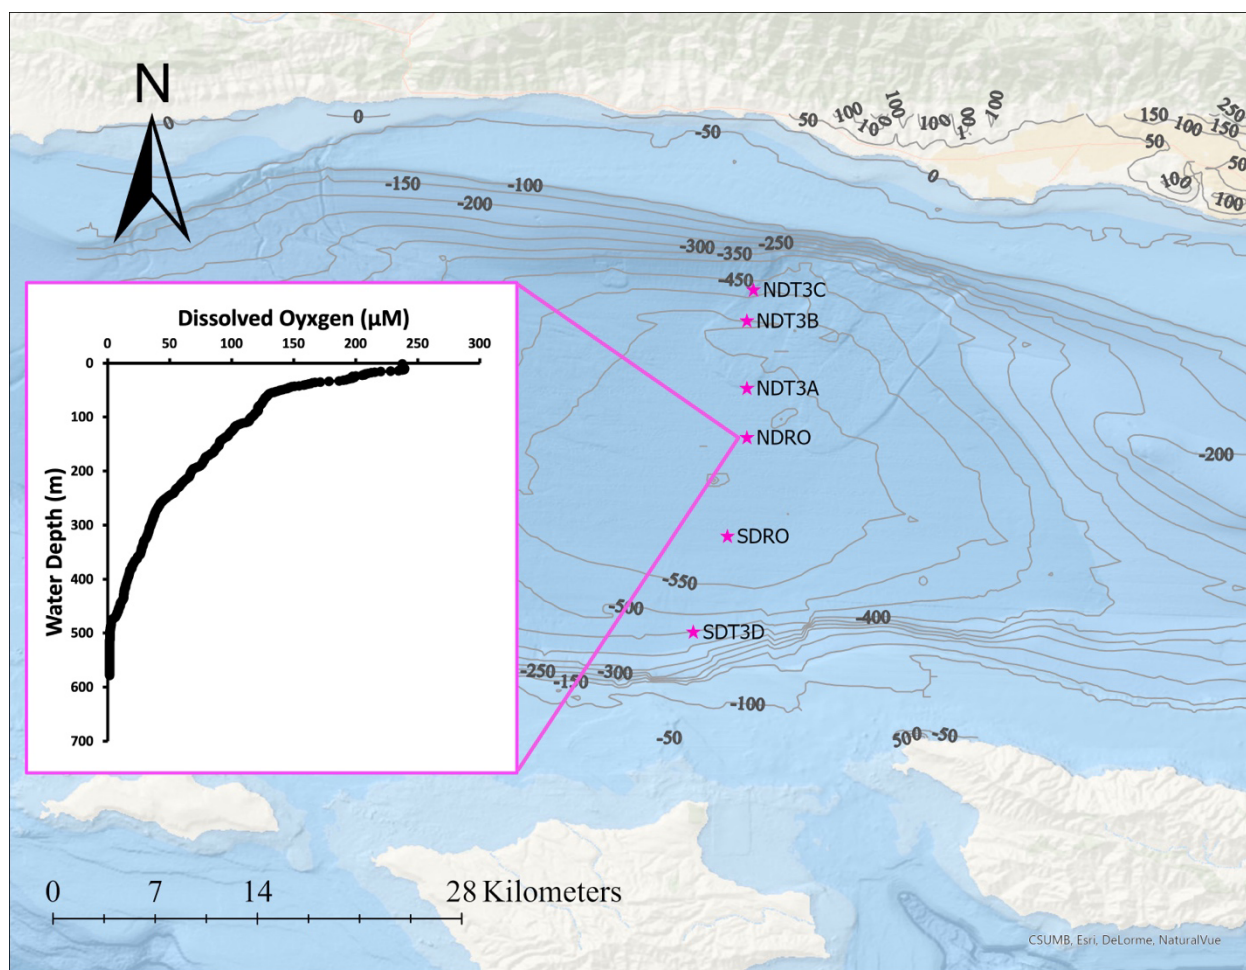

105 In this study, we explore the connection between benthic Fe flux and surface primary production  
106 in the CCS, by investigating the influence of enhanced benthic Fe fluxes from low-oxygen waters  
107 with a combination of field observations and experiments with a numerical model. We focus on  
108 the SBB, where we provide a new set of benthic Fe flux estimates determined by in-situ benthic  
109 flux chamber measurements. We combine these new observations with existing data (Severmann  
110 et al., 2010) to revise the representation of benthic Fe fluxes in UCLA's Regional Ocean Modeling  
111 System coupled to the Biogeochemical Elemental Cycling (ROMS-BEC) model (Deutsch et al.,  
112 2021). We then use the model to evaluate the effect of benthic Fe fluxes on surface nutrient  
113 consumption and NPP, and compare their impact to that of aeolian Fe deposition in the SBB and  
114 beyond.

115 **2. Materials and Methods**

116 **2.1 Study Site**

117 Fieldwork in the SBB was conducted between Oct 29 and Nov 11, 2019, during the R/V Atlantis  
118 cruise AT42-19. Sampling occurred during the anoxic, non-upwelling season along one bimodal  
119 transect with six stations total at depths between 447 and 585 m (**Fig. 1, Table 1**).

120

121

122 **Figure 1.** Station locations in the SBB during the AT42-19 expedition with R/V Atlantis. NDT3  
123 (with stations A, B, C) = Northern Depocenter Transect Three, NDRO = Northern Depocenter  
124 Radial Origin, SDRO = Southern Depocenter Radial Origin, SDT3 (with station D) = Southern  
125 Depocenter Transect Three. The small insert figure displays dissolved oxygen concentrations in  
126 the water column at the NDRO station profiled by an optical oxygen sensor attached to the AUV

127 Sentry. The profile was measured at the following position: Latitude 34.2618 N, Longitude -  
128 120.0309 E. The map was created using ArcGIS Ocean Basemap, with bathymetric contour lines  
129 representing depth information taken from the General Bathymetric Chart of the Ocean (GEBCO)  
130 database.

131 Transects were divided into northern (NDT3 = Northern Depocenter Transect Three) and southern  
132 (SDT3 = Southern Depocenter Transect Three) sites based on basin geography (**Fig. 1**). Stations  
133 were labeled alphabetically from A (deepest) to D (shallowest) according to their location along  
134 the transect, except for the deepest stations at the bottom of the basin, which were labeled Northern  
135 Depocenter Radial Origin (NDRO) and Southern Depocenter Radial Origin (SDRO).

## 136 **2.2 Benthic Flux Chambers**

137 Custom-built cylindrical benthic flux chamber systems (Treude et al., 2009) were deployed by the  
138 ROV Jason at the six stations (**Fig. 1**). Polycarbonate chambers (19 cm inner diameter) were  
139 installed in a small lightweight frame made from fiber-reinforced plastics. A stirrer (Type K/MT  
140 111, K.U.M. Umwelt- und Meerestechnik, Kiel, Germany) was used to keep the water overlying  
141 the sediment enclosed by the chamber well mixed. One or two replicate chamber systems were  
142 deployed at each site. Since sediment in the SBB is quite soft and poorly consolidated, especially  
143 towards the deeper stations, frames were fitted with platforms attached to the feet of the frame and  
144 with buoyant syntactic foam to reduce sinking into the sediment. A syringe sampler was equipped  
145 with 6 glass sampling syringes that were connected with 50 cm long plastic tubes (2.5mm inner  
146 diameter, Vygon, Aachen, Germany). Each sampling syringe withdrew 50 mL of the overlying  
147 seawater at pre-programmed times. A seventh syringe was used to inject 50 mL of de-ionized  
148 water shortly after chambers were deployed to calculate chamber volume from the salinity-drop  
149 recorded with a conductivity sensor (type 5860, Aanderaa Data Instruments, Bergen, NO) in the  
150 overlying water, following the approach described in (Kononets et al., 2021). Water samples were  
151 analyzed for Fe(II) on the ship using a Shimadzu UV-Spectrophotometer (UV-1800), equipped  
152 with a sipper unit, following the procedure of (Grasshoff and Ehrhardt, 1999). Fe fluxes were  
153 calculated from the slope of linear fits of Fe concentration time series vs. time (**Fig. S1**), multiplied  
154 by the chamber volume, and divided by the surface area of the sediment (Kononets et al., 2021).

## 155 **2.3 Numerical model (ROMS-BEC)**

156 To explore the impacts of benthic Fe fluxes on surface primary production, we used a well-  
157 established ocean biogeochemical model of the CCS (Renault et al., 2016; Deutsch et al., 2021).  
158 The physical model component consists of the Regional Ocean Modeling System (ROMS),  
159 (Shchepetkin, 2015; Shchepetkin and McWilliams, 2005) a primitive-equation, hydrostatic,  
160 topography-following ocean model. As in prior work, the model domain spans the entire U.S. West  
161 Coast, from Baja California to Vancouver Island, with a horizontal resolution of 4 km, enough to  
162 resolve the mesoscale circulation (Capet et al., 2008). The baseline model configuration was run  
163 over the period 1995–2017 with interannually varying atmospheric forcings. We refer the reader  
164 to earlier publications (Renault et al., 2021; Deutsch et al., 2021) for a complete description of the  
165 model configuration, setup, forcings and boundary conditions used in this study.

166 ROMS is coupled online to the Biogeochemical Elemental Cycling (BEC) model (Moore et al.,  
167 2004), adapted for the U.S. West Coast by (Deutsch et al., 2021). BEC solves the equations for the  
168 evolution of six nutrients (nitrate ( $\text{NO}_3^-$ ), ammonium ( $\text{NH}_4^+$ ), nitrite ( $\text{NO}_2^-$ ), silicate ( $\text{SiO}_2$ ),  
169 phosphate ( $\text{PO}_4^{3-}$ ), and iron (Fe)), three phytoplankton groups (small phytoplankton, diatoms, and  
170 diazotrophs), a single zooplankton group, inorganic carbon, oxygen ( $\text{O}_2$ ), and dissolved organic  
171 matter (carbon, nitrogen, phosphorus, and iron). Nutrient and carbon cycles are coupled by a fixed  
172 stoichiometry, except for silica and Fe, which use variable stoichiometries (Deutsch et al., 2021;  
173 Moore et al., 2001, 2004). The Fe cycle in BEC includes four separate pools: dissolved inorganic  
174 Fe (dFe), dissolved and particulate organic Fe, and Fe associated with mineral dust. Of these, only  
175 dissolved organic and inorganic Fe are explicitly tracked as state variables, while particulate Fe is  
176 treated implicitly by resolving vertical sinking particle fluxes (Moore et al., 2001; Moore and  
177 Braucher, 2008). Four main processes control the cycle of Fe in the model: atmospheric deposition,  
178 biological uptake and remineralization, scavenging by sinking particles, and release by sediment.  
179 The atmospheric dFe deposition is based on the dust climatology of (Mahowald et al., 2006), and  
180 dissolution rates from (Moore and Braucher, 2008). Different from (Deutsch et al., 2021), we re-  
181 evaluated the dependence of benthic dFe fluxes on bottom water  $\text{O}_2$  concentrations in the  
182 California margin based on a merged dataset that combines our measurements from the SCB, with  
183 those presented in (Severmann et al., 2010) (see Section 2.5). The model Fe scavenging scheme  
184 removes dFe from the water column at a rate proportional to sinking particle fluxes and dFe  
185 concentrations, assuming a uniform concentration of 0.6 nM of Fe-binding ligands (Moore et al.,  
186 2004; Moore and Braucher, 2008). Accordingly, scavenging rates increase strongly at dFe

187 concentrations greater than 0.6 nM, and vice versa rates decrease strongly below 0.5 nM (**Fig. S2**).  
188 Note that, while simplistic, this formulation is still widely adopted by global ocean  
189 biogeochemistry models (Tagliabue et al., 2014, 2016), although improvements have been  
190 proposed (Moore and Braucher, 2008; Aumont et al., 2015; Pham and Ito, 2019, 2018).

191 As shown in previous work, the model captures the main patterns of physical and biogeochemical  
192 variability in the CCS, providing a representation of nutrient cycles and NPP in good agreement  
193 with observations (Renault et al., 2021; Deutsch et al., 2021). We further evaluate the model  
194 against an extended set of dissolved Fe measurements for the CCS (see Sections **2.4** and **3.1**).

## 195 **2.4 Fe dataset along the U.S. West Coast**

196 To assess the ability of the model to capture observed patterns in dFe along the U.S. West Coast,  
197 we gathered available dFe concentration measurements from published studies, including a global  
198 compilation (Tagliabue et al., 2016), regional programs such as CalCOFI, CCE-LTER, IRNBRU  
199 and MBARI cruises (Bundy et al., 2016; Hogle et al., 2018; Johnson et al., 2003; King and  
200 Barbeau, 2011), and other individual studies (Biller and Bruland, 2013; Boiteau et al., 2019; Bundy  
201 et al., 2014, 2015, 2016; Chappell et al., 2019; Chase, 2002; Chase et al., 2005; Firme et al., 2003;  
202 Hawco et al., 2021; John et al., 2012; Till et al., 2019). In the final compilation, we define dFe as  
203 the sum of the dissolved Fe and dissolvable Fe, based on the definitions used in each publication.  
204 Different studies used different filter sizes to define the dFe pool, most commonly 0.20, 0.40, and  
205 0.45  $\mu\text{m}$ , and different sampling methods, such as bottles, pump systems and/or surface tows. In  
206 some studies, samples were briefly acidified before being analyzed. Despite the differences in  
207 sampling and measurement approaches, we found that these datasets generally agreed with each  
208 other, suggesting that the final compilation accurately represents the dFe distribution along the  
209 U.S. West Coast. The final dataset includes observations from 1980 to 2021, with most samples  
210 collected between 1997 and 2015, and from the upper 100 m of the water column.

## 211 **2.5 Experimental Design**

212 To evaluate the impact of Fe fluxes from low- $\text{O}_2$  sediment in the SBB on surface biogeochemistry,  
213 we designed a suite of model sensitivity experiments with ROMS-BEC in which external sources

214 of Fe are modified relative to a baseline simulation. Accordingly, we run the following model  
215 experiments:

216 **High-flux:** This experiment is the baseline model simulation, using a Fe flux parameterization  
217 calculated as an exponential fit to a data set of benthic Fe fluxes consisting of the new benthic  
218 measurements from AT42-19 and previous observations from the U.S. West Coast (Severmann et  
219 al., 2010) (see Section 3.2), thus updating the parameterization by (Deutsch et al., 2021). Benthic  
220 Fe release follows the equation:

$$221 \log_{10}(\text{Fe}) = 2.86 - 0.01 \cdot \text{O}_2 \quad (\text{Equation 1})$$

222 Where  $\text{O}_2$  is the concentration of oxygen in  $\text{mmol m}^{-3}$  and (Fe) is the Fe flux in  $\mu\text{mol m}^{-2} \text{d}^{-1}$ . This  
223 revised formulation is only applied in the SBB where we performed our measurements, while a  
224 different formulation, solely based on data by (Severmann et al., 2010) is used outside of the SBB:

$$225 \log_{10}(\text{Fe}) = 2.6178 - 0.0128 \text{O}_2 \quad (\text{Equation 2})$$

226 For this parameterization, we corrected a model bias that resulted in modeled bottom  $\text{O}_2$   
227 concentrations greater than  $30 \text{ mmol m}^{-3}$  over most of the deep basins where observations indicated  
228 lower concentrations, down to oxygen-free conditions (**Fig. S3**). We therefore reduced modeled  
229 bottom water  $\text{O}_2$  concentrations in the Southern California Borderland by  $30 \text{ mmol m}^{-3}$ , based on  
230 the average difference between model and observed  $\text{O}_2$  in the region. This correction is crucial to  
231 producing realistic benthic Fe fluxes under the anoxic conditions observed in the SBB, rather than  
232 fluxes at  $\text{O}_2$  concentrations of  $30 \text{ mmol m}^{-3}$ .

233 **Hypoxia-off:** The purpose of this experiment is to evaluate the importance of enhanced Fe fluxes  
234 under low- $\text{O}_2$  conditions in the SBB. Benthic Fe fluxes are calculated as in *High-flux* experiment  
235 (Equation 2), but they are capped at a constant value when  $\text{O}_2$  decreased below a threshold of  $65$   
236  $\text{mmol m}^{-3}$ , which we chose as representative of hypoxic conditions (Deutsch et al., 2011). This  
237 change is applied only to in the SBB, and effectively bounds the benthic Fe release at  $1.48 \mu\text{mol}$   
238  $\text{m}^{-2} \text{d}^{-1}$  when  $\text{O}_2$  drops below the threshold for hypoxia.

239 **Dust-off:** The purpose of this experiment is to evaluate the importance of aeolian Fe deposition in  
240 the CCS, and to compare it with the benthic Fe fluxes. In this experiment, the atmospheric Fe  
241 deposition is set to zero; all other settings are identical to the *High-flux* experiment.

242 The baseline (*High-flux*) model simulation is run from 1995 to 2017. The other two model  
243 sensitivity experiments (*Hypoxia-off* and *Dust-off*) are branched off from the *High-flux* simulation  
244 in year 2008 and run separately for 10 additional years (2008-2017). All model experiments use  
245 the same set of forcings and initial conditions. Results from the final 3 years (2015-2017) of the  
246 *Hypoxia-off* and *Dust-off* simulations are averaged and analyzed by comparing differences in  
247 biogeochemical fields (Fe, NO<sub>3</sub><sup>-</sup>, and NPP) to the final 3 years of the *High-flux* run.

248 **3. Results**

249 **3.1 In-situ benthic Fe fluxes and model parameterization**

250 Benthic Fe fluxes from in-situ benthic chamber measurements during the AT42-19 expedition are  
251 shown in **Table 1**. High Fe flux was recorded at the anoxic depocenter stations (4.90 and 3.92  
252 mmol m<sup>-2</sup> d<sup>-1</sup> at SDRO and 3.49 mmol m<sup>-2</sup> d<sup>-1</sup> at NDRO). Fe fluxes at the shallower hypoxic  
253 stations (NDT3C, NDT3B, and SDT3D) were an order of magnitude lower. The Fe flux at the  
254 hypoxic NDT3A station between NDRO and NDT3B was approximately half the flux observed at  
255 the depocenter.

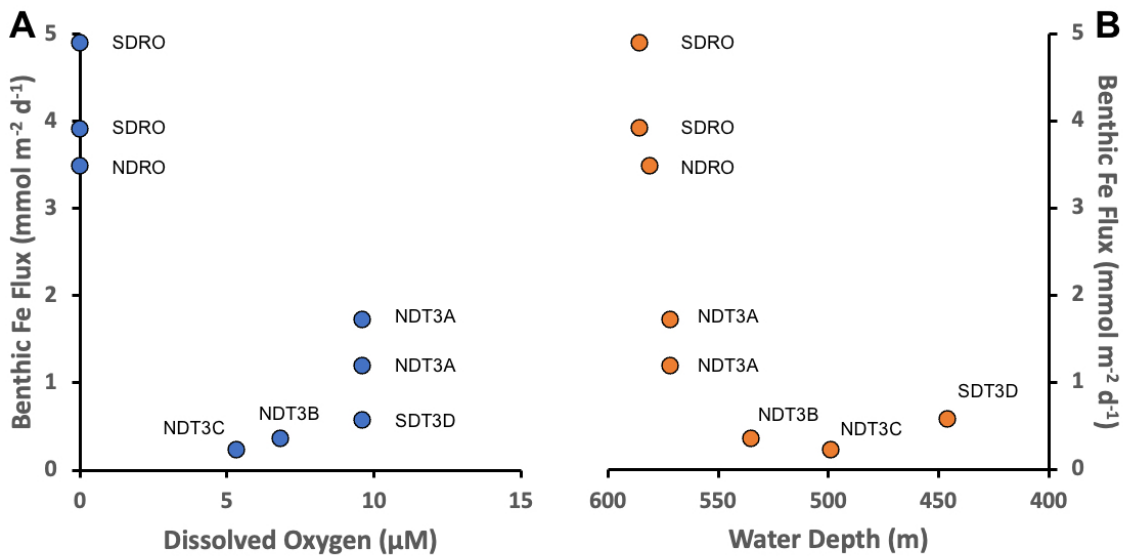

256 **Table 1.** Station details and geochemical parameters determined during the AT42-19 expedition.  
257 Benthic Fe fluxes were determined using in-situ benthic chambers. Dissolved O<sub>2</sub> concentrations  
258 were measured in the water column at 10 m above the seafloor using a Seabird optode sensor  
259 attached to the ROV Jason. At stations with two benthic chamber deployments (NDT3A and  
260 SDRO), O<sub>2</sub>, geographical coordinates, and depth were averaged as there were only minimal  
261 differences between the two chamber deployments.

Station	Fe Flux [mmol m <sup>-2</sup> d <sup>-1</sup> ]	O <sub>2</sub> [mmol m <sup>-3</sup> ]	Latitude [N]	Longitude [E]	Depth [m]
NDT3C	0.23 (n=1)	5.3	34.3526	-120.0160	499
NDT3B	0.36 (n=1)	6.8	34.3336	-120.0188	535
NDT3A	1.73; 1.20 (n=2)	9.6	34.2921	-120.0258	572
NDRO	3.49 (n=1)	0.0	34.2618	-120.0309	581
SDRO	4.90; 3.92 (n=2)	0.0	34.2011	-120.0446	586
SDT3D	0.58 (n=1)	9.6	34.1422	-120.0515	446

262

263 Trends in the Fe fluxes suggest modulation by O<sub>2</sub> concentration, water depth, and/or bathymetry.  
264 We also note that observed oxygen concentration represents a snapshot of bottom water conditions,  
265 while Fe fluxes likely reflect the oxygenation history at any given site. We observed a decrease in  
266 the Fe flux with a decrease in water depth (**Fig. 2**). There was also a slight trend of higher Fe fluxes  
267 with lower O<sub>2</sub> concentrations (most pronounced when O<sub>2</sub> reaches zero); however, since O<sub>2</sub>

268 concentrations were relatively low at all stations ( $<10 \text{ mmol m}^{-3}$ ) it is difficult to distill a clear  
 269 pattern based on the small dataset. Notably, the NDT3A station showed a high Fe flux despite  
 270 exhibiting the same  $\text{O}_2$  concentration as the shallower station SDT3D. Basin bathymetry may also  
 271 contribute to observed differences in the flux. For instance, the deeper depocenter and A-station  
 272 showed higher averaged fluxes than the B, C, and D stations. We further noticed differences  
 273 between the north and south extension of the transect. The southern stations (SDRO and SDT3D)  
 274 showed a higher Fe flux than the northern stations (NDRO and NDT3C).

275

276 **Figure 2.** Benthic in-situ Fe fluxes. A: Fluxes as a function of  $\text{O}_2$ . B: Fluxes as a function of  
 277 (station) water depth. Note that water depth is shown from deep to shallow depths. See Table 1 for  
 278 station details.

279 We combined Fe fluxes determined during AT42-19 with previous estimates along the CCS, as  
 280 compiled by (Severmann et al., 2010), and analyzed them as a function of bottom water  $\text{O}_2$  (**Fig.**  
 281 **3**). Pooled together, the measurements can be described reasonably well by an exponential increase  
 282 of Fe fluxes with declining bottom water  $\text{O}_2$  (Severmann et al., 2010), although significant  
 283 variability around an exponential fit remains. This relationship is consistent with the Fe flux  
 284 parameterization adopted in the ROMS-BEC model (Deutsch et al., 2021). Several observations  
 285 from the AT42-19 cruise (red dots in **Fig. 3**) exceed the range of previous measurements (blue  
 286 dots in **Fig. 3**), likely owing to the anoxic or near-anoxic conditions in the water. Relative to the

287 exponential fit to the dataset by (Severmann et al., 2010) (yellow line in **Fig. 3**, see Equation 2)  
288 the revised fit to the pooled data (purple line in **Fig. 3**, see Equation 1) expands Fe fluxes by  
289 approximately a factor of two at O<sub>2</sub> concentrations close to zero, but decreases the magnitude of  
290 the Fe fluxes at concentrations above approximately 130 mmol m<sup>-3</sup>.

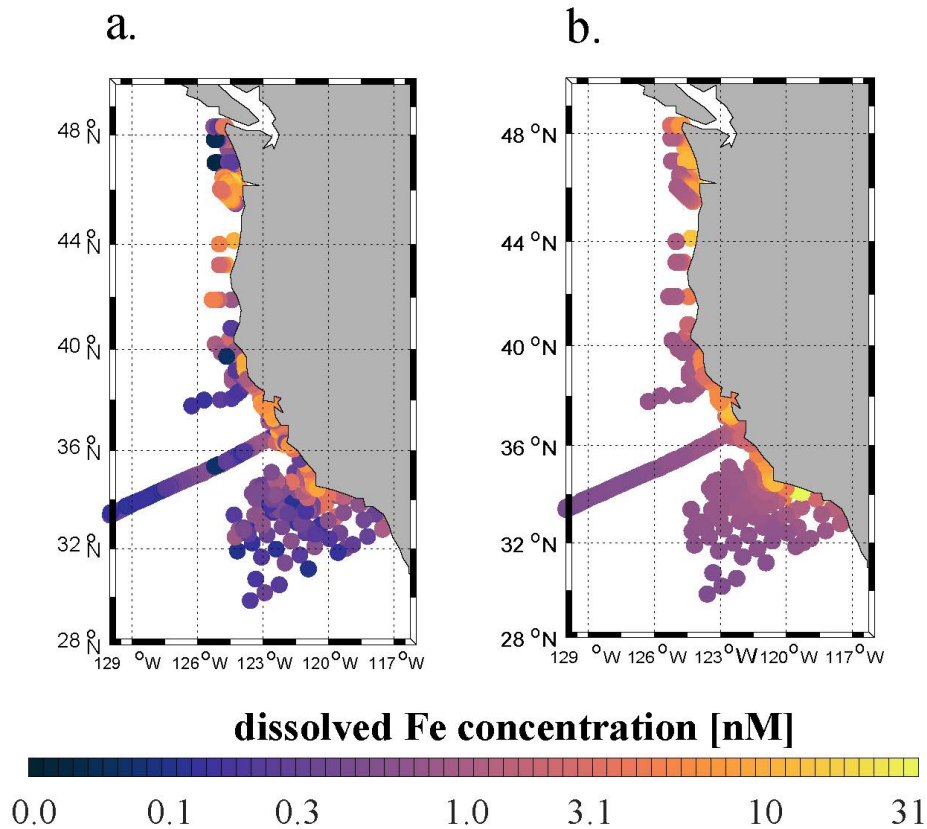

### 291 3.2 Model evaluation: High flux simulation

292 The *High-flux* simulation captures the magnitude and patterns of the observed dFe distribution in  
293 the upper ocean (**Fig. 4**), consistently with our knowledge of the ocean Fe cycle. In both model  
294 and observations, dFe concentrations are low at the surface, as a result of phytoplankton uptake,  
295 and increase gradually in subsurface waters due to organic matter remineralization in the water  
296 column and at the seafloor, and benthic Fe fluxes from the sediment (**Fig. S4**). The highest dFe  
297 concentrations are found along the coast, likely related to high surface productivity and shallow  
298 carbon export and remineralization, combined with basin bathymetry and O<sub>2</sub> deficiency. In the  
299 open ocean, dFe concentrations are low in both model and observations, reflecting a combination  
300 of phytoplankton uptake, scavenging by sinking particles, and low external inputs.

301  
302 **Figure 3.** Combined benthic Fe flux data as a function of bottom oxygen. Blue dots show data  
303 from the compilation by (Severmann et al., 2010); red dots measurements from the AT42-19  
304 cruise. The yellow line shows an exponential fits to the dataset by (Severmann et al., 2010)

305 (Equation 2). The purple line shows an exponential fit to the combined dataset (Equation 1). Note  
306 the logarithmic scale used for the y-axis.

307

308

309 **Figure 4.** (a) Observed dFe concentrations (nM) from the U.S. West Coast compilation (see  
310 Section 2.4) averaged between 0 and 100 m depth. (b) Annual mean modeled dFe concentrations  
311 (nM) averaged between 0 and 100 m depth, sampled at the same locations as the observations in  
312 panel (a).

313 Observational limitations prevent a more detailed validation of subsurface dFe patterns.  
314 Measurements of dFe concentrations in subsurface and deep waters (> 100 m) are currently very  
315 sparse in the CCS region and Southern California Borderland. Most of the dFe measurements for  
316 the SBB come from limited sampling conducted quarterly as part of selected CalCOFI (California  
317 Cooperative Oceanic Fisheries Investigations) cruises (King and Barbeau, 2011). These samples  
318 mostly focus on the mixed layer and are too sparse in space and time to capture the effects of deep-

319 water renewal events that ventilate the anoxic basins and allow uplifting and transport of deep  
320 waters towards the surface.

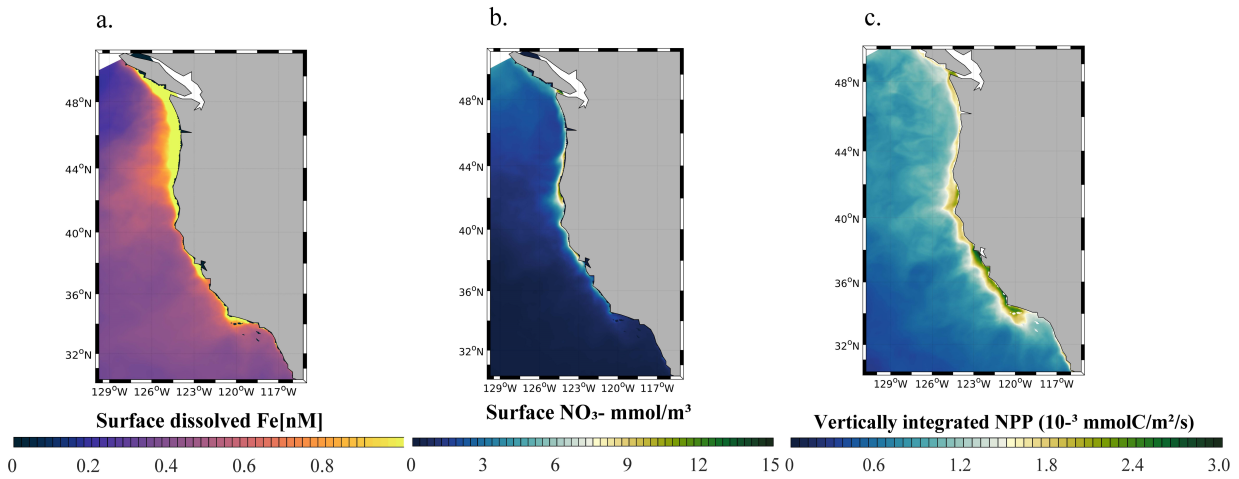

321 The agreement of the model dFe with observations (correlation coefficient  $R=0.22$ ,  $p<0.01$ ) is  
322 similar to that of other ocean biogeochemical models (Tagliabue et al., 2016). The model tends to  
323 underestimate the sharp dFe gradient between coastal and open ocean waters, overestimating dFe  
324 in the open ocean and producing too uniform concentrations offshore and at depth (**Fig. 4**). These  
325 biases are likely related to the simple Fe scavenging scheme, which assumes a constant Fe-binding  
326 ligand concentration of 0.6 nM. The small number and episodic nature of in-situ measurements  
327 may also explain some of the mismatches between model and observations.

328 At the scale of the CCS, the *High-flux* simulation produces lower surface dFe in the southern part  
329 of the domain (33°N to 36°N), and higher surface concentration in the northern part (40°N to  
330 45°N) and near the central coast (**Fig. 5a**). While these patterns reflect a combination of internal  
331 Fe cycling and external inputs, the elevated dFe in the northern CCS, in particular offshore, can be  
332 partly attributed to higher aeolian deposition in that region (**Fig. S5**) as well as coastal inputs from  
333 the Juan De Fuca strait (Deutsch et al., 2021).

334 The model reproduces the typical signature of coastal upwelling, with higher concentrations of  
335  $\text{NO}_3^-$  nearshore in the central coast (36°N-40°N) and low concentrations in the Southern California  
336 Bight and offshore (**Fig. 5b**). Similarly, the model reproduces high values of NPP near the coast,  
337 in particular along the central coast, and rapidly decreasing values offshore (**Fig. 5c**). Relative to  
338 previous modeling work (Deutsch et al., 2021) our simulations generate somewhat lower surface  
339  $\text{NO}_3^-$  concentrations close to the coast, and sharper NPP gradients between the nearshore and  
340 offshore regions, which are consistent with the rapid decrease in primary productivity and  
341 chlorophyll shown by both satellite-based estimates and *in situ* data (Deutsch et al., 2021). These  
342 changes likely reflect the higher benthic Fe fluxes in our simulations (Equation 1), which increase  
343 phytoplankton productivity and promote nutrient drawdown near the coast.

344

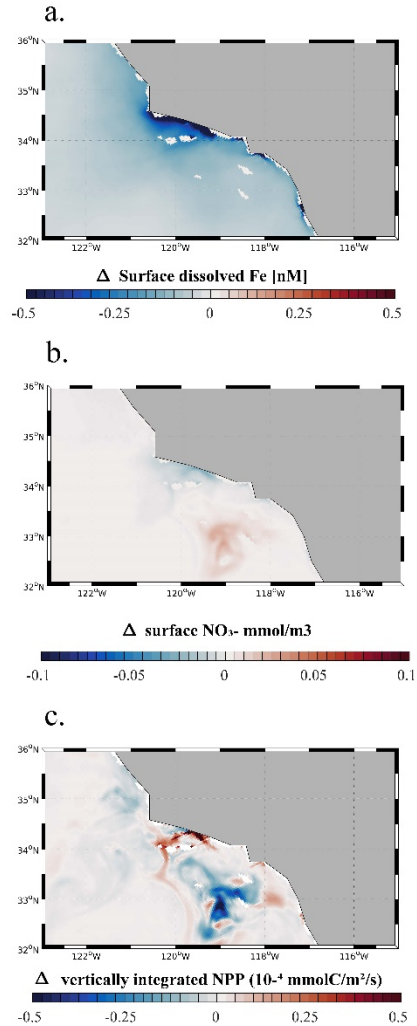

346 **Fig. 5.** (a) Surface dFe concentration, (b) surface  $\text{NO}_3^-$  concentration, and (c) vertically integrated  
347 net primary production (NPP) from the *High-flux* model simulation.

348

### 349 **3.3 Hypoxia-off: Impact of benthic Fe flux from low-oxygen bottom water**

350 We quantify the importance of benthic Fe fluxes from low- $\text{O}_2$  bottom waters in the Southern  
351 California Borderland by analyzing results from the *Hypoxia-off* experiment, in which we cap the  
352 high benthic Fe flux at a constant value ( $1.48 \mu\text{mol m}^{-2} \text{d}^{-1}$ ) when  $\text{O}_2$  declines below hypoxic  
353 conditions ( $65 \text{ mmol m}^{-3}$ , see Section 2.5) (**Fig 6**).

354  
355

356 **Figure 6.** (a) Surface dFe anomalies, (b) Surface NO<sub>3</sub><sup>-</sup> anomalies, and (c) vertically integrated net  
357 primary production (NPP) from the *Hypoxia-off* model run relative to the *High-flux* model run.  
358 The maps focus on the region around the SBB.

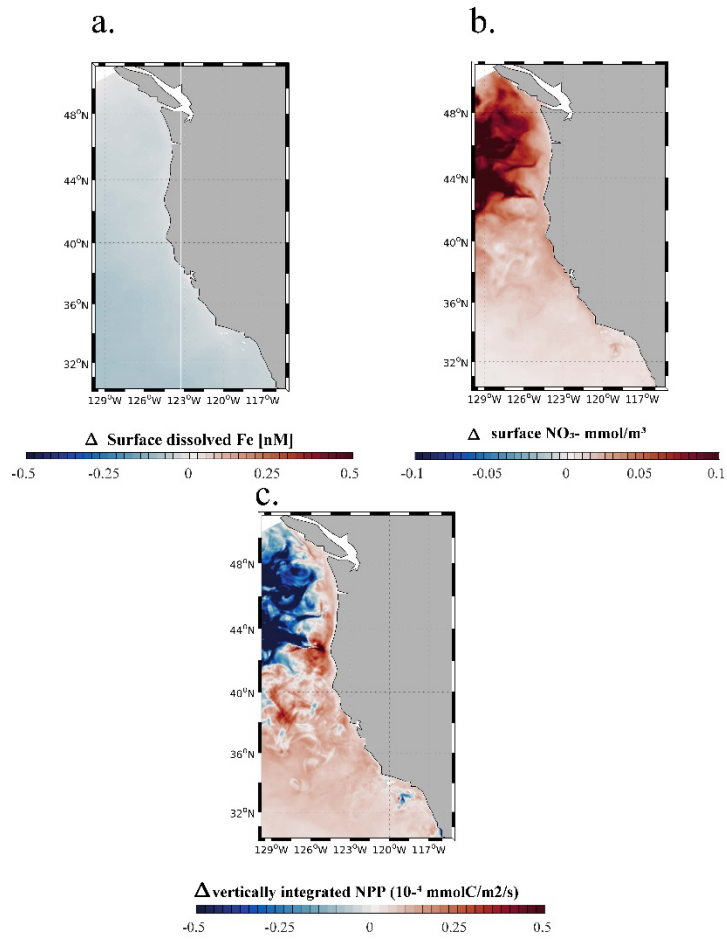

359 As expected, a decrease in benthic Fe flux from the anoxic basins in the *Hypoxia-off* simulation  
360 leads to a decrease in the surface dFe concentration (**Fig. 6a**). This decrease is particularly  
361 significant along the coast of the SBB, but also extends slightly into the open ocean (**Fig S6**).  
362 This trend indicates that dFe released from low-O<sub>2</sub> sediment is effectively transported to the  
363 surface and offshore, where it can affect primary production. The decrease in surface dFe caused  
364 by reduced benthic release causes a decline in NPP near the coast (**Fig. 6c**), where phytoplankton  
365 rely the most on benthic-derived Fe. NPP also shows a patchy increase in some regions,

366 especially between 32°N and 33°N and between 34°N and 35°N. This patchy increase can be  
367 explained by the relative importance of Fe vs. N limitation along a cross-shore productivity  
368 gradient. While near the SBB coast, phytoplankton is frequently Fe limited (up to 50% of the  
369 time in the model), especially following upwelling events, it tends to be almost exclusively N-  
370 limited moving offshore (Deutsch et al., 2021). This limitation pattern is consistent with  
371 observations from (King and Barbeau, 2011), who show that N:Fe ratios decrease moving from  
372 the coast to the open ocean (i.e., N is likely more limiting than Fe offshore). As Fe limitation  
373 reduces NPP near the coast in the *Hypoxia-off* experiment, NO<sub>3</sub><sup>-</sup> utilization also declines, so that  
374 more NO<sub>3</sub><sup>-</sup> can accumulate in surface waters (**Fig. 6b**). Shallow transport of excess NO<sub>3</sub><sup>-</sup> in  
375 mesoscale eddies can further fertilize offshore waters (Damien et al., 2023), releasing local N  
376 limitation and fueling an increase in NPP (**Fig. 6c**).

### 377 **3.4 Dust-off: Role of atmospheric Fe deposition**

378 We evaluate the importance of aeolian Fe sources in the *Dust-off* simulation, in which  
379 atmospheric Fe deposition is set to zero. In this experiment, surface dFe decreases everywhere in  
380 the CCS, but the decrease is particularly evident in the open ocean and the northern part of the  
381 domain (**Fig. 7a**). This dFe decrease leads to a widespread reduction in NPP in the northern CCS  
382 (40°N to 48°N, **Fig. 7c**), with stronger negative anomalies away from the coast. The decline in  
383 NPP is accompanied by a broad decrease in NO<sub>3</sub><sup>-</sup> utilization, particularly evident offshore, where  
384 phytoplankton rely mostly on Fe delivery by dust. In contrast, we observe a broad increase in  
385 NPP in the southern CCS (south of 40°S) and in coastal areas, likely reflecting increased  
386 availability of NO<sub>3</sub><sup>-</sup> transported southward by the broad California Current. The response of NPP  
387 in coastal areas and the southern CCS, when the dust deposition of Fe is set to zero, demonstrates  
388 that phytoplankton in those regions relies mostly on benthic Fe fluxes, rather than dust  
389 deposition, as the main source of Fe.

390

391  
 392 **Figure 7.** (a) Surface dissolved Fe, (b) surface NO<sub>3</sub><sup>-</sup> anomalies, and (c) vertically integrated net  
 393 primary production (NPP) from the *Dust-off* model run relative to the *High-flux* model run.

394 **4. Discussion**

395 **4.1 Benthic Fe flux feedbacks on SBB biogeochemistry**

396 The influence of bottom water O<sub>2</sub> concentration on the exchange of solutes between the sediment  
397 and the water column has been well documented (Soetaert et al., 2000; Sommer et al., 2016; Testa  
398 et al., 2013). Under hypoxic or anoxic bottom water conditions, organic matter sedimentation  
399 sustains anaerobic respiration at the sediment-water interface and in the sediment (Furrer and  
400 Wehrli, 1993; Middelburg and Levin, 2009a). Reduced compounds accumulate in pore waters  
401 forming chemical gradients (Widdows and Brinsley, 2002) that result in the flux of solutes such  
402 as Fe(II) out of the sediment, and their accumulation in bottom water (Jørgensen and Nelson, 2004;  
403 McMahon and Chapelle, 1991; Middelburg and Levin, 2009b; Yao et al., 2016). Similar conditions  
404 are observed in the SBB, where high sedimentation rates, water column denitrification below the  
405 sill depth, and high pore-water concentrations of sulfide and Fe(II) have been observed (Behl and  
406 Kennett, 1996; Bray et al., 1999; Goericke et al., 2015; Sholkovitz and Soutar, 1975; Sigman et  
407 al., 2003; White et al., 2019).

408

409

410

411

412  
413

414 **Figure 8.** Schematic illustrating feedback loops between benthic Fe release, nutrient cycles, and  
 415 productivity in the Santa Barbara Basin. (a) Positive feedback loop: 1. Benthic Fe is released into  
 416 the oxygen-poor bottom water. 2. Upwelled Fe reaches the surface ocean increasing dissolved Fe  
 417 concentrations. 3. Dissolved Fe is assimilated by phytoplankton, fueling blooms and production  
 418 of organic matter and siderophores, i.e., ligands used to chelate ferric iron. 4. Organic matter is  
 419 exported from the surface to the deep ocean. 5. Organic matter accumulates at the sediment-water  
 420 interface. 6. During remineralization, iron-reducing bacteria reduce Fe(III) to Fe(II), increasing  
 421 benthic dFe release. (b) Positive feedback loop – dampening: 1-3 (not including 3b and 3c) and 4-  
 422 6 are identical to (a). Parts 3b and 3c illustrate the decline of  $\text{NO}_3^-$  at the surface caused by the  
 423 reduction in Fe limitation, which together with increased denitrification in anoxic waters and  
 424 sediment would limit the potential increase in primary production and export from the surface  
 425 caused by Fe fertilization. Together with enhanced release of phosphate from anoxic sediment, a  
 426 reduction in the available  $\text{NO}_3^-$  could also reduce the N:P ratio of phytoplankton. Ultimately, the  
 427 effect of a decrease of  $\text{NO}_3^-$  on export and remineralization of organic matter would limit the  
 428 increase of benthic Fe(II) fluxes, dampening the positive feedback.

429 The intense flux of dFe from the sediment suggests the potential for biogeochemical feedbacks in  
430 the SBB and more broadly in the CCS (as shown by Figs. 5 – 7). Under a positive feedback scenario  
431 (illustrated in Fig. 8a), anoxic and nearly anoxic bottom water conditions facilitate Fe(II) diffusion  
432 from the sediment into the bottom water. In the SBB, this Fe eventually reaches the surface via  
433 upwelling and mixing processes, which are likely enhanced in the presence of complex bathymetry  
434 and islands in the Southern California Bight (Kessouri et al., 2020). This additional dFe input  
435 fertilizes coastal waters and increases primary production. Newly formed organic matter  
436 eventually sinks towards the seafloor as a rain of organic particles, supporting low-oxygen  
437 concentrations in the bottom water, and fueling anaerobic respiration, including Fe reduction, in  
438 the sediment. This chain of processes thus represents a positive feedback loop that maintains high  
439 Fe(II) release from the sediment, as long as the bottom water remains hypoxic or anoxic (Mills et  
440 al., 2004; Noffke et al., 2012; Sañudo-Wilhelmy et al., 2001; Dale et al., 2015; Wallmann et al.,  
441 2022).

442 Our simulations also indicate the potential for complex biogeochemical responses between Fe,  
443  $\text{NO}_3^-$  and NPP, which could limit the effects of these feedbacks. Specifically, the positive feedback  
444 loop is damped in our conceptual model by increased  $\text{NO}_3^-$  limitation and elevated N-loss in anoxic  
445 sediments under oxygen-deficient bottom waters at higher Fe supply (illustrated by Fig. 8b), which  
446 would in turn limit the increase in NPP. Transport of N-depleted coastal waters can further reduce  
447 NPP offshore, counteracting the positive feedback. In addition, the positive feedback would be  
448 also damped by Fe scavenging, which is magnified at high dissolved Fe concentrations, unless Fe-  
449 binding ligands also increase. This damping effect is particularly strong in our model, where a  
450 constant ligand concentration of 0.6 nM is used, above which scavenging rapidly increases  
451 (Section 2). Such a negative feedback between scavenging and benthic Fe fluxes is consistent  
452 with the global modeling study by Somes et al. (2021).

453 Additional processes may further modulate these feedback loops. Increased anoxia in bottom water  
454 and sediment favors the removal of fixed N by denitrification (Goericke et al., 2015; White et al.,  
455 2019). Upwelling of  $\text{NO}_3^-$ -depleted waters would then reduce surface productivity by increasing  
456 N limitation (Gruber and Deutsch, 2014). Release of Fe(II) from the sediment could also impact  
457 phosphate dynamics. Phosphate is scavenged by Fe during oxidation of Fe(II) in the water column  
458 and sediment because of the ability of Fe(III) minerals to bind it. After burial, phosphate is released

459 due to reduction of solid Fe(III) minerals to dissolved Fe(II), and diffuses upward to be either re-  
460 adsorbed by Fe(III) at the oxic sediment-water interface, or released to the bottom water under  
461 anoxic conditions (Dijkstra et al., 2014). The latter scenario is consistent with our in-situ benthic  
462 flux chamber measurements revealing increased phosphate release from the sediment with  
463 increased depth in the SBB (Yousavich et al., 2023). Higher release of phosphate into the water  
464 column, and transport to the surface, could decrease the N:P ratio of phytoplankton, especially  
465 downstream of waters where denitrification occurred (Deutsch et al., 2007). In the presence of N  
466 limitation, these conditions could favor the activity of nitrogen-fixing microorganisms (Mills et  
467 al., 2004; Noffke et al., 2012; Sañudo-Wilhelmy et al., 2001), which could further modulate  
468 surface NPP (Deutsch et al., 2007).

#### 469 **4.2 Contribution of physical transport on surface Fe**

470 Our numerical experiments suggest that Fe released into the deep SBB can reach surface waters  
471 and fertilize them. This finding highlights the critical role of bottom water upwelling and mixing  
472 in the deep basins of the Southern California Borderland. There is ample literature describing  
473 seasonal surface circulation and bottom water renewal and their effect on nutrients in the SBB  
474 (Bray et al., 1999; Hendershott and Winant, 1996; Sholkovitz and Gieskes, 1971). However, the  
475 frequency and rate of seasonal bottom water flushing events, and the processes responsible for  
476 vertical mixing and upwelling across hundreds of meters remain poorly understood (Shiller et al.,  
477 1985; Sholkovitz and Gieskes, 1971; White et al., 2019). It is likely that interaction between wind-  
478 driven upwelling events and submesoscale eddies, which are particularly intense inside the Santa  
479 Barbara Channel (Kessouri et al., 2020), favors upward mixing of deep bottom water in the wake  
480 of flushing events, connecting deep bottom waters to the surface.

#### 481 **4.3 Quantifying expansion of anoxia in the SBB**

482 Changes in source waters and global O<sub>2</sub> loss have contributed to decreasing O<sub>2</sub> levels throughout  
483 the Southern California Bight and the SBB (Zhou et al., 2022). With the outlook of a continuing  
484 decline in oceanic O<sub>2</sub> (Bopp et al., 2013; Kwiatkowski et al., 2020), quantifying the expansion of  
485 hypoxic and anoxic zones in the SBB is vital to understand the dynamics and fate of Fe(II) and  
486 other reduced compounds, such as ammonium and hydrogen sulfide, in deep low-oxygen waters.  
487 In the SBB, bottom water renewal events have experienced a decline in frequency and magnitude,

488 driving an expansion of hypoxic and anoxic conditions in deep waters (White et al., 2019). This  
489 expansion has led to an increase in anaerobic reactions, such as denitrification in the water column  
490 (White et al., 2019) as well as sulfur cycling in the sediment (Valentine et al., 2016). Expansion  
491 of low O<sub>2</sub> waters could intensify the positive feedback loop between Fe release, NPP and O<sub>2</sub> loss  
492 (**Fig. 8**). However, to date, despite growing evidence for more frequent anoxia, there is no clear  
493 quantitative record of the vertical or horizontal expansions of oxygen-deficient waters in the SBB.

## 494 5. Conclusion

495 Our field campaign in the SBB measured a remarkably high flux of Fe(II) from the sediment (0.23  
496 – 4.9 mmol m<sup>-2</sup> d<sup>-1</sup>), greater than in previous studies from this region (Severmann et al., 2010) and  
497 from other oxygen minimum zones (Dale et al. 2015; Homoky et al. 2021). While these  
498 observations are based on snapshots of O<sub>2</sub> and Fe fluxes, they have implications for the temporal  
499 variability of Fe supply. High benthic Fe fluxes are observed during the anoxic fall season, while  
500 seasonal flushing in winter and spring likely decreases them by increasing bottom water O<sub>2</sub> and  
501 Fe oxidation and retention near the sediment.

502 Using a series of simulations with an ocean biogeochemical model, we show that this high Fe  
503 release from deep, low-oxygen sediment can reach the surface and impact nutrients and  
504 productivity in the SBB and the Southern California Bight, where Fe is often limiting (Hogle et  
505 al., 2018). We also highlight the impacts of coastal Fe inputs on waters further offshore. While  
506 phytoplankton in coastal areas directly benefits from Fe fertilization, increased NO<sub>3</sub><sup>-</sup> utilization in  
507 coastal waters can increase N-limitation of phytoplankton further downstream in open-ocean areas.  
508 Thus, benthic Fe fluxes can modulate Fe and NO<sub>3</sub><sup>-</sup> limitation in ways that partially counteract one  
509 another along the cross-shore productivity gradient of the CCS. Our simulations also suggest that  
510 Fe inputs from atmospheric deposition are mostly important in the open ocean north of 40°N,  
511 where phytoplankton rely on Fe delivery by dust. However, we also show that changes in  
512 atmospheric Fe deposition can affect ocean productivity in the southern CCS by altering NO<sub>3</sub><sup>-</sup>  
513 utilization further downstream. Our results support the idea that benthic Fe fluxes are the major  
514 source of Fe in the southern CCS and are supplemented by atmospheric deposition in northwestern  
515 and offshore waters, leading to relatively high NPP coastwide.

516 We suggest that benthic Fe fluxes from deep anoxic basins reach the surface in the SBB,  
517 contributing to feedbacks between Fe and NO<sub>3</sub><sup>-</sup> limitation and NPP. Specifically, high Fe fluxes  
518 from low-oxygen sediment support higher NPP near the coast, in turn leading to increased  
519 respiration and O<sub>2</sub> loss at depth, maintaining high Fe release. This positive feedback is damped by  
520 increased NO<sub>3</sub><sup>-</sup> limitation, which reduces NPP downstream of coastal regions. This benthic-pelagic  
521 coupling demonstrates the importance of sediment-derived Fe fluxes on the coastal ecosystem of  
522 the CCS, and the role of vertical transport processes in connecting deep environments to surface

523 waters along continental margins. Our results are thus consistent with previous work from the  
524 Peruvian coastal upwelling (Wallmann et al., 2022), suggesting that oceanic O<sub>2</sub> loss could drive  
525 an increase in benthic Fe fluxes, enhancing local productivity and leading to further O<sub>2</sub> loss. This  
526 positive feedback could be stabilized by loss of fixed nitrogen under expanded anaerobic  
527 conditions.

528 It is likely that feedbacks of the type highlighted by (Wallmann et al., 2022) and our work in the  
529 SBB are at play more broadly along low-oxygen upwelling systems and coastal OMZ. Further  
530 studies should focus on the coupling between benthic processes and Fe and nutrient cycling in  
531 these regions. For example, fixed nitrogen loss by denitrification and enhanced release of  
532 phosphorous under low-oxygen bottom water are likely to further modulate these interactions.  
533 Seasonal studies based on stable isotope, radiotracer, and geochemical techniques are required to  
534 track the fate and transport of nutrients in low-O<sub>2</sub> coastal regions, clarifying the dynamics and  
535 sensitivities of the underlying microbial metabolisms. Ocean biogeochemical models for regional  
536 and global studies should incorporate new observations of benthic fluxes and their sensitivity to  
537 bottom O<sub>2</sub> and other environmental variables. This would expand the ability of models to better  
538 capture the effects of long-term oceanic O<sub>2</sub> loss, and the feedbacks between benthic nutrient fluxes  
539 and surface productivity.

540 **Acknowledgements**

541 We thank the captain and crew of R/V Atlantis, the crew of ROV Jason, the crew of AUV Sentry,  
542 and the science party of research cruise AT42-19 for their technical and logistical support. We  
543 thank Q. Qin, M. O’Beirne, A. Mazariegos, X. Moreno, and A. Eastman for assisting with  
544 shipboard analyses. Funding for this work was provided by the US National Science Foundation,  
545 NSF OCE-1829981 (to TT), OCE-1756947 and OCE-1830033 (to DLV), and OCE-2023493 (to  
546 DB and ALP). Computational resources were provided by the Expanse system at the San Diego  
547 Supercomputer Center through allocation TG-OCE170017 from the Extreme Science and  
548 Engineering Discovery Environment (XSEDE), which was supported by National Science  
549 Foundation grant 1548562.

550 **Code availability**

551 The physical and biogeochemical codes used for our simulations can be accessed at:  
552 <https://github.com/UCLA-ROMS/Code>.

553 The model output can be accessed through Zenodo: [\(link will be provided before publication\)](#)

554

555 **Data availability**

556 In-situ benthic Fe flux data are accessible through the Biological & Chemical Oceanography Data  
557 Management Office (BCO-DMO) under the following DOI: 10.26008/1912/bco-dmo.896706.1.

558 **Author contributions.**

559 DR, TT, DB, and AP conceived this study. DM, DJY, FJ, FW, ECA, KMG, DLV and TT  
560 conducted the sampling at sea. DJY transformed and interpreted ROV Jason data. FJ and FW  
561 constructed and managed benthic flux chambers. DYJ and DR analyzed Fe(II) and assisted with  
562 the flux calculation. MM provided the compiled Fe measurements along the U.S. West Coast. AP  
563 and MS performed the model simulations. DR, DB, AP and TT wrote the manuscript with input  
564 from all co-authors.

565 **Competing interests**

566 Some authors are members of the editorial board of Biogeosciences. The peer-review process was  
567 guided by an independent editor, and the authors have no other competing interests to declare.
