Abstract. Major mass extinctions in the Phanerozoic Eon occurred during abrupt global climate changes accompanied by environmental destruction driven by large volcanic eruptions and projectile impacts. However, relationships between those physical conditions and the magnitude of animal extinctions have not been quantitatively evaluated. My analyses show that the magnitude of major extinctions in marine invertebrates and that of terrestrial tetrapods correlate well with the
10 coincidental anomaly of global and habitat surface temperatures during biotic crises, respectively, regardless of the difference between warming and cooling. More than >20% of genera and 40% of marine species loss correlate to more than 8 °C absolute global surface temperature anomalies. Higher extinction percentages appear in the terrestrial realm than in the marine realm under the same global temperature anomaly due to 2.2 times higher surface temperature anomalies in the
15 terrestrial realm than in the marine realm. Marine animals are more likely than tetrapods to become extinct under a habitat temperature anomaly, possibly due to a higher sensitivity of marine animals to temperature change than terrestrial animals, which have access to places of refuge. These relationships indicate that abrupt changes in climate and environment associated with high energy input by volcanism and impact relate to the magnitude of mass extinctions.

1 Introduction

20 There are two habitat realms for animals: marine and terrestrial realms. Major mass extinctions of animals have occurred five times: 444, 372, 252, 201, and 66 million years ago (Ma) after fundamental animal diversification was finished at ~520 Ma, commonly marked by high extinction percentages of animals inhabiting the marine realm (Sepkoski, 1996; Bambach, 2006; Stanley, 2016; Fan et al., 2020); these events were driven by large volcanic eruptions and projectile impacts (Schulte et al., 2010; Davies et al., 2017; Burgess et al., 2017; Bond and Grasby, 2020; Kaiho et al., 2021a, 2021b). The last three
25 mass extinctions after the initial diversification of tetrapods at ~300 Ma had high extinction percentages for terrestrial tetrapods (Sahney et al., 2010) and marine animals (Sepkoski, 1996; Bambach, 2006; Stanley, 2016; Fan et al., 2020). These major biotic crises were related to abrupt global climate changes (Balter et al., 2008; Korte et al., 2009; Finnegan et al., 2011; Chen et al., 2011; Vellekoop et al., 2014; Chen et al., 2016) and the accompanying environmental changes, such as acid rain, ozone depletion, reduced sunlight and oceanic anoxia, driven by large volcanic eruptions and projectile impacts
30 (Schulte et al., 2010; Bond and Grasby, 2020), and the relationship has not been quantitatively studied. Long-term surface temperature changes did not cause mass extinctions because animals migrate to survive. Abrupt high energy input by

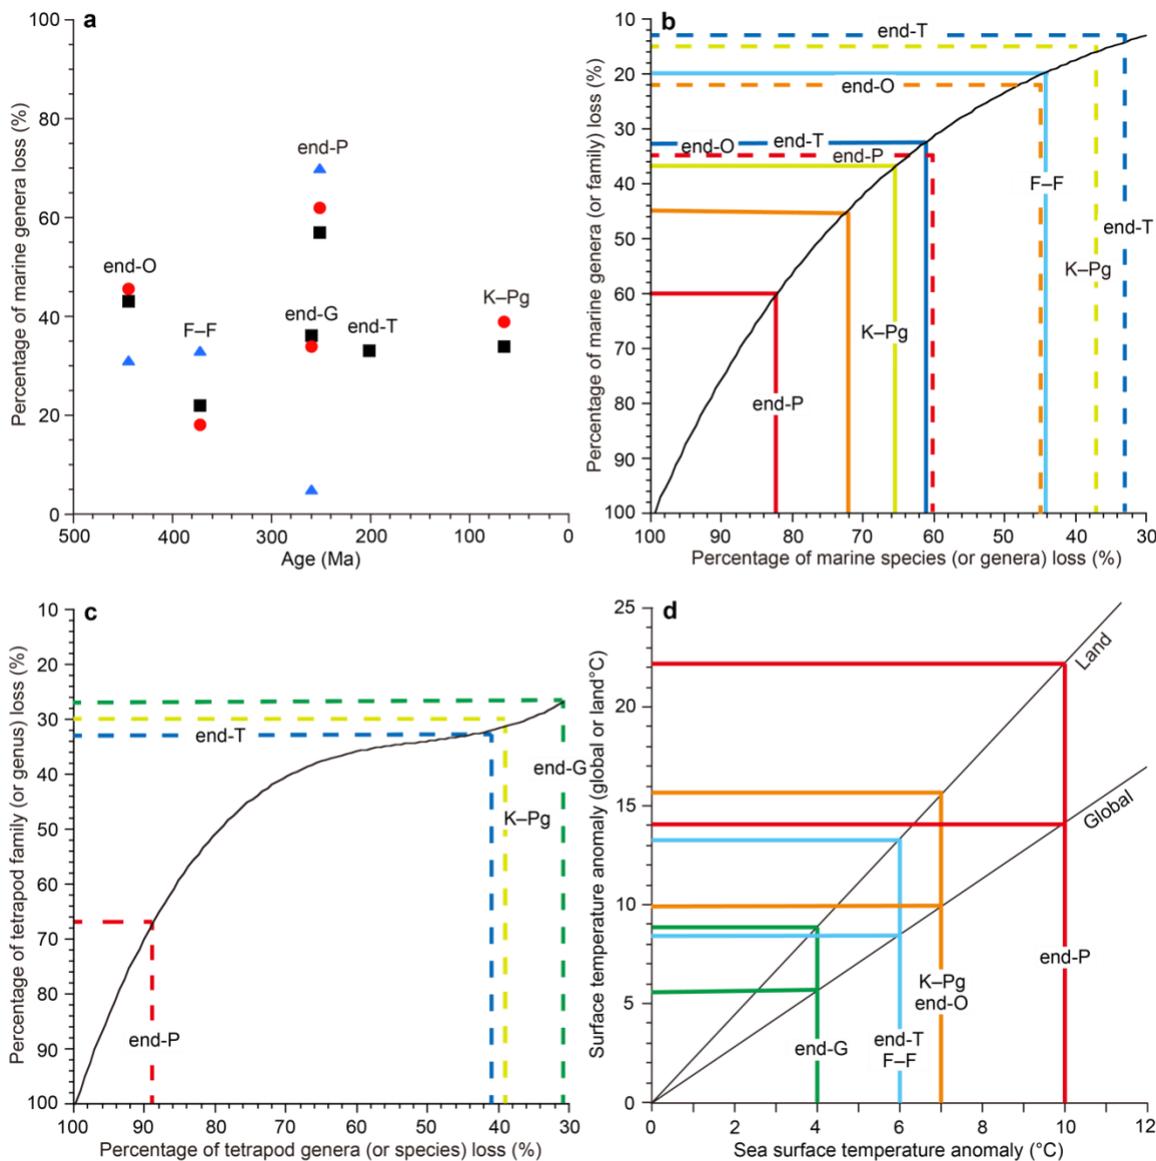

volcanism and impact to the surface of the Earth caused abrupt climate changes accompanied by abrupt environmental destruction, leading to animal crises.

In this study, I aimed to clarify the relationship between the magnitude of biotic crises in marine invertebrates and 35 terrestrial vertebrates (tetrapods) and the global and habitat [marine or terrestrial realm] surface temperature anomalies during the five major mass extinctions as well as the late Guadalupian crisis, which was added to the list of major mass extinctions in some literature (Stanley and Yang, 1994; Rampino and Shen, 2019).

2 Data and methods

40 2.1 Diversity reduction percentage

Genera loss % data of marine animals at the six major biotic crises analyzed by Bambach (2006) and Stanley (2016) are similar (Fig. 1a, Table 1), and the species losses produced by Raup (1979) and Sepkoski (1986) for the terminal Permian crisis were artificially elevated because they combined data for the Guadalupian and terminal Permian crises (Stanley, 2016). Therefore, I used average diversity reduction percentage data for marine invertebrate genera of Bambach (2006) and Stanley 45 (2016) and marine species data converted from genera data using the relationship between genera loss % and species loss % (Fig. 1b). I do not use their data for the end of the Guadalupian because the uncertain high loss % of Bambach (2006) and Stanley (2016) likely due to “smear back” (Signor-Lipps Effect) from the great end-Permian event is enhanced by the loss of record from lower sea level in the later Permian (Bambach, 2006) (Fig. 1a, Table 1). Instead, I used the marine species data 50 because their sedimentary rock sequences of the GSSP section and nearby sections contain continuous sedimentary rocks without a time gap (Fan et al., 2020). The data from China are not affected by the Signor-Lipps Effect because they contain continuous sedimentary rocks without a time gap (Fan et al., 2020; Huang et al., 2019). Diversity reduction percentage data for tetrapod genera of Benton (2013) and Sahney and Benton (2017) are used to represent those for terrestrial animals because it is difficult to obtain good data for diversity losses among insects and plants. The tetrapod species data were 55 converted from genus extinction percentage to species extinction percentage using the relationship curve between family and genera for tetrapods in Fig. 1c (Stanley, 2016) since the actual marine family/genus data mostly fit the conversion relationship curve of genus/species (Figs. 1b, c). The error for genera and species loss percentages is approximately $\pm 5\%$ based on Bambach (2006) and Stanley (2016) data for $>15\%$ loss values (Fig. 1a, Table 1).

60 **Figure 1:** Marine genus loss (%) distribution (a), relationship between extinction percentages of species, genera, and families (b for marine invertebrates, c for terrestrial tetrapods) and between global surface temperature anomalies, land-surface temperature anomalies, and sea-surface temperature (SST) anomalies (d). Black square data from Bambach (2006), red circle data from Stanley (2016), and blue triangle data from Fan et al. (2020) in the graph (a). Graphs (b, c) were used to convert extinction percentages among species, genera, and families. Dashed lines show the genus-family loss relationship (b, c). The black curve in (b) is after Stanley (2016). Graph (d) is based on the model calculation data from Kaiho and Oshima (2017) and is used to convert between the global surface temperature anomaly, land-surface temperature anomaly (global mean), and SST anomaly (global mean). All data are from Table 1. O: Ordovician. F–F: Frasnian–Famennian boundary. P: Permian. T: Triassic. K–Pg: Cretaceous–Paleogene boundary.

(2015); 9: Sahney et al. (2010); 10: Benton et al. (2013); 11: Sahney and Benton (2017); 12: IUCN (2021); 13: Waters et al. (2016); 14: Working Group I Contribution to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (2013); 15: Vellekoop et al. (2014); 16: Korte et al. (2009); 17: Chen et al. (2016); 18: Chen et al. (2011); 19: Balter et al. (2008); 20: Finnegan et al. (2011).

2.2 Surface temperature anomaly

80 The largest absolute sea-surface temperature (SST) anomalies during each crisis were obtained from the oxygen isotope ratios ($^{18}\text{O}/^{16}\text{O}$) of marine animal fossils (Balter et al., 2008; Korte et al., 2009; Finnegan et al., 2011, Chen et al., 2011) and the organic biomarker index (TEX86) (Vellekoop et al., 2014) (Table 1). All the SST data are from low latitudes (Table 2). Global surface temperature anomalies at low latitudes are always intermediate values (near average values) regardless of (i) source latitudes of greenhouse gases or aerosols blocking sunlight (Kaiho and Oshima, 2017) (Table 1) and (ii) global
85 warming and cooling because the highest anomaly appears at middle–high latitudes in the source hemisphere and the lowest anomaly appears at middle–high latitudes in the other hemisphere based on warming case data (Pinsky et al., 2019) and cooling case data (Kaiho et al., 2016). Therefore, I used each SST anomaly at low latitudes as an intermediate value (near average) in the Earth at each age. The error for the SST anomaly in geologic ages is approximately $\pm 1^\circ\text{C}$, approximately $\pm 0.5^\circ\text{C}$ depending on the sample location to obtain the average value and approximately $\pm 0.5^\circ\text{C}$ depending on detection of
90 the largest anomaly for abrupt short-term events from sedimentary rocks, which usually deposited 1–100 mm/kyr, except for impact ejecta sediment. I converted SST anomalies of various geologic ages to global surface temperature anomalies and land-surface temperature anomalies using Fig. 1d, which was generated from global cooling and warming (recovery) data of the climate model calculation (Kaiho and Oshima, 2017) (Fig. 1d).

Table 2: Source latitudes of causal gas and aerosols and SST data

Crisis	Source of causal gas and aerosols	SST data site
K–Pg	~25°N	~30°N
end-T	~20°S – ~30°N	~30°N
end-P	~50°N	~15°N
end-G	~30°N	~30°N
F–F	~10°S – ~30°N	~25°S
end-O	?	~20°S – ~10°S

95 O: Ordovician. F–F: Frasnian–Famennian boundary. G: Guadalupian. P: Permian. T: Triassic. K–Pg: Cretaceous–Paleogene boundary.

3 Results

3.1 Magnitude of marine/terrestrial crises

My analysis of the major mass extinctions shows that the Late Ordovician mass extinction (LOME) was marked by only a
100 marine crisis (45% genera loss and 72% species loss) since terrestrial tetrapods had not yet appeared. The Late Devonian mass extinction (LDME) resulted in the loss of 20% genera and 44% species for marine animals at the Frasnian–Famennian boundary (F–F) (I ignored the tetrapod extinction percentage due to the very low apparent diversity) (Kaiho et al., 2016). The last three major mass extinctions, end-Permian, end-Triassic, and Cretaceous–Paleogene (K–Pg) boundary, were

characterized by high extinction percentages of both marine and terrestrial genera (marine: 60%, 33%, and 37%; terrestrial: 89%, 41%, and 39%; Fig. 2, Table 1) and species (marine: 82%, 61%, and 65%; terrestrial: 97%, 70%, 67%; Fig. 2, Table 1). In total, the five major mass extinctions were marked by high marine genera and species extinction percentages (20%–60% and 44%–82%). However, the end-Guadalupian extinction was marked by low marine genera and species loss (5% and 11%) and higher terrestrial genera and species loss (31% and 38%), corresponding to a major terrestrial crisis, not a major mass extinction, accompanied by a large reduction in shallow marine fusulinids (Feng et al., 2020) and reef animals (Flügel and Kiessling, 2002) due to terrestrial disturbance. All these biotic crises following the diversification of tetrapods had higher extinction percentages of terrestrial animals than of marine animals.

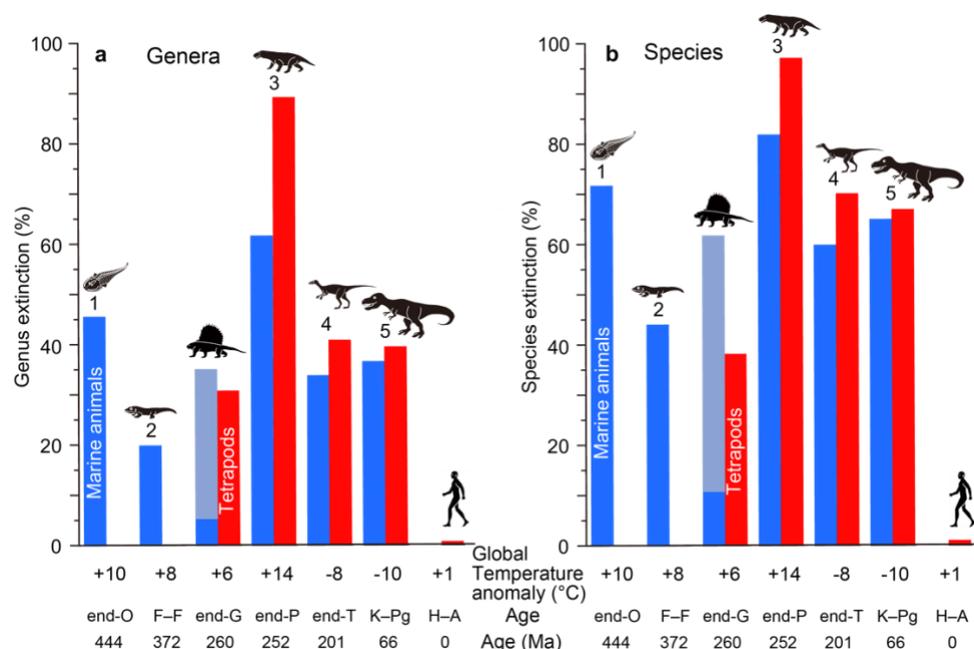

Figure 2: Genera (a) and species (b) extinction percentages of marine animals (blue columns) and tetrapods (red columns) for major mass extinctions and the end-Guadalupian and Holocene–Anthropocene crises. All data are from Table 1. Marine genus extinction values are average values of Bambach (2006) and Stanley (2016). Pale blue columns show uncertain high loss %, probably due to the loss of records from lower sea levels in the later Permian (Bambach, 2006). The blue columns in the end-G are from Fan et al. (2020). Global temperature anomaly: Global surface temperature anomaly. O: Ordovician. F–F: Frasnian–Famennian boundary. G: Guadalupian. P: Permian. T: Triassic. K–Pg: Cretaceous–Paleogene boundary. H–A: Holocene–Anthropocene (1850 to 2010 on going). Numbers 1 to 5: five major mass extinction. Each silhouette shows a representative vertebrate animal from each age.

120

3.2 Sea-surface temperature anomaly during crises

There are two extinction levels on the LOME at the Katian–Hirnantian boundary (445.2 Ma) and late Hirnantian (~444 Ma) (Bond and Grasby, 2020). Between the two extinctions, global cooling occurred, as evidenced by conodont apatite oxygen isotopes and glacial deposits (Finnegan et al., 2011); however, the two extinction levels coincided with the two shorter-term

125 global warming events based on the oxygen isotope data of conodont apatite (Bond and Grasby, 2020). I select the largest
anomaly +7 °C SST in late Hirnantian from the data of Finnegan et al. (2011) for LOME based on the common method for
the major crises (largest SST anomaly in short-term climate changes). The trigger is estimated to be volcanism as evidenced
by coincidental mercury concentration for LOME (Jones et al., 2017; Bond and Grasby, 2020).

130 The LDME is composed of the Frasnian, Kellwasser, and Hangenberg crises at 383, 372, and 359 Ma, respectively, and
the Kellwasser is the largest crisis (Barash, 2016). The trigger was the large igneous province (LIP) emplacement of Viluy
and PDD LIPs, as evidenced by mercury and coronene concentrations (Racki, 2020; Kaiho et al., 2021b). I use the largest
abrupt warming marked by a +6 °C SST anomaly at the Frasnian–Famennian (F–F) boundary in the Kellwasser crisis from
the oxygen isotope data of conodont apatite of Balter et al. (2008) for LDME, whereas the long-term gradual SST change
across the F–F boundary shows global cooling.

135 The Late Guadalupian crisis (LGC) occurred in the mid-Capitanian, 262 Ma, followed by the Guadalupian–Lopingian
(G–L) boundary event at 259 Ma (Chen and Xu, 2019). The coincidental volcanic eruptions of the Emeishan Large Igneous
Province (ELIP) in South China are thought to be the trigger of the crisis (Chen and Xu, 2019), as evidenced by mercury
concentration peaks beginning in the mid-Capitanian and peaking during the G–L transition (Grasby et al., 2016). The
largest abrupt anomaly +4 °C SST coinciding with the volcanism and extinction at the G–L boundary from the data of Chen
140 et al. (2011) is used for LGC.

The largest biodiversity loss in the Phanerozoic occurred at the end of the Permian, with local extinction during the
earliest Triassic, ~252.0–251.9 million years ago (Song et al., 2013; Kaiho et al., 2021a), marking the end of the Mesozoic.
The LIP in Siberia caused sill emplacement and large eruptions at that time (Burgess et al., 2017). The coincidence of
volcanic eruption and the biotic crisis was shown using the correlation of mercury, coronene, and coal fly ash (Grasby et al.,
145 2011, 2013; Kaiho et al., 2021a). I use the largest anomaly +10 °C SST from just before the mass extinction (Bed 24) to the
first minimum $\delta^{18}\text{O}$ apatite value (base of Bed 27) at GSSP Meishan based on new conodont apatite $\delta^{18}\text{O}$ data showing the
2.5 permil anomaly of Chen et al. (2016) for the end-Permian mass extinction (EPME).

The age of the end-Triassic mass extinction (ETME) is estimated to be 201.564 ± 0.015 Ma, which corresponds to the
emplacement of the Central Atlantic Magmatic Province (CAMP, 201.6 to 201.0 Ma) (Davies et al., 2017). The SST
150 anomaly during the crisis is estimated as -6 °C from the averaged $\delta^{18}\text{O}$ of oyster shells, assuming stable salinity, which was
followed by long-term (10^5 years) global warming (Korte et al., 2009; Kaiho et al., 2022). There were no crises during the
long-term warming (Kaiho et al., 2022). I use the -6 °C anomaly for ETME, indicating global cooling.

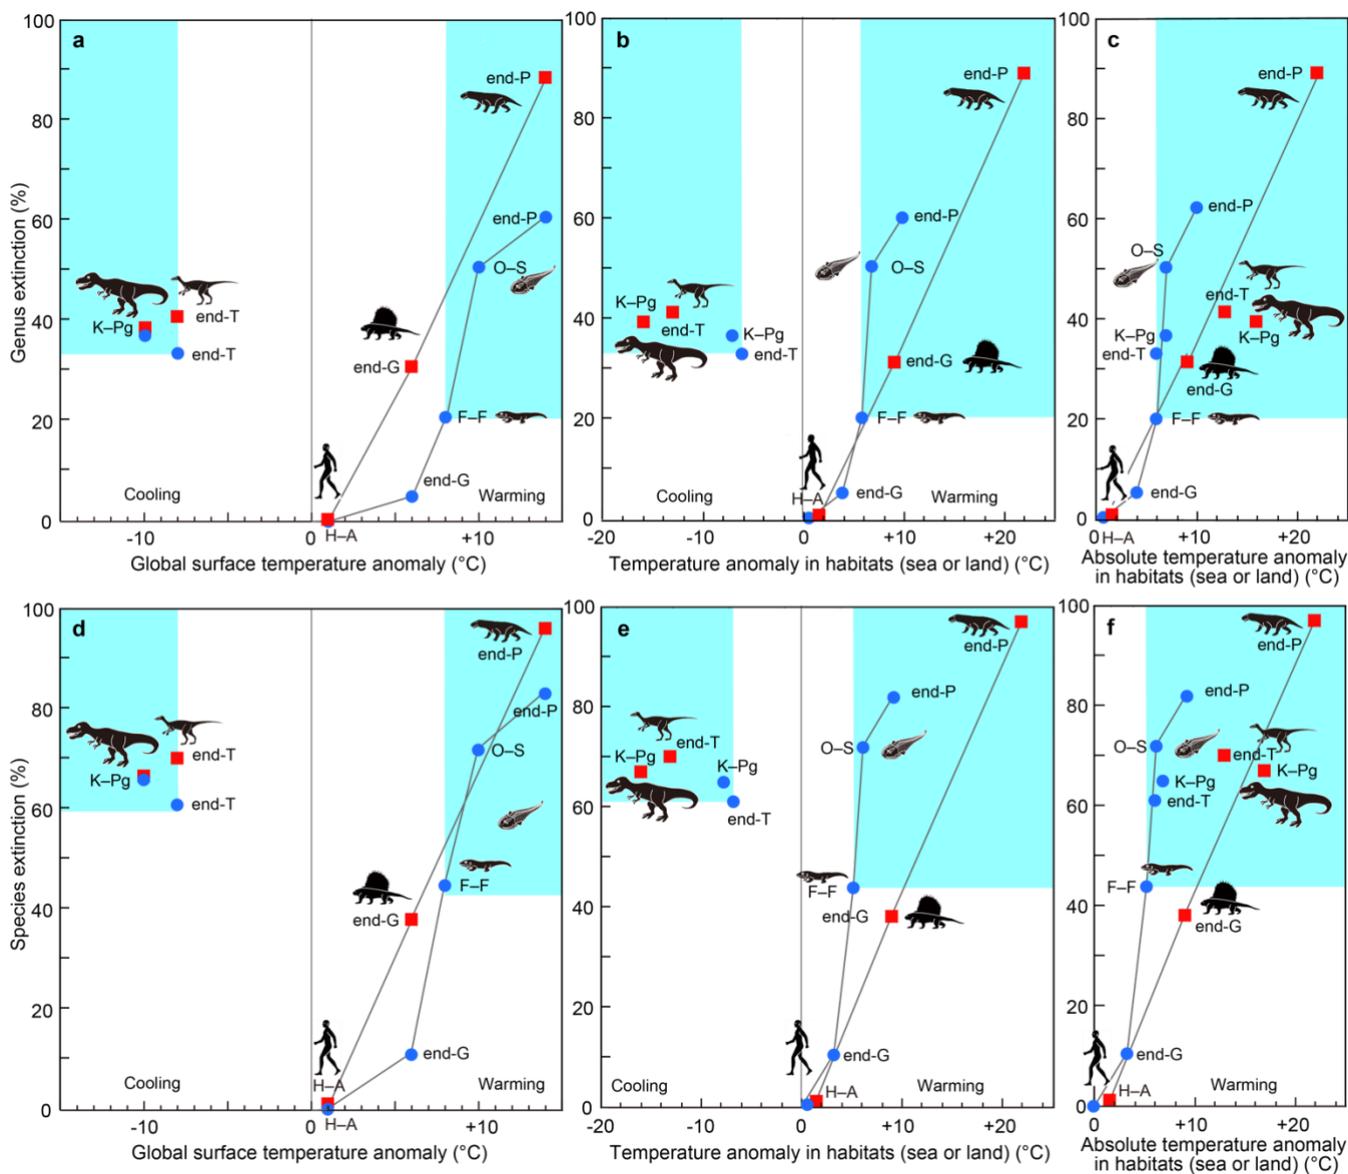

Only the K–Pg mass extinction (KPME) at 66 Ma occurred as the result of an asteroid impact (Schulte et al., 2010).
This impact produced large amounts of soot and sulfuric acid aerosols in the stratosphere by the ignition and melting of
155 sedimentary rocks (Kaiho et al., 2016; Kaiho and Oshima, 2017). Stratospheric aerosols efficiently absorb and scatter solar
radiation and reduce sunlight reaching the Earth's surface, which induces strong global cooling and a significant decrease in
precipitation, particularly over equatorial areas, over ten years, with the maximum occurring in the second year (Kaiho et al.,
2016; Kaiho and Oshima, 2017). Organic biomarker TEX86 values show -7 °C as the SST largest absolute anomaly during

160 the crisis (Vellekoop et al., 2014). This SST anomaly is consistent with the $-10\text{ }^{\circ}\text{C}$ global cooling estimated by climate model calculations and the survival of equatorial crocodilians (Kaiho et al., 2016).

3.3 Relationship between extinction magnitudes and surface temperature anomalies

I compare those data on each biotic crises based on an assumption that the Earth and contemporary life at the time of each crisis are themselves more-or-less comparable through time. My results for the relationship between past mass extinctions and surface temperature anomalies show the following features. A $4\text{ }^{\circ}\text{C}$ SST warming was detected at the end of the Guadalupian (Chen et al., 2011), corresponding to $9\text{ }^{\circ}\text{C}$ warming on land ($6\text{ }^{\circ}\text{C}$ global warming), as shown in Fig. 1d, which was correlated with 5% and 11% marine genera and species extinction and 31% and 38% terrestrial genera and species extinction, respectively (Figs. 3a, 3d; Table 1). However, the higher $6\text{ }^{\circ}\text{C}$ SST (Balter et al., 2008) ($13\text{ }^{\circ}\text{C}$ warming on land and $8\text{ }^{\circ}\text{C}$ global warming) occurred at the Frasnian–Famennian (F–F) boundary, which is correlated with 20% and 44% marine genera and species loss, respectively, that is, a marine crisis and the smallest major mass extinction, respectively. The end-Ordovician mass extinction had higher temperature anomalies ($7\text{ }^{\circ}\text{C}$ SST [Finnegan et al., 2011], $16\text{ }^{\circ}\text{C}$ on land, and $10\text{ }^{\circ}\text{C}$ global warming) and higher extinction percentages (45% and 72% marine genera and species, respectively). The EPME was marked by the highest temperature anomalies ($10\text{ }^{\circ}\text{C}$ SST (Chen et al., 2016), $22\text{ }^{\circ}\text{C}$ on land, and $14\text{ }^{\circ}\text{C}$ global warming) and the highest extinction percentages (60% and 82% marine genera and species and 89% and 97% terrestrial tetrapod genera and species, respectively). In contrast, the end-Triassic and Cretaceous–Paleogene (K–Pg) boundary mass extinctions coincided with $6\text{ }^{\circ}\text{C}$ and $7\text{ }^{\circ}\text{C}$ SST (Korte et al., 2009; Vellekoop et al., 2014) cooling corresponding to $13\text{ }^{\circ}\text{C}$ and $16\text{ }^{\circ}\text{C}$ cooling on land and $8\text{ }^{\circ}\text{C}$ and $10\text{ }^{\circ}\text{C}$ global cooling (Fig. 1). The ETME correlated with 33% and 61% marine genera and species loss and 41% and 70% terrestrial tetrapod genera and species loss, respectively, and the KPME correlated with 37% and 65% marine genera and species loss and 39% and 67% terrestrial tetrapod genera and species loss, respectively (Figs. 3a, 180 d). These results indicate that a larger absolute value of the global temperature anomaly corresponds to a higher extinction percentage in the marine and terrestrial realms, regardless of whether the change is due to global warming or global cooling, considering a $\pm 5\%$ error (Figs. 3c, f). These relationships indicate that abrupt temperature anomalies and coincidental environmental changes associated with high energy input by volcanism and impact relate to the magnitude of mass extinctions.

185

Figure 3: Relationship between genera and species extinction percentage and surface temperature anomaly in major mass extinctions, the end-Guadalupian crisis, and the current crisis in the Anthropocene. All vertical axes show species extinction (%). (a)–(c): genera extinction. (d)–(f): species extinction. (a) and (d): relationship between that and global surface anomaly. (b) and (e): relationship between that and surface temperature anomaly in habitats (global sea or land). (c) and (f): relationship between that and absolute surface temperature anomaly in habitats (global sea or land). Blue circles: marine extinctions. Red squares: terrestrial extinctions represented by tetrapods. All data are from Table 1. Light blue areas show major extinctions. O: Ordovician. F–F: Frasnian–Famennian boundary. G: Guadalupian. P: Permian. T: Triassic. K–Pg: Cretaceous–Paleogene boundary.

190

195 4. Discussion

When summarizing and interpreting these results for the past six representative crises, I find that (i) higher global surface temperature anomalies are correlated to higher extinction percentages in both marine and terrestrial realms, respectively (Figs. 3a, 3d), which suggests that climate change and related or coincidental environmental destruction is the main cause of mass extinctions; (ii) >20% genera and >40% species loss correlate to > +8 °C global warming and < -8 °C global cooling, respectively (Figs. 3a, 3d); (iii) higher extinction percentages appear in the terrestrial realm (tetrapods) than in the marine realm (invertebrate) under the same global temperature anomaly in warming events (Figs. 3a, 3d) because the ratio of the surface temperature anomaly in the terrestrial realm to that in the marine realm is 2.2 (Fig. 1d); (iv) marine animals are more likely to become extinct under a lower habitat temperature anomaly than tetrapods regardless of the difference between warming and cooling (Figs. 3c, 3f); and (v) a similar absolute habitat temperature anomaly correlates with a similar extinction magnitude in marine invertebrates and terrestrial tetrapods, respectively (Figs. 3c, 3f).

More major terrestrial crises occur under lower global temperature anomalies than major marine crises (Figs. 3a, 3d), which implies that major terrestrial crises must have occurred more frequently than major marine crises. Evidence for this difference is nine decreases in tetrapod diversity having $\geq 20\%$ genus loss during the late Carboniferous to Early Jurassic (Benton et al., 2013) compared with two marine crises having $\geq 20\%$ genus extinctions during the same interval (end-Permian, end-Triassic). Marine animals are more likely to become extinct under lower habitat temperature anomalies than tetrapods (Figs. 3b, 3e), which is consistent with a higher sensitivity of marine animals to warming than terrestrial animals based on the current global temperature and thermal tolerance data (Pinsky et al., 2019). The physical law of the temperature anomaly extinction relationship shown in Figs. 1d and 3 controls the extinction of terrestrial and marine animals, as shown in Fig. 2.

The good correlation between the surface temperature anomaly and extinction magnitude indicates that the cause of major extinctions is not only surface temperature change but also coincidental environmental changes, such as acid rain, ozone depletion, reducing sunlight, desertification, soil erosion, and oceanic anoxia, driven by large volcanic eruptions and projectile impacts; these causal climatic and environmental conditions changed in parallel due to the same controls as each volcanism and impact. These climatic and environmental anomalies are controlled by stratospheric aerosols, such as sulfuric acid and black carbon, for reducing sunlight – global cooling – acid rain, halogen for ozone depletion, and atmospheric greenhouse gases, such as CO₂ and methane, for surface warming.

Global cooling and warming have been reported in many periods in the Phanerozoic based on oxygen isotopes (Stanley, 2010); however, most of them are long-term climate changes. When surface temperature changes slowly ($> \sim 10^3$ years), animals migrate and survive; an abrupt temperature change is thought to be essential for mass extinctions. There were no significant marine extinctions during global warming of two famous global warming events at the end-Cenomanian and Paleocene–Eocene transitions (Kaiho, 1994); which were due to volcanism under the oceanic crust (Bond and Wignall, 2014). This type of volcanism cannot eject volcanic SO₂ gas into the stratosphere, resulting in no short-term global cooling and gradual global warming by the gradual release of CO₂ from volcanism under the ocean; conversely, the Late Devonian,

end-Permian, and end-Triassic LIPs were emplaced on land, resulting in SO₂ gas emissions into the stratosphere, causing
230 short-term global cooling and accompanying environmental changes, followed by global warming due to volcanic
greenhouse gas emissions. An eruption causes global cooling that lasts for a few to ten years; thus, detection is difficult;
however, LIP volcanism causes thousands of eruptions (Svensen et al., 2009), resulting in the detection of decreases in SST
from sedimentary rocks when the release of SO₂ gas to the stratosphere exceeds >10³ years (Kaiho et al., 2022), but no
detection occurs in cases of < 10²-year SO₂ emissions. Global cooling is followed by global warming due to the cessation of
235 SO₂ release to the stratosphere and the accumulation of CO₂ in the atmosphere from volcanisms (Kaiho et al., 2022). Global
warming lasts for a long time (>10³ years, usually ~10⁵ years), resulting in easy detection.

Global warming has been detected in some volcanic cases, whereas global cooling has been detected from (i)
sedimentary rocks formed under volcanism characterized by massive SO₂ gas emissions and relatively low CO₂ emissions by
low-temperature volcanism to the stratosphere (ETME) (Kaiho et al., 2022) and (ii) quickly deposited impact ejecta
240 (Vellekoop et al., 2014) near the impact crater in an impact case (KPME). There is a possibility of undetected short-term
global cooling before global warming in the other four volcanism-induced major biotic crises. Larger volcanisms generally
cause larger SO₂, CO₂, and halogen emissions, which could have resulted in a good correlation between the global warming
temperature anomaly and extinction magnitude, even if the real main cause of crises is reduced sunlight – global cooling –
acid rain, ozone depletion or oceanic anoxia. Therefore, Figs. 3c and 3f show the relationship between the absolute
245 temperature anomaly and extinction magnitude. The good correlation in marine and terrestrial animals clarified in this study
indicates that the global climate and the accompanying environmental changes are related to the magnitude of mass
extinctions.

5. Conclusions

250 I conclude that (i) the magnitude of major extinctions in marine invertebrates and that of terrestrial tetrapods correlates
well with the coincidental abrupt anomaly of global surface temperature, respectively; (ii) >20% genera and >40% species
loss correlate to > 8 °C absolute global surface temperature anomaly regardless of the difference between warming and
cooling; (iii) there is a good correlation between extinction magnitude of marine invertebrates and absolute SST anomaly as
well as that of terrestrial tetrapods and absolute land-surface temperature anomaly; (iv) higher extinction percentages appear
255 in the terrestrial realm (tetrapods) than in the marine realm (invertebrate) under the same global temperature anomaly due to
2.2 times higher surface temperature anomaly in the terrestrial realm than that in the marine realm; and (v) marine animals
become extinct under a lower habitat temperature anomaly than tetrapods regardless of the difference between warming and
cooling, which is likely due to a higher sensitivity of marine animals than terrestrial animals. These relationships indicate
that abrupt temperature anomalies and coincidental environmental changes are associated with abrupt high energy input by
260 LIP volcanism and that an asteroid impact relates to the magnitude of mass extinctions.

Author contribution: Conceptualization: KK. Methodology: KK. Investigation: KK. Visualization: KK. Writing—original draft: KK. Writing—review & editing: KK.

Competing interests: The authors declare that they have no competing interests.

265 **Acknowledgments:** This study was supported by the Japan Society for the Promotion of Science (KAKENHI—Grants in-Aid for Scientific Research; Grant Numbers #25247084 for K.K. I thank anonymous referees for useful comments for the previous version.

Data and materials availability: All data is available in the main text.
