Abstract. Knowing the components of ecosystem scale carbon exchange is crucial in order to develop better models and future predictions of the terrestrial carbon cycle. However, there are several uncertainties and unknowns related to current photosynthesis estimates. In this study, we test the use of four different methods for quantifying photosynthesis at the ecosystem scale, of which two are based on carbon dioxide (CO₂) and two on carbonyl sulfide (COS) flux measurements. The CO₂-based methods use traditional flux partitioning and artificial neural networks to separate the net CO₂ flux into respiration and photosynthesis. The COS-based methods make use of a unique five year COS flux data set at a boreal forest and include two different approaches to determine the leaf scale uptake ratio of COS and CO₂ (LRU), of which one (LRU_{CAP}) was developed in this study. LRU_{CAP} was based on stomatal conductance theories, while the other was based on an empirical relation to measured radiation (LRU_{PAR}).

We found that for the measurement period 2013–2017 the artificial neural networks method gave a GPP estimate very close to that of traditional flux partitioning at all time scales. COS-based methods gave on average higher GPP estimates than the CO₂-based estimates on daily (23 and 7 % higher, if using LRU_{PAR} or LRU_{CAP} in GPP calculation, respectively) and monthly scales (20 and 3 % higher), as well as a higher cumulative sum over three months in all years (on average 25 and 3 % higher). LRU_{CAP} was higher than measured LRU at high radiation leading to an underestimated GPP during midday. However, in general it compared better with the CO₂-based methods than LRU_{PAR}-based GPP calculations. The applicability of LRU_{CAP} at other measurement sites is potentially better than that of LRU_{PAR} since its parameters are based on literature values and simple meteorological measurements, while the radiation relation in LRU_{PAR} might be site-specific. This, however, requires further testing at other measurement sites.

20 1 Introduction

Photosynthetic carbon uptake (described by gross primary production, GPP) is a crucial part of carbon cycling and removes approximately 30 % of the annual anthropogenic carbon dioxide (CO₂) emissions from the atmosphere (Luo et al., 2015; Friedlingstein et al., 2020). With the current climatic warming it is suggested that both photosynthesis and respiration are increased, due to a CO₂ fertilization effect and rising temperatures allowing more optimal conditions for photosynthesis but also
25 for respiration (Dusenke et al., 2019). However, it is not known at which ratio these two processes are changing and whether they cancel each other out or not. In addition, there is a seasonal variation in their relative importance, as photosynthesis is predicted to increase more than respiration in spring, causing greater carbon uptake, while respiration is predicted to increase more than photosynthesis in autumn, causing carbon emissions in the northern terrestrial ecosystems (Piao et al., 2008). Methods to measure and study photosynthesis and respiration processes individually are thus crucial for future carbon cycle predictions.

30 Eddy covariance (EC) is widely used globally to measure the biosphere-atmosphere exchange of CO₂ at the ecosystem scale. With EC it is, however, only possible to measure the net ecosystem CO₂ flux (NEE), which includes contributions from both the CO₂ uptake by photosynthesis (GPP) as well as ecosystem respiration (R). NEE partitioning into GPP and respiration is most commonly done using a method introduced by Reichstein et al. (2005), in which temperature response curves are fitted to nighttime CO₂ flux data (respiration). However, this method is problematic due to the reliance on nighttime EC flux
35 measurements, which are uncertain and often filtered out due to low turbulence conditions and possible advective gas transport (Aubinet, 2008). Partitioning methods that are based on a combination of nighttime respiration temperature response (nighttime method) and daytime GPP radiation response (daytime method) have also been developed in order to not rely on nighttime responses only (Lasslop et al., 2010; Kulmala et al., 2019). Both the nighttime method and the combination of nighttime and daytime methods, however, assume that the respiratory processes are the same in the daytime and nighttime and have
40 uncertainties due to assumptions of functional relationships (Tramontana et al., 2020). These limitations lead to uncertainties in the derivation of mechanistically sound descriptions of respiration and its drivers, especially when contributions of different biomass compartments to total CO₂ efflux vary across ecosystems and seasonally even within one ecosystem (Kolari et al., 2009; Keenan et al., 2019). Recently, there has been discussion on leaf respiration inhibition under radiation, the so-called Kok effect (Kok, 1949; Heskell et al., 2013; Yin et al., 2020). Keenan et al. (2019) and Wehr et al. (2016) also suggest that the global
45 GPP estimates based on the nighttime method are exaggerated due to this phenomenon. On the other hand, photorespiration, which is an oxidation process competing with carboxylation under radiation, might cancel out the inhibition by the Kok effect (Heskell et al., 2013).

One way to address biases related to flux partitioning is using machine learning methods, such as artificial neural networks in separating NEE into respiration and GPP (Tramontana et al., 2020). The benefit of NN_{C-part} is that it requires no predefined
50 knowledge on responses to environmental drivers but determines them purely based on data. A pioneering experiment from Desai et al. (2008), attempted to use artificial neural network to emulate the nighttime partitioning method without significant

improvements. Recently a new approach (NN_{C-part}) has been proposed by Tramontana et al. (2020). The proposed method is innovative for the peculiarity of the implemented network's structure and a novel way to infer GPP and R signals from NEE. Both nighttime and daytime NEE are used for network training, so the dynamics of biophysical processes are accounted in a comprehensive way.

Another recent development to tackle the GPP problem is to use proxies for CO_2 uptake. One such proxy is carbonyl sulfide (COS), which is a sulfur compound with a tropospheric mixing ratio around 500 ppt (Montzka et al., 2007). It is mainly produced by oceans and anthropogenic sources (Kettle et al., 2002; Berry et al., 2013; Launois et al., 2015; Whelan et al., 2018) while vegetation is the largest sink (Sandoval-Soto et al., 2005; Blonquist et al., 2011). COS has been suggested as a proxy for GPP since it is taken up by plants through the same diffusive pathway as CO_2 and transported to the chloroplast surface, where it is destroyed by a hydrolysis reaction triggered by the enzyme carbonic anhydrase (CA), while CO_2 continues its journey inside the chloroplast, where it is assimilated in the Calvin cycle (Wohlfahrt et al., 2012). It is assumed that COS is totally destroyed in hydrolysis and thus there is no back-flux from the leaf to the atmosphere (Protoschill-Krebs et al., 1996). When determining GPP from COS flux measurements one needs to take into account the leaf relative uptake ratio (LRU), that is, the ratio of COS and CO_2 deposition rates at the leaf scale. While LRU has been treated either as a global or plant-specific constant value in the past (Asaf et al., 2013; Stimler et al., 2012), recent studies have shown that LRU is a function of solar radiation because CO_2 uptake is highly radiation dependent while COS uptake is not (Yang et al., 2018; Kooijmans et al., 2019; Spielmann et al., 2019), and could even vary with vapour pressure deficit (Sun et al., 2018b; Kooijmans et al., 2019). In addition to uncertainties related to LRU, the COS-based GPP estimates have uncertainty due to ecosystem scale COS flux measurements that typically have a low signal-to-noise ratio and high random uncertainty at 30 min timescale, which reduces when fluxes are averaged over longer time periods (Kohonen et al., 2020). While the use of different partitioning methods or machine learning in GPP calculation primarily aims at more accurate GPP estimation, the use of COS as a GPP proxy aims at a better process understanding.

In this study, we compare the annual, seasonal, daily and sub-daily variation of i) traditionally partitioned GPP (GPP_{NLR} , NLR referring to non-linear regressions) that is based on a combination of the daytime and nighttime methods, ii) a GPP estimate based on NEE and NN_{C-part} (GPP_{ANN}), iii) a GPP estimate from COS flux measurements using the radiation-dependent LRU function from Kooijmans et al. (2019) ($GPP_{COS,PAR}$) and iv) a GPP estimate from COS flux measurements using a new, theory-based method for LRU calculation ($GPP_{COS,CAP}$) in a boreal evergreen needle-leaf forest during years 2013–2017. Our aim is to study inconsistencies in diel or seasonal patterns of GPP which could arise from the extrapolation of temperature responses to daytime and discuss the limitations and uncertainties of all four methods.

2 Materials and methods

2.1 Site description

The measurements were done at the Hyttiälä forest Station for Measuring Ecosystem Atmosphere Relations (SMEAR) II measurement site (61°51'N, 24°17'E), where first flux measurements started in 1996 while the forest stand is already more

85 than 50 years old (Hari and Kulmala, 2005). The forest stand is dominated by Scots Pine (*Pinus Sylvestris L.*) with some Norway spruce (*Picea abies L. Karst.*) and deciduous trees (e.g. *Betula sp.*, *Populus tremula*, *Sorbus aucuparia*). The daytime flux footprint covers c. 50 ha area of the forest. The canopy height increased from approximately 18 to 20 m during the measurement period (2013–2017) and the all-sided leaf area index (LAI) was c. $8 \text{ m}^2 \text{ m}^{-2}$.

2.2 Measurements

90 2.2.1 Eddy covariance fluxes and environmental measurements

EC measurements were conducted at a 23 m high tower. The setup consisted of Gill HS (Gill Instruments Ltd., England, UK) sonic anemometer measuring horizontal and vertical wind velocities and sonic temperature, and a quantum cascade laser (QCL; Aerodyne Research Inc., Billerica, MA, USA) for measuring COS, CO₂ and H₂O mixing ratios at 10 Hz frequency. The setup is described in more detail in Kohonen et al. (2020) and flux data presented in Vesala et al. (2021). Flux processing was done using
95 EddyUH software (Mammarella et al., 2016) following the methods presented by Kohonen et al. (2020). Fluxes were corrected for storage change and filtered according to friction velocity. Storage change fluxes of COS were calculated from the COS profile measurements in 2015–2017 and from one level concentration measurement in other years, as described in Kohonen et al. (2020), while CO₂ storage change fluxes were calculated from CO₂ concentration profile measurements. The friction velocity threshold was determined from CO₂ fluxes (Papale et al., 2006) and a threshold of 0.3 m s^{-1} was applied to the whole
100 data set to exclude time periods with low turbulence. COS flux processing was done otherwise similarly to CO₂ processing, but time lag and spectral corrections were determined from CO₂ measurements and applied to COS as recommended in Kohonen et al. (2020). Gap-filling of the COS flux was done using empirical formulas based on photosynthetically active radiation (PAR) and vapor pressure deficit (VPD), described in Kohonen et al. (2020). CO₂ fluxes were gap-filled and partitioned with a procedure explained in more detail in Sect. 2.3.1.

105 Environmental measurements used in the study include air temperature (T_a) at 16.8 m (measured with a Pt100 temperature sensor inside a custom shield), PAR above the canopy (Li-190SZ quantum sensor, LI-COR, Lincoln, NE, USA), relative humidity (RH) at 16.8 m height (Rotronic MP102H, Rotronic Instrument Corp., NY, USA), soil temperature (T_{soil}) at 2–5 cm depth (KTY81-110 temperature sensor, Philips, The Netherlands) as a mean of five locations and soil water content (SWC) in the humus layer (Delta-T ML2 soil moisture sensor, Delta-T Devices, Cambridge, UK).

110 2.3 GPP calculations

In this section, all used GPP calculation methods are explained in detail. Daily average GPP was only calculated if more than 50% of measured flux data was available for each day and monthly averages calculated from these data. Gap-filled flux data were used in diurnal variation and in calculating the cumulative GPP. All comparisons between the methods were done to measured (non gap-filled) data only, when both CO₂ and COS flux data were available.

115 2.3.1 GPP from traditional CO₂ flux partitioning

NEE was partitioned into respiration (R) and GPP_{NLR} as

$$NEE = R - GPP_{NLR} \quad (1)$$

where the GPP model followed the formula

$$GPP_{NLR} = \frac{\alpha PAR + P_{max} - \sqrt{(\alpha PAR + P_{max})^2 - 4\Theta PAR \cdot P_{max}}}{2\Theta} f(T_a) \quad (2)$$

120 where α , P_{max} and Θ are fitting parameters and $f(T_a)$ an instantaneous temperature response that forces GPP to zero when $T_a < 0$ °C as

$$f(T_a) = \frac{1}{1 + e^{2(T_0 - T_a)}} \quad (3)$$

where T_0 is the inflection point (Kolari et al., 2014).

R was estimated as

$$125 R = R_C Q_{10}^{T_{sa}/10} \quad (4)$$

where R_C is the respiration at a reference temperature ($T=0$ °C), Q_{10} is the temperature sensitivity of R and T_{sa} is the mean of the air temperature at 18 m height and soil temperature at 5 cm depth. T_{sa} has been found to be a good choice as the respiration driver at Hyytiälä forest in previous studies (Kolari et al., 2009; Lasslop et al., 2012).

Parameters α , P_{max} and R_C were estimated for 11-day periods while Q_{10} was estimated from the weighted mean of monthly
130 Q_{10} values from June–August over several years. Weights were the inverse of the confidence interval of each Q_{10} estimate. Θ was determined as the value that gave the best model fit when the partitioning was run over the summer months (June–August) over several years (Kulmala et al., 2019).

2.3.2 GPP from artificial neural networks

GPP_{ANN} from data driven model was estimated by applying the NN_{C-part} algorithm (Tramontana et al., 2020). NN_{C-part} is a
135 customized neural network that emulates the bio-physical processes driving both GPP and R at ecosystem spatial scale and was applied to several vegetation types distributed globally. The network is composed by two subnetworks: one used to simulate GPP fluxes and the other one for R. The two subnetworks are joined together in the last node of the overall structure in which, the GPP and R signals were combined to calculate NEE. The subnetwork simulating GPP was composed by three layers and it estimated the ecosystem level gross photosynthesis by applying a light use efficiency (LUE) approach; in particular
140 instantaneous LUE was estimated by the first two layers while GPP was finally calculated as the product between LUE and shortwave incoming radiation in the third layer.

Each subnetwork rely on specific predictors. Characteristics that distinguish the model are a) GPP and R derived by other models are not used, b) functional relationships are derived directly from the data and c) the network's weights are tuned by

training the machine learning only on NEE measurements. In this experiment we used the same predictors (VPD, incoming
145 shortwave radiation, potential incoming radiation, T_a , T_{soil} , SWC, wind speed and wind direction) and network structure as
applied in Tramontana et al. (2020). However, to assure the operability of the method, which is limited by the availability
of both predictors and NEE measurements, we set lower requirements concerning the minimum percentage of measured data
for both predictors and half hourly NEE. Moreover, data from all available years were put together in the same dataset to be
used in a unique “multi-years” training process. In particular, we applied the following setting: for each year, less than 55%
150 of predictors were gap-filled and at least 365 half hourly NEE should be measured for both nighttime and daytime. Despite
high percentage of missing data in observations, gaps had generally short duration with limited effects on the uncertainty of
predicted outputs. The final GPP_{ANN} products were derived by applying trained networks on meteorological inputs, and thus
do not include NEE data after network training.

2.3.3 GPP from COS flux measurements

155 Based on previous soil chamber measurements it was known that the soil COS flux at Hyytiälä forest site varies only by 1
pmol m⁻² s⁻¹ during the growing season and the diurnal variation is negligible (Kooijmans et al., 2019; Sun et al., 2018a). An
average soil flux of -2.7 pmol m⁻² s⁻¹ was thus first subtracted from the quality filtered and gap-filled COS EC fluxes in order
to only account for the vegetation contribution to the ecosystem COS exchange. GPP was then calculated from the ecosystem
COS fluxes (FCOS) using formula (Sandoval-Soto et al., 2005; Blonquist et al., 2011)

$$160 \quad GPP_{COS} = \frac{-FCOS}{LRU} \frac{[CO_2]_a}{[COS]_a} \quad (5)$$

where $[CO_2]_a$ and $[COS]_a$ denote the atmospheric concentrations of CO₂ and COS (in mol m⁻³) measured by the QCL,
respectively. LRU (-) was calculated as a function of PAR (LRU_{PAR}) as described by the empirical equation presented in
Kooijmans et al. (2019):

$$LRU_{PAR} = \frac{607.26}{PAR} + 0.57 \quad (6)$$

165 This LRU equation was based on field measurements of branch CO₂ and COS fluxes in 2017 at the same site and were thus
independent from the EC flux measurements (Kooijmans et al., 2019).

A new theoretical LRU estimate (LRU_{CAP}) was developed based on the stomatal optimization model CAP (Dewar et al.,
2018). The LRU_{CAP} formulation was based on the following general expression for LRU given by Eqs. (10-11) of Wohlfahrt
170 et al. (2012):

$$LRU = \frac{1}{1 - \frac{c_i}{c_a}} \frac{\frac{1}{1.21} + \frac{1}{1.14} \frac{g_s^{COS}}{g_b^{COS}}}{1 + \frac{g_s^{COS}}{g_b^{COS}} + \frac{g_m^{COS}}{g_b^{COS}}} \quad (7)$$

where g_x^{COS} ($x = b, s, m$) are, respectively, the boundary layer, stomatal and mesophyll conductances for COS, c_a is the atmospheric CO₂ molar mixing ratio (mol mol⁻¹), c_i is the leaf intercellular CO₂ molar mixing ratio (mol mol⁻¹), and the numerical factors 1.21 and 1.14 are the ratios of the conductances of CO₂ to COS for stomata and the boundary layer (Wohlfahrt et al., 175 2012). If it is assumed that the boundary layer and mesophyll conductances are infinite (as done by Dewar et al. (2018)), Eq. (7) reduces to

$$LRU = \frac{1}{1.21} \left(1 - \frac{c_i}{c_a} \right)^{-1}. \quad (8)$$

An analytical expression for c_i was derived from the stomatal optimization model CAP by Dewar et al. (2018), according to which stomatal conductance maximise leaf photosynthesis, reflecting a trade-off between stomatal limitations to CO₂ diffusion and non-stomatal limitations (NSLs) to carboxylation capacity. The CAP model predicts the value of c_i as an analytical function 180 of various environmental and physiological factors. Inserting this function into Eq. (8), LRU_{CAP} can then be expressed as

$$LRU_{CAP} = \frac{1}{1.21} \frac{c_a}{c_a - \Gamma^*} \left(1 + \sqrt{\frac{K_{sl} |\psi_c|}{1.6 g_c VPD}} \sqrt{1 + \frac{2\Gamma^* g_c}{\alpha PAR}} \right), \quad (9)$$

where Γ^* is the CO₂ photorespiratory compensation point (mol mol⁻¹), K_{sl} the soil-to-leaf hydraulic conductance (mol m⁻² s⁻¹ MPa⁻¹), ψ_c is the assumed critical leaf water potential (MPa) at which NSLs reduce photosynthesis to zero, g_c 185 is the carboxylation conductance in the absence of NSLs (mol m⁻² s⁻¹) and α is the photosynthetic quantum yield (mol mol⁻¹) in the absence of NSLs (Duursma et al., 2008; Dewar et al., 2018). While Γ^* and α vary seasonally with temperature (Bernacchi et al., 2001; Leverenz and Öquist, 1987), we decided to use fixed values of 50×10^{-6} mol mol⁻¹ and 0.05 mol mol⁻¹, respectively, for simplicity. In addition to PAR (mol m⁻²s⁻¹) and VPD measurements (mol mol⁻¹), LRU_{CAP} requires soil moisture measurements through the soil component of K_{sl} . All parameter definitions and values are listed in Table 1 and 190 a more detailed derivation of Eq. (9) is given in the Appendix (Sect. A1 and A2).

3 Results and discussion

3.1 Environmental conditions

March 2013 was colder than other years (average -7.0 °C) with also a higher average PAR (207.3 μmol m⁻² s⁻¹) and lowest soil moisture (0.23 m³ m⁻³) of all years (Fig. 1). May 2017 had high amounts of radiation (monthly average PAR of 478.4 195 μmol m⁻²) and soil temperature was low (3.4 °C), while soil moisture and VPD were at a normal level at 0.28 m³ m⁻³ and 0.47 kPa, respectively. July 2014 was warmer (19.0 °C) and dryer (VPD 0.88 kPa) than other years but soil moisture remained high at 0.25 m³ m⁻³. A clear increase in VPD and a drop in soil moisture were seen in August 2013 and 2015 when soil moisture decreased from 0.24 (0.31 in 2015) in July to 0.19 (0.24 in 2015) m³ m⁻³ in August in 2013 and afternoon median VPD increased to 1.00 kPa in August 2013. Soil moisture in September–December in 2017 was 10 % higher than other years, 200 while no significant differences between years were found in other environmental variables in late autumn.

Table 1. Explanations and literature values of the parameters used in the LRU_{CAP} formulation for Hyttiälä forest. c_a was derived from the measurements in Kooijmans et al. (2019), SWC, PAR and VPD from measurements done in this study, other values are from Dewar et al. (2018), Duursma et al. (2008), (Bernacchi et al., 2001) and Nikinmaa et al. (2013). Soil-related values ($K_{soil,sat}$, r_{cyl} , SWC_{sat} and b) are for soil horizon B (which was considered to be representative of the rooting zone), where the SWC measurements were also made. Values measured at the site are written in bold.

Symbol	Definition	Default value or formula and unit
c_a	Atmospheric CO ₂ molar mixing ratio	$415 \times 10^{-6} \text{ mol mol}^{-1}$
Γ^*	Photorespiratory compensation point of CO ₂	$50 \times 10^{-6} \text{ mol mol}^{-1}$
g_c	Carboxylation conductance in the absence of non-stomatal limitations	$0.5 \text{ mol m}^{-2} \text{ s}^{-1}$
ψ_c	Critical leaf water potential	-2 MPa
α	Photosynthetic quantum yield	$0.05 \text{ mol mol}^{-1}$
K_{sl}	Leaf-specific soil-to-leaf hydraulic conductance	$\frac{K_{soil} K_x}{K_{soil} + K_x}$; $\text{mol m}^{-2} \text{ s}^{-1} \text{ MPa}^{-1}$
K_x	Leaf-specific root-to-leaf xylem hydraulic conductance	$0.78 \times 10^{-3} \text{ mol m}^{-2} \text{ s}^{-1} \text{ MPa}^{-1}$
K_{soil}	Leaf-specific soil hydraulic conductance	$\frac{R_1}{LAI} \frac{2\pi k_{soil}}{\log\left(\frac{r_{cyl}}{r_{root}}\right)}$; $\text{mol m}^{-2} \text{ s}^{-1} \text{ MPa}^{-1}$
k_{soil}	Soil hydraulic conductivity	$k_{soil,sat} \left(\frac{SWC}{SWC_{sat}}\right)^{2b+3}$; $\text{mol m}^{-1} \text{ s}^{-1} \text{ MPa}^{-1}$
$k_{soil,sat}$	Saturated soil hydraulic conductivity	$5.7 \text{ mol m}^{-1} \text{ s}^{-1} \text{ MPa}^{-1}$
R_1	Root length index	5300 m^{-1}
LAI	Leaf area index, all-sided	$8 \text{ m}^2 \text{ m}^{-2}$
r_{cyl}	Radius of the cylinder of soil accessible to a root	0.00458 m
r_{root}	Fine root radius	$0.3 \times 10^{-3} \text{ m}$
SWC_{sat}	Saturation soil water content	$0.52 \text{ m}^3 \text{ m}^{-3}$
SWC	Soil water content	$\text{m}^3 \text{ m}^{-3}$
b	Parameter of the soil water retention curve	4.46
VPD	Vapor pressure deficit	mol mol^{-1}
PAR	Photosynthetically active radiation	$\text{mol m}^{-2} \text{ s}^{-1}$

3.2 GPP comparison from sub-daily to seasonal scales

GPP_{ANN} showed slightly higher midday values than GPP_{NLR} during summer months (May–July) in 2014 and 2017 (Figs. 2,3,4a), opposite to what was found in Tramontana et al. (2020) when comparing GPP_{ANN} to standard FLUXNET partitioning during summer months for multiple sites. The difference during other months was negligible. We tested how the more widely

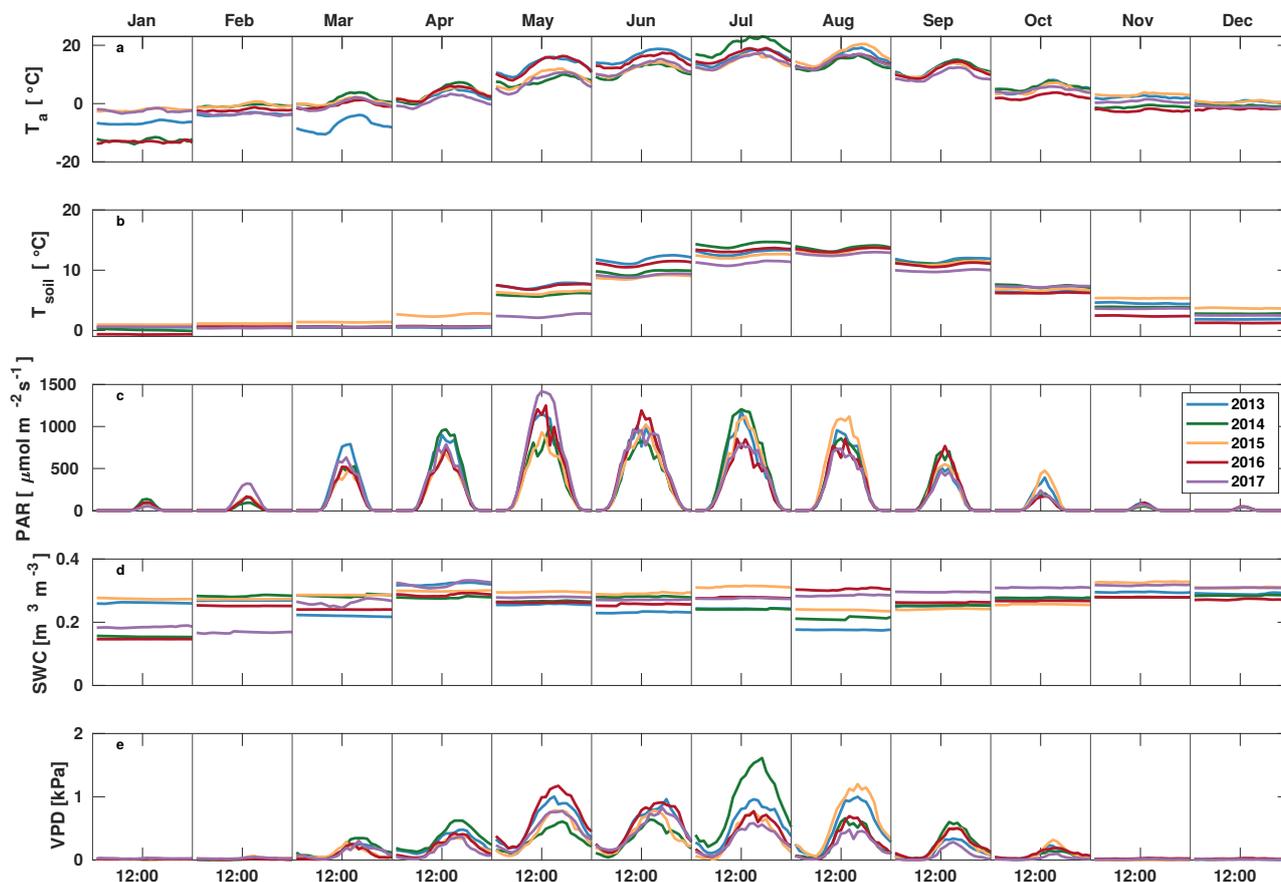

Figure 1. Median diurnal variation of T_a , T_{soil} , PAR, SWC and VPD in different months during the measurement period 2013–2017.

205 used partitioning method of using only air temperature as the respiration driver, GPP_{airT} , (instead of the average of soil and
air temperatures) would perform against GPP_{NLR} and found the two methods to agree very well with each other at all time
scales studied (Fig. B1). The small differences in the diurnal variations of GPP_{NLR} and GPP_{ANN} are thus not due to the chosen
temperature measurement as respiration driver. During the measurement period 2013–2017, daily GPP_{ANN} did not differ from
 GPP_{NLR} statistically (tested with Student's t-test). However, at 30 min time scale the GPP_{ANN} was on average 15 % lower
210 than GPP_{NLR} . The lower agreement of 30 min GPP_{ANN} and GPP_{NLR} than at longer time scales may result from the NN_{C-part}
method restricting GPP_{ANN} to only positive values while GPP_{NLR} may have even negative values due to random noise in the
NEE measurements. The relative and absolute differences of GPP_{ANN} to GPP_{NLR} are, however, very small when averaging
over longer time periods (Fig. 5).

$GPP_{COS,PAR}$ performed very similarly to GPP_{NLR} especially during morning and early evening (Fig. 2,3), but showed
215 higher midday values than GPP_{NLR} , especially during summer months (May–August) in all years. At the daily scale, $GPP_{COS,PAR}$

was on average 23 % higher than GPP_{NLR} (Figs. 4d,5) and also differed from GPP_{NLR} statistically ($p < 0.01$) as tested with Student's t-test.

To investigate further the causes of the higher $GPP_{COS,PAR}$, we tried another LRU approach based on a stomatal conductance model, LRU_{CAP} (Sect. 2.3.3). LRU_{CAP} uses PAR, SWC and VPD as well as ecosystem specific literature values for some parameters as input variables, while LRU_{PAR} by Kooijmans et al. (2019) only uses PAR. LRU_{CAP} could potentially better take into account e.g. the effects of drought on stomatal control. In spring, the diurnal variation of $GPP_{COS,CAP}$ follows closely those of GPP_{NLR} and GPP_{ANN} until June (Fig. 2, 3). Especially in June and July $GPP_{COS,CAP}$ is lower than the other GPP estimates. At 30 min time scale $GPP_{COS,CAP}$ is on average 12 % lower than GPP_{NLR} , but there is large scatter due to noisy FCOS measurements, as in $GPP_{COS,PAR}$. However, there is less scatter in $GPP_{COS,CAP}$ than $GPP_{COS,PAR}$, indicating that some of the scatter is due to LRU estimation. At daily scale $GPP_{COS,CAP}$ is 7% higher than GPP_{NLR} and at monthly scale the difference decreases to 3%. However, there is no statistically significant difference between the daily values of GPP_{NLR} and $GPP_{COS,CAP}$, as tested with Student's t-test. The relative and absolute difference of $GPP_{COS,CAP}$ to GPP_{NLR} is also mostly lower than that of $GPP_{COS,PAR}$ to GPP_{NLR} throughout the year (Fig. 5). In addition, $GPP_{COS,CAP}$ finds the same two distinctive probability density function peaks as GPP_{NLR} and GPP_{ANN} at 1.7 and 6.6 $\mu\text{mol m}^{-2}\text{s}^{-1}$ while $GPP_{COS,PAR}$ finds weaker peaks at 2.4 and 7.4 $\mu\text{mol m}^{-2}\text{s}^{-1}$ (Fig. 6). It can be thus said, that $GPP_{COS,CAP}$ gives a better agreement with traditional GPP_{NLR} partitioning than $GPP_{COS,PAR}$. However, it was noted that LRU_{CAP} was overestimated at high radiation ($PAR > 1000 \mu\text{mol m}^{-2}\text{s}^{-1}$, Fig. B2a).

LRU_{CAP} was also calculated based on a combination of literature values and fitted parameters (Sect. A1) by fitting parameters $X = \frac{|\psi_c|}{1.6g_c}$ and $Y = \frac{2\Gamma^*g_c}{\alpha}$ to Eq. (9). This exercise allows for better analysis of the uncertainties of LRU_{CAP} . While literature values would give $X = 2.5$ and $Y = 0.001$, the fitting resulted in $X = 2.64$ and $Y = 0.0033$ and a better agreement of LRU_{CAP} with measured LRU (RMSE=1.89, while without fitting RMSE=2.01). While X was close to its literature value, Y was estimated three times higher. This mismatch suggests there may be scope for further model improvement, such as the inclusion of dark respiration and/or finite mesophyll conductance in the LRU_{CAP} model. However, as the difference between fitted LRU_{CAP} and LRU_{CAP} with only literature values was not large and the applicability of the model without fitting is better, we decided to use the literature value-based LRU_{CAP} in this study, without fitting to measured LRU.

LRU_{CAP} was also calculated assuming finite mesophyll conductance as a test (Sect. A2). The agreement of this method was better than assuming infinite mesophyll conductance at high PAR, but worse at low PAR (Fig. B2d), very similar to the results from Maignan et al. (2021), who modelled LRU at Hyytiälä using the ORCHIDEE model. This version of LRU_{CAP} was also fitted to measured LRU in terms of parameters X and Y (Sect. A2) to make the low PAR LRU_{CAP} better, which resulted in $X = 3.45$ and $Y = 0.0057$, both higher than their expected literature values. We thus concluded that the assumption of infinite g_m is more valid. Kooijmans et al. (2019) found that internal conductance (a combination of mesophyll conductance and biochemical reactions) might limit leaf-scale FCOS during daytime. We find a better agreement of LRU_{CAP} with measured LRU if g_m is assumed infinite, but there is a mismatch at high PAR, supporting the possibility that g_m might indeed be a limiting factor under high radiation.

Table 2. Cumulative GPP (gC m^{-2}) over May–July with different GPP estimates. All sums are calculated from same data coverage and the fraction of gap-filled flux data (CO_2 flux for GPP_{NLR} , COS flux for $\text{GPP}_{\text{COS,PAR}}$ and $\text{GPP}_{\text{COS,CAP}}$) is presented in parentheses. GPP_{ANN} does not include gap-filled NEE data, since it is based on meteorological variables. *In 2015, the cumulative sum covers only July.

Year	GPP_{NLR}	GPP_{ANN}	$\text{GPP}_{\text{COS,PAR}}$	$\text{GPP}_{\text{COS,CAP}}$
2013	481 (0.16)	473	597 (0.28)	510 (0.28)
2014	294 (0.20)	324	414 (0.24)	343 (0.24)
2015	193 (0.23)*	188*	212 (0.31)*	165 (0.31)*
2016	623 (0.40)	565	722 (0.43)	599 (0.43)
2017	387 (0.35)	399	522 (0.34)	428 (0.34)

250 All cumulative GPP estimates over May–July (Table 2) were about half of the yearly GPP reported previously (Lagergren
et al., 2008; Ilvesniemi et al., 2009; Kolari et al., 2009; Suni et al., 2003), since we did not measure GPP over the whole growing
season (that lasts c. 30 weeks) but only 13 weeks around the peak growing season. Cumulative $\text{GPP}_{\text{COS,PAR}}$ was (on average
25 % higher than cumulative GPP_{NLR} in all studied years. This is higher than the 4.3 % difference reported in Spielmann et al.
(2019) and 3.5 % agreement reported in Commane et al. (2015). Cumulative $\text{GPP}_{\text{COS,CAP}}$ on the other hand varied from 17 %
255 higher in 2014 to 15 % lower in 2015 being on average only 3 % higher than cumulative GPP_{NLR} . Cumulative GPP_{ANN} varied
from 10 % higher in 2014 to 9 % lower in 2016 than GPP_{NLR} , on average being 0.1 % lower than GPP_{NLR} . As stated above,
overall GPP_{ANN} was closest to GPP_{NLR} from the three GPP estimates. $\text{GPP}_{\text{COS,CAP}}$ was closer to both of the CO_2 -based GPP
estimates than $\text{GPP}_{\text{COS,PAR}}$. However, at high PAR, $\text{LRU}_{\text{COS,CAP}}$ was overestimated in comparison to observations, leading
to underestimated GPP. Still, no firm conclusions can be drawn on this as the LRU observations only cover measurements at
260 the top of the canopy, and may not reflect LRU over the whole canopy.

It has been suggested that, due to the Kok effect, leaf respiration is inhibited under radiation (Kok, 1949). This inhibition has
been estimated to be approximately 13 % in the evergreen needle-leaf forests during summer (Keenan et al., 2019). Isotopic
studies measuring the CO_2 isotope fluxes have come to the conclusion that due to the Kok effect, the traditional GPP from
 CO_2 flux partitioning using the nighttime method is overestimated and isotopic flux measurements support this statement
265 (Wehr et al., 2016). However, the ecosystem respiration at the Hyytiälä forest site is dominated by soil respiration (Ilvesniemi
et al., 2009), which could limit the importance of the Kok effect in this ecosystem (Keenan et al. (2019); Yin et al. (2020)).
Reduced leaf respiration under radiation would be visible as a break point around the compensation point with a change of
the slope of NEE against radiation. However, such a break point was not detected in our observations, as is demonstrated in
Fig. B3. It is thus not expected that independent GPP estimates in Hyytiälä would necessarily result in lower GPP than the
270 traditional methods. Moreover, as demonstrated in Tramontana et al. (2020), the uncertainties and biases in NEE (and COS
flux) measurements exceed those resulting from the possible Kok effect.

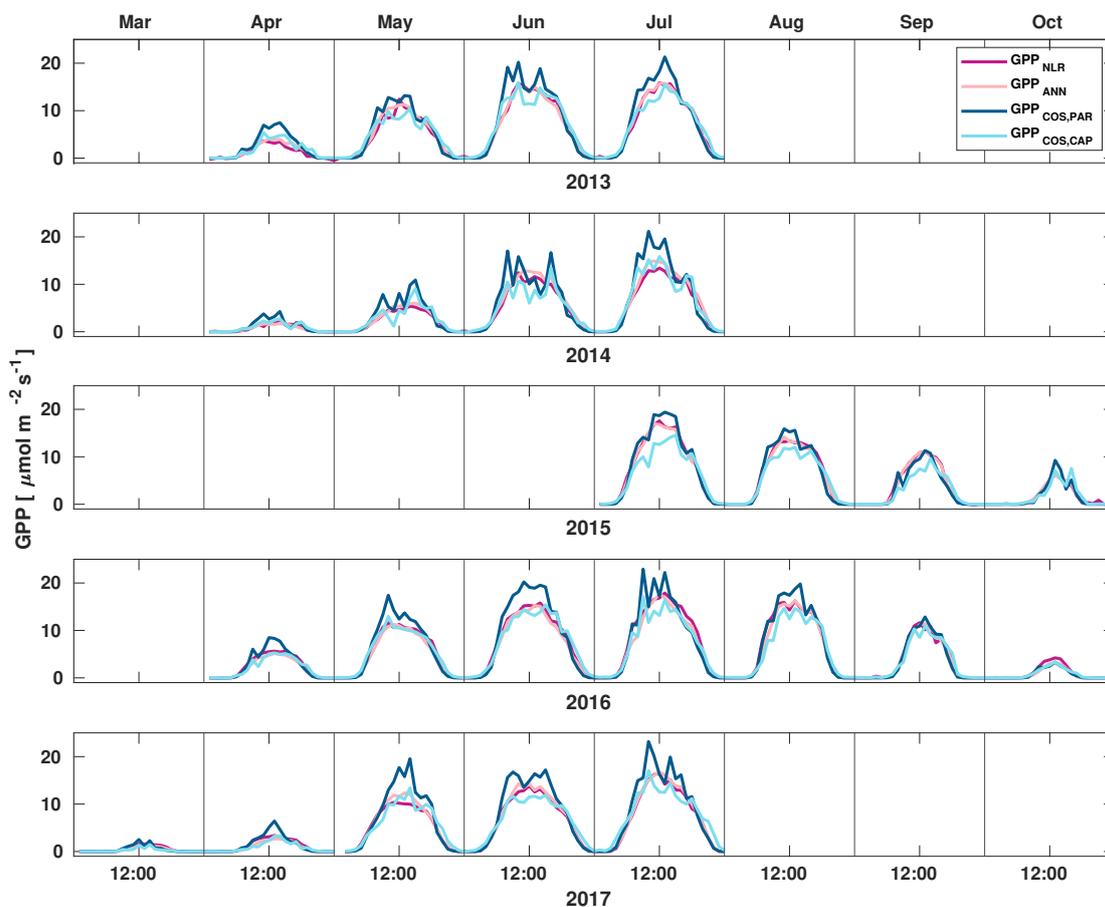

Figure 2. Median diurnal variation of traditionally partitioned GPP (GPP_{NLR} , purple line), GPP from artificial neural networks (GPP_{ANN} , pink line), GPP from COS flux measurements with LRU determined according to Kooijmans et al. (2019) ($GPP_{COS,PAR}$, dark blue line) and GPP from COS flux measurements using a new approach for LRU (Sect. 2.3.3, $GPP_{COS,CAP}$, light blue line) in different months during the measurement period 2013–2017. Averaging was done to the same data points and only months with more than 55 % of data coverage were included.

3.3 GPP responses to environmental conditions

All four GPP estimates responded similarly to environmental forcing (PAR, T_a , VPD) both in spring and summer (Fig. 7). In spring, all GPP estimates increased with increasing radiation levels, while in summer a saturation point was found at $PAR > 500$ $\mu\text{mol m}^{-2}\text{s}^{-1}$. $GPP_{COS,PAR}$ was higher than $GPP_{COS,CAP}$ at $PAR > 400$ $\mu\text{mol m}^{-2}\text{s}^{-1}$ while at low PAR values they agreed well with each other both in spring and summer, as well as with GPP_{NLR} and GPP_{ANN} . $GPP_{COS,PAR}$ thus has a stronger

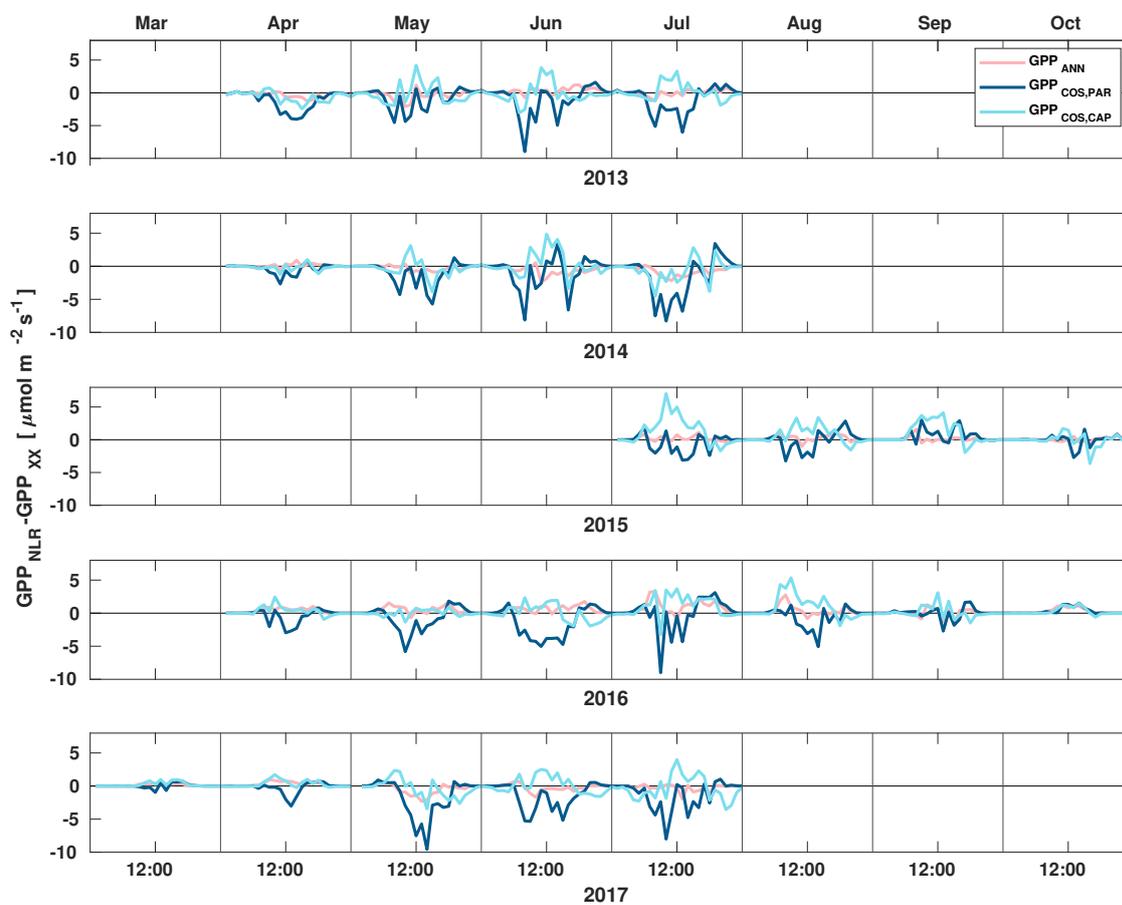

Figure 3. Diurnal variation of the difference of GPP_{ANN} (pink), $GPP_{COS,PAR}$ (dark blue) and $GPP_{COS,CAP}$ (light blue) to the reference GPP_{NLR} in different months during the measurement period 2013–2017. Averaging was done to the same data points and only months with more than 55 % of data coverage were included.

radiation response than the other GPP estimates. A similar PAR response was found in Spielmann et al. (2019), who studied $GPP_{COS,PAR}$ with a traditional GPP partitioning method in four different sites in Europe. Although $GPP_{COS,CAP}$ agrees well with both GPP_{NLR} and GPP_{ANN} at high PAR, it is likely underestimated due to overestimated LRU_{CAP} at high PAR.

280 In spring, increasing air temperature increased all GPP estimates similarly until T_a reached 17°C . However, again $GPP_{COS,PAR}$ was higher than other GPP estimates. In summer, air temperature did not have a notable effect on any GPP estimate. Responses to VPD were similar for each GPP estimates both in spring and summer. In spring, decreasing air humidity (increasing VPD) was increasing GPP until $VPD > 0.7$ kPa after which VPD did not have an effect. In summer, dryness started to limit GPP at

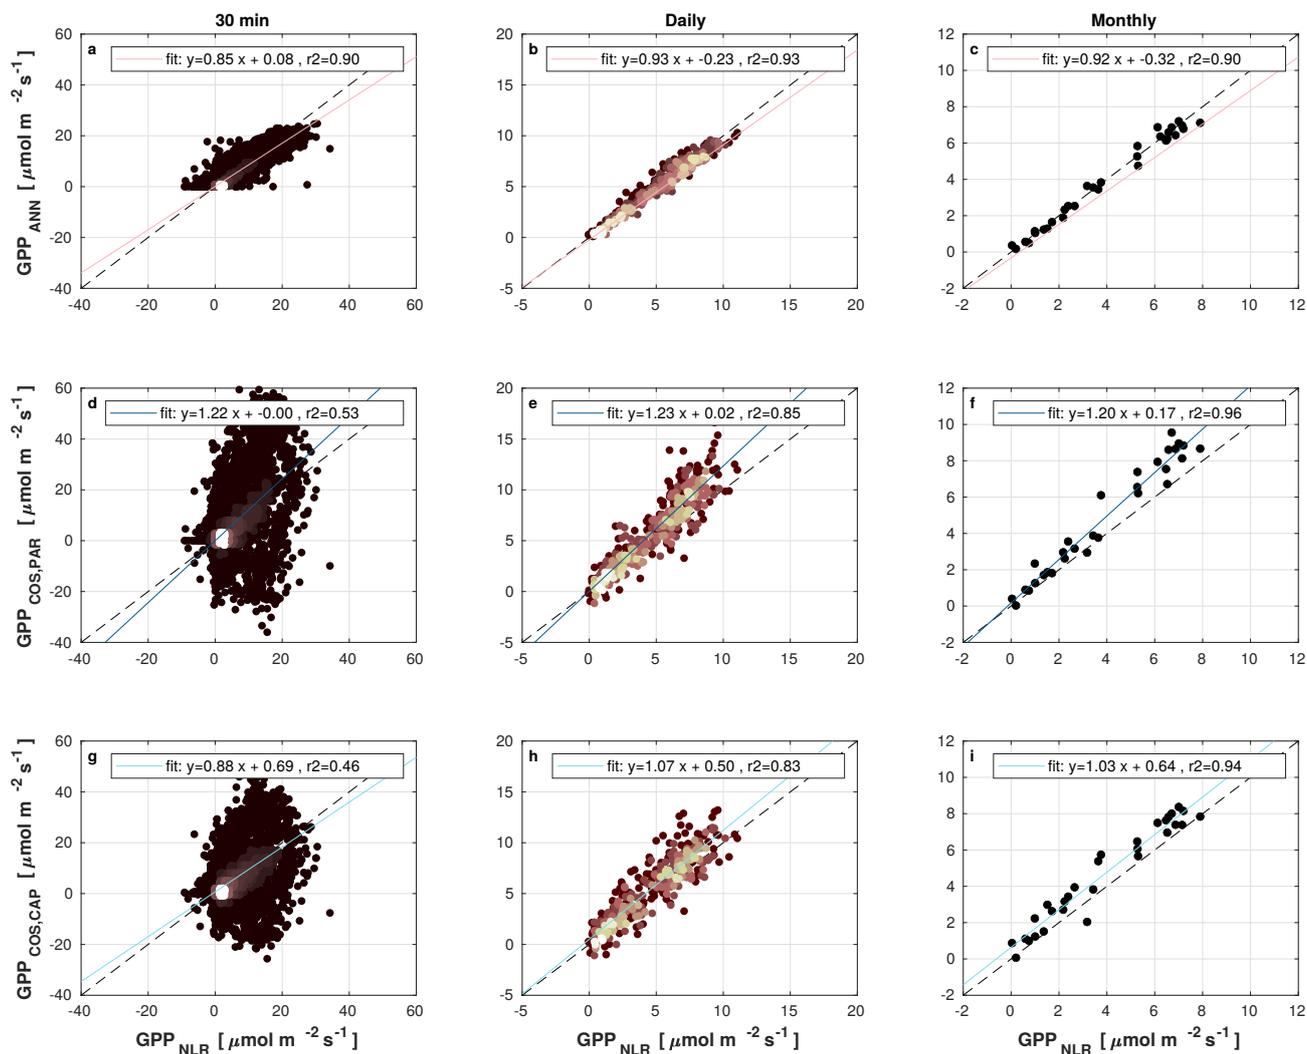

Figure 4. Scatter plots of GPP_{ANN}, GPP_{COS,PAR} and GPP_{COS,CAP} against GPP_{NLR} in 30 min, daily and monthly time scales. The color of data points in 30 min and daily scatter plots indicate the data density, lighter colors indicating higher point density than dark.

VPD > 1 kPa. We found that similar to PAR and T_a responses, GPP_{COS,PAR} was higher than other GPP estimates at low VPD values, but decreased to similar levels at high VPD (1 kPa) both in spring and summer.

Wohlfahrt et al. (2018) used FCOS to determine whether a reduction in GPP during a heatwave is due to diffusional or biochemical limitations, because FCOS tracks the diffusional limitations only while CO₂ flux is a combination of both. As we did not observe drought or heatwaves in Hyytiälä during the measurement period, we cannot assess the effects of drought to GPP_{COS,PAR} or GPP_{COS,CAP}. We can, however, see that GPP_{COS,PAR} gives higher GPP at low VPD than the CO₂-based

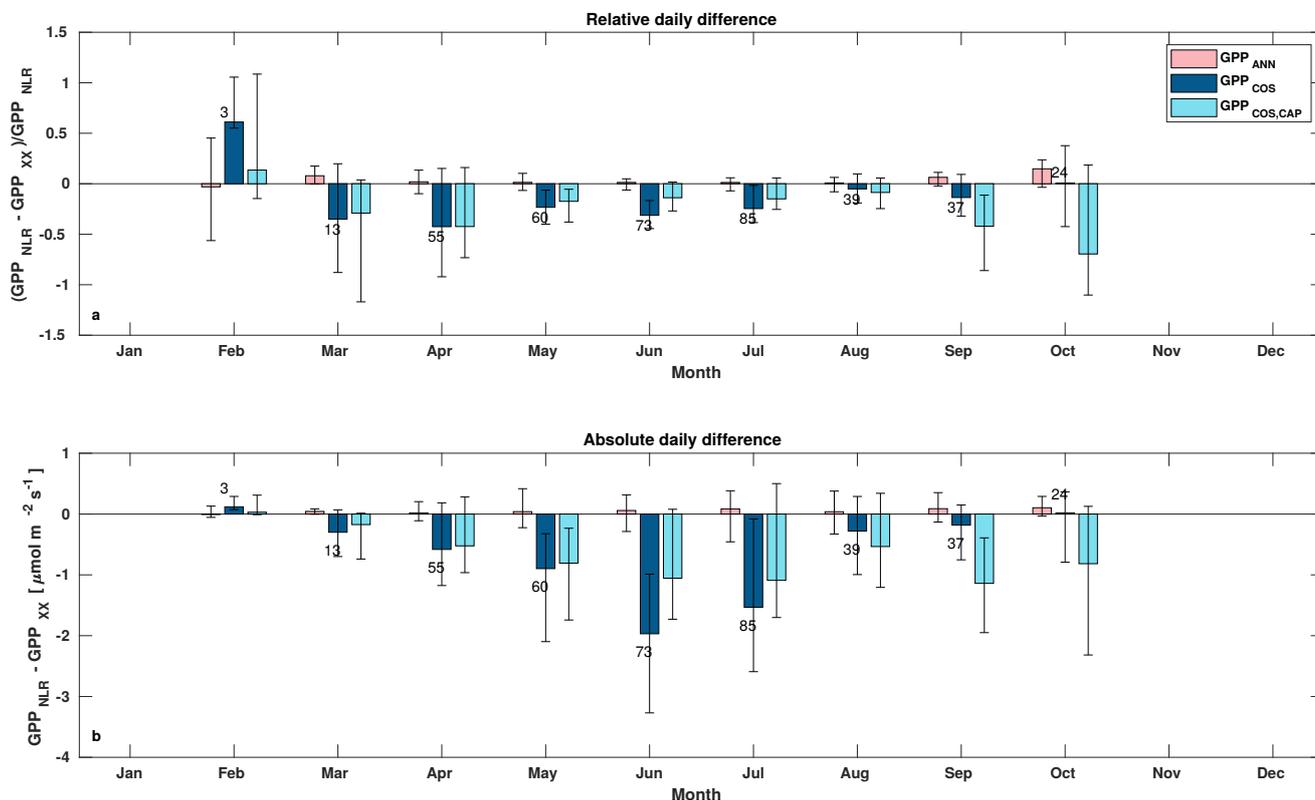

Figure 5. Relative (a) and absolute (b) difference of daily GPP_{ANN} (pink), $GPP_{COS,PAR}$ (dark blue) and $GPP_{COS,CAP}$ (light blue) to GPP_{NLR} in different months, averaged over the whole measurement period 2013–2017. Bars represent the median difference, and whiskers show the 25th and 75th percentiles. Numbers on top of the bars indicate how many daily flux data points have been used for calculating the medians. All medians have been calculated using the same number of data points.

290 methods, as does $GPP_{COS,CAP}$ in spring (Fig. 7). This may indicate that something is limiting the photosynthesis reaction (e.g. biochemical limitations in CO_2 assimilation) even though the diffusion into the leaf is not limited.

3.4 Uncertainties and limitations of the GPP methods

Because GPP_{ANN} is purely based on data, it has high sensitivity to the uncertainty in the input data. Moreover, it is sensitive to missing data especially in the case of long data gaps (Tramontana et al., 2020). The method also requires large data sets for training NN_{C-part} , not available at all measurement sites. However, GPP_{ANN} does not require prescribed relationships of GPP to environmental data making it an attractive method for sites with good data availability.

$GPP_{COS,PAR}$ uses an empirical PAR relation that is based on measurements done at Hyytiälä forest. This relation should be tested against branch scale COS and CO_2 flux measurements at other sites, as a different PAR relation was found in Yang et al.

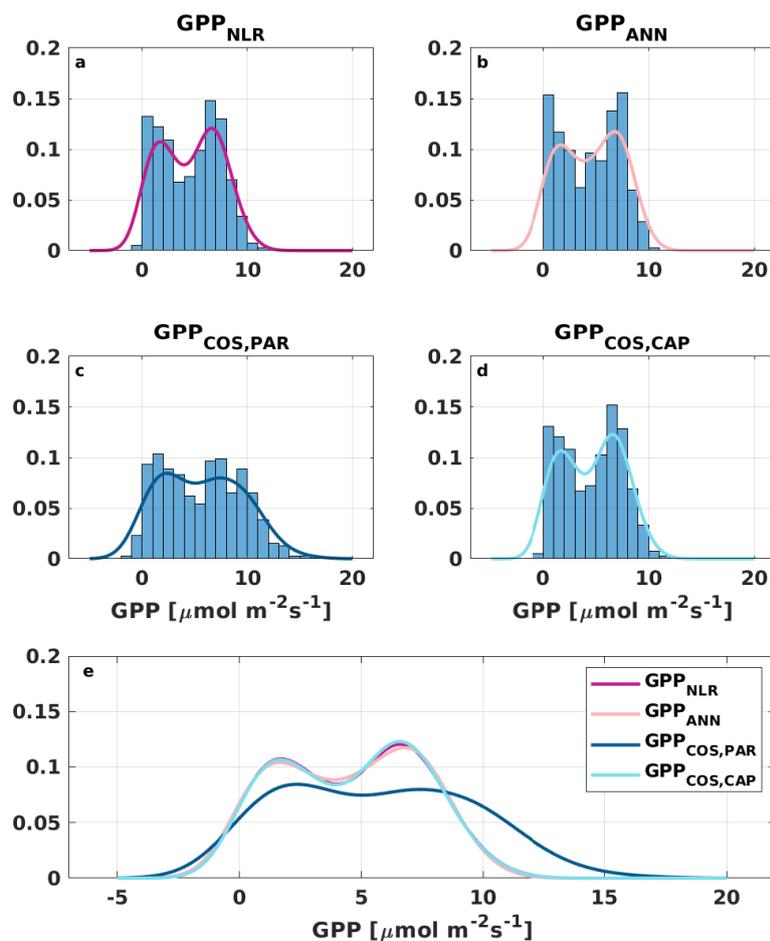

Figure 6. Distribution (bars) and probability density functions (lines) of daily average (a) GPP_{NLR} , (b) GPP_{ANN} , (c) $GPP_{COS,PAR}$ and (d) $GPP_{COS,CAP}$. All probability density functions are combined in (e) for better comparison.

300 (2018) and it is not known if this relation holds elsewhere. While the LRU_{PAR} function is simple, and in that sense attractive, it does not take into account e.g. stomatal regulation during drought or non-stomatal limitations. Moreover, as an empirical fit, it does not provide process-based understanding for LRU. While the results of $GPP_{COS,PAR}$ are promising, we observed a difference similar to what was found in Kooijmans et al. (2019) and did not find as good agreement with CO_2 -based GPP
305 in Mediterranean pine forests and crop fields. However, they also reported higher GPP_{COS} assumed to be related to soil COS uptake, which was not measured or taken into account in GPP calculations in their study. In our study, we have subtracted an average measured soil flux (Sun et al., 2018a) from the ecosystem COS uptake. The diurnal variation in soil COS flux

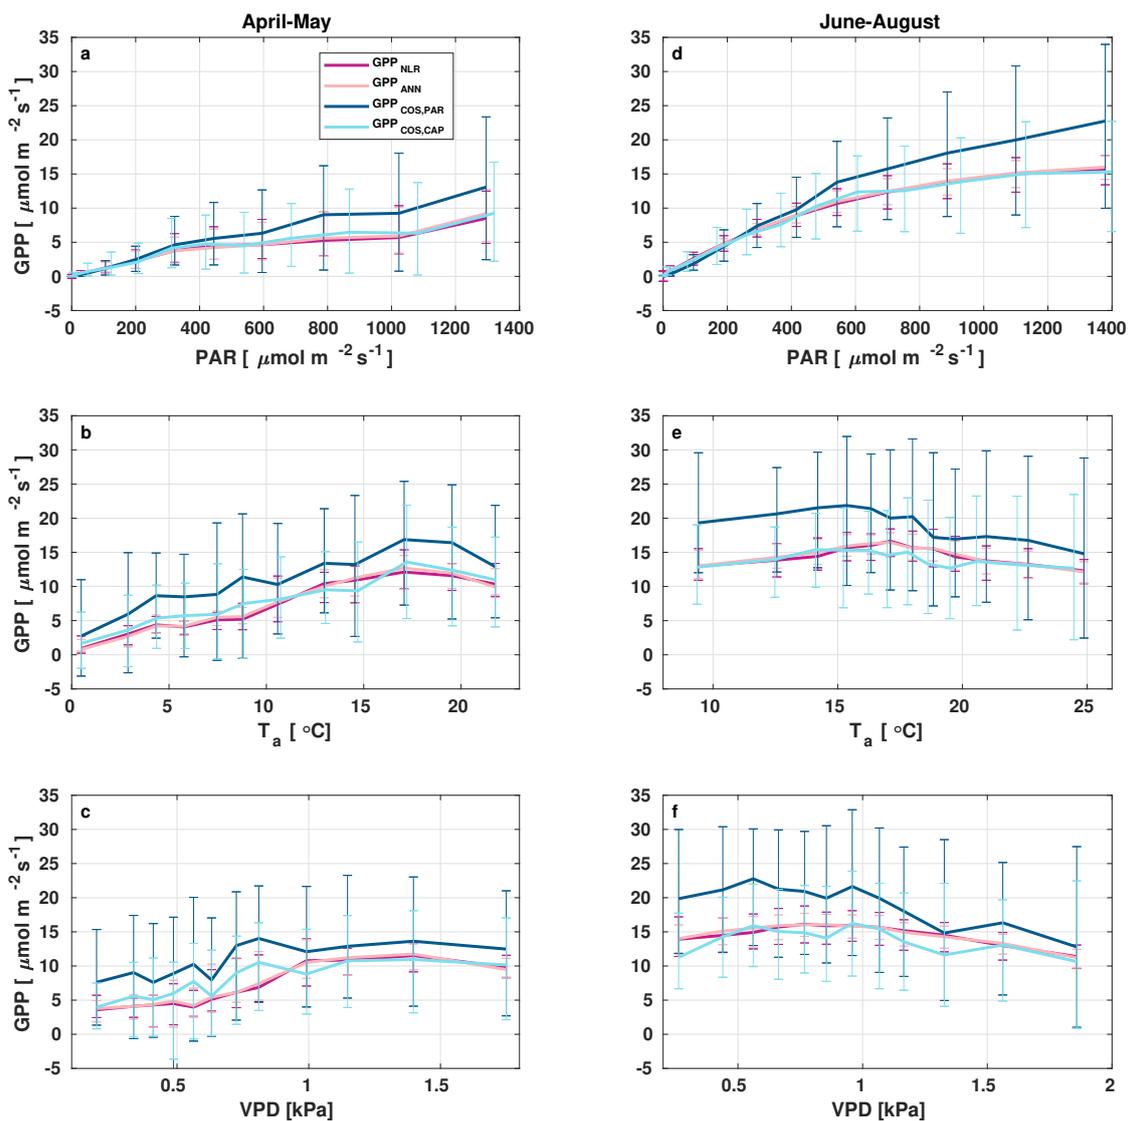

Figure 7. Responses of the different GPP estimates (GPP_{NLR} (purple), GPP_{ANN} (pink), $\text{GPP}_{\text{COS,PAR}}$ (dark blue) and $\text{GPP}_{\text{COS,CAP}}$, light blue) to environmental parameters – photosynthetically active radiation (a,d), air temperature (b,e) and vapor pressure deficit (c,f) – in spring (a–c) and summer (d–f). Data are binned to 12 equal sized bins (same number of data points in each bin) and all GPPs have the same data coverage. Only measured (non-gap-filled) 30 min flux data was used and GPP was filtered to include only $\text{PAR} > 700 \mu\text{mol m}^{-2} \text{s}^{-1}$ in responses to T_a and VPD to avoid simultaneous correlation with PAR.

was small (less than $1 \text{ pmol m}^{-2}\text{s}^{-1}$) throughout the season, so averaging did not make a large difference and thus soil does not explain the differences found here. However, as soil COS flux measurements are not necessarily available at all sites, this may be one source of uncertainty in wider application. Yang et al. (2018) studied COS flux components and GPP_{COS} in a Mediterranean citrus orchard and found GPP_{COS} to be on average 7 % lower than traditionally partitioned GPP. They also presented a light-dependent and seasonally varying LRU which, however, could not be applied to Hyttiälä COS fluxes due to the very different ecosystem types studied, indicating that the PAR responses may differ between ecosystems.

$\text{GPP}_{\text{COS,CAP}}$ could be more applicable at other sites than $\text{GPP}_{\text{COS,PAR}}$ due to the use of only literature values and simple meteorological variables in LRU_{CAP} without requiring fits to measured LRU. However, as LRU_{PAR} , LRU_{CAP} should also be tested at other sites as well against measured LRU to verify its applicability at other ecosystems. Moreover, this version of LRU_{CAP} assumes infinite mesophyll conductance, which may be a limiting factor of the method. We also provide a formulation of LRU_{CAP} with finite g_m , which was not comparable to measured LRU at Hyttiälä forest, but could be so at other measurement sites.

One source of uncertainty in both of the LRU approaches is that they are based on measurements on top of the canopy where there is no foliage blocking the incoming radiation. The branch chamber measurements (which the parameterized LRU_{PAR} function is based on) were done at the top of the canopy and the LRU_{CAP} model is also based on top of the canopy. The measured needles were thus well-adjusted to high radiation conditions and the radiation measurements used in both LRU calculations are also only from above the canopy. Therefore, we did not take into account the light penetration and scatter through canopy. However, the needles and leaves within the canopy are also well adjusted to low light conditions and may be more efficient with their stomatal control in varying light conditions than the needles on top of the canopy. Thus, we do not assume this to be a large source of uncertainty.

4 Conclusions

Daily GPP_{ANN} did not statistically differ from daily GPP_{NLR} and differences were very small also in the sub-daily and seasonal scales. We found that $\text{GPP}_{\text{COS,PAR}}$ was in general higher than GPP_{NLR} at all time scales studied, including a cumulative GPP estimate over a three-month period during the peak growing season. Instead, a better agreement was found between the newly introduced $\text{GPP}_{\text{COS,CAP}}$ and GPP_{NLR} at all time scales. $\text{GPP}_{\text{COS,CAP}}$ was also less scattered at 30 min time scale than $\text{GPP}_{\text{COS,PAR}}$. Moreover, the new LRU_{CAP} function provides a new, theoretical formulation for COS-based GPP estimates that can be used at other measurement locations as well, ideally without additional branch chamber measurements. This is vast improvement from the previous LRU functions that are site-specific empirical fits. However, the LRU_{CAP} model still overestimates LRU at high radiation, when compared to LRU observations at the top of the canopy, leading to an underestimated $\text{GPP}_{\text{COS,CAP}}$ at midday, especially in summer. This may result from the assumption of infinite mesophyll conductance or the lack of dark respiration in the CAP stomatal optimization model, on which LRU_{CAP} is based. All GPP estimates were close to values reported earlier for Hyttiälä. Both COS-based GPP estimates suggest a higher GPP than the CO_2 -based methods at longer time scales. The new LRU_{CAP} model development would benefit from further testing at other measurement sites

with COS and CO₂ branch flux measurements, including measurements inside the canopy for better canopy-integrated LRU estimates. The COS-based GPP estimates provide an opportunity for better process-based understanding of photosynthesis, rather than a method applicable everywhere, since the COS flux measurements are noisier, expensive and more difficult than those of CO₂. In addition to COS, other proxies, such as solar induced fluorescence and isotopic flux measurements should
345 be tested simultaneously to properly investigate their deficiencies and advantages in estimating GPP and processes underlying photosynthesis.

Data availability. Environmental data used in the study are available in the AVAA – Open research data publishing platform (<https://smear.avaa.csc.fi/>). The metadata of the observations are available via the Etsin service. Flux data will be published in a public repository before publication.

350 Appendix A: LRU predicted by the CAP stomatal optimization model

A1 LRU_{CAP} assuming infinite mesophyll conductance

The general expression for the leaf relative uptake ratio (LRU) according to Wohlfahrt et al. (2012) is

$$\text{LRU} = \frac{1}{1 - \frac{c_i}{c_a}} \frac{\frac{1}{1.21} + \frac{1}{1.14} \frac{g_s^{COS}}{g_b^{COS}}}{1 + \frac{g_s^{COS}}{g_b^{COS}} + \frac{g_s^{COS}}{g_m^{COS}}}. \quad (\text{A1})$$

where g_x^{COS} ($x = b, s, m$) are the boundary layer, stomatal and mesophyll conductances for COS, respectively, c_a is the atmospheric, c_i the leaf intercellular CO₂ molar mixing ratio (mol mol⁻¹), and the numerical factors 1.21 and 1.14 are the ratios of the conductances of CO₂ to COS for stomata and the boundary layer (Wohlfahrt et al., 2012).

If it is assumed that boundary layer and mesophyll conductances are infinite, Eq. (A1) reduces to

$$\text{LRU} = \frac{1}{1.21} \left(1 - \frac{c_i}{c_a}\right)^{-1} \quad (\text{A2})$$

$$= \frac{1}{1.21} \frac{c_a}{\hat{c}_a} \left(1 - \frac{\hat{c}_i}{\hat{c}_a}\right)^{-1} \quad (\text{A3})$$

360 where $\hat{c}_i \equiv c_i - \Gamma^*$, $\hat{c}_a \equiv c_a - \Gamma^*$ and Γ^* is the photorespiratory compensation point of CO₂ (mol mol⁻¹). c_i was found from a stomatal optimization model in which the CAP optimization hypothesis is applied to the bi-substrate photosynthesis model as in Dewar et al. (2018). The bi-substrate photosynthesis model is closely based on the one presented by Thornley and Johnson (1990) in their Eq. (9.12i). The CAP solution for stomatal conductance (Dewar et al., 2018) predicts

$$\frac{\hat{c}_i}{\hat{c}_a} = \frac{1}{1 + \beta}, \quad (\text{A4})$$

365 where

$$\beta = \sqrt{\frac{1.6D}{K_{sl}|\psi_c|} \left(\frac{1}{g_c} + \frac{2\Gamma^*}{\alpha Q}\right)^{-1}}, \quad (\text{A5})$$

where D is vapor pressure deficit (VPD; mol mol⁻¹), K_{sl} is the leaf-specific soil-to-leaf hydraulic conductance (mol m⁻²s⁻¹MPa⁻¹), ψ_c is the assumed critical leaf water potential (MPa) at which non-stomatal limitations (NSLs) reduce photosynthesis to zero, g_c is the carboxylation conductance in the absence of NSLs (mol m⁻² s⁻¹), α is the photosynthetic quantum yield (mol mol⁻¹) in the absence of NSLs and Q is the photosynthetically active radiation (PAR; mol m⁻²s⁻¹). Substituting Eqs. (A4) and (A5) and the definition of \hat{c}_a into Eq. (A3) gives

$$\text{LRU}_{\text{CAP}} = \frac{1}{1.21} \frac{c_a}{\hat{c}_a} \left(1 + \frac{1}{\beta}\right) \quad (\text{A6})$$

$$= \frac{1}{1.21} \frac{c_a}{c_a - \Gamma^*} \left(1 + \sqrt{\frac{K_{sl}|\psi_c|}{1.6Dg_c}} \sqrt{1 + \frac{2\Gamma^*g_c}{\alpha Q}}\right). \quad (\text{A7})$$

In addition to purely using literature values in LRU_{CAP} , some of the parameters were also fitted in order to analyze the
 375 deficiencies of the model. In particular, two fitting parameters $X = \frac{|\psi_c|}{1.6g_c}$ and $Y = \frac{2\Gamma^*g_c}{\alpha}$ were assigned so that Eq. (A7)
 became

$$LRU_{CAP} = \frac{1}{1.21} \frac{c_a}{c_a - \Gamma^*} \left(1 + \sqrt{\frac{K_{sl}X}{D}} \sqrt{1 + \frac{Y}{Q}} \right). \quad (A8)$$

Parameters X and Y were then optimized to minimize the RMSE of $\log(LRU_{CAP})$ to measured $\log(LRU)$, due to the logarithmic nature of LRU, with Matlab's *fminsearch* function.

380 A2 LRU_{CAP} assuming finite mesophyll conductance

In the case that mesophyll conductance is not assumed infinite, but boundary layer conductance is, Eq. (A1) becomes

$$LRU = \frac{1}{1.21} \frac{1}{1 + \frac{g_s^{COS}}{g_m^{COS}}} \left(1 - \frac{c_i}{c_a} \right)^{-1}. \quad (A9)$$

Further assuming the ratios of stomatal to mesophyll conductance same for CO_2 and COS and knowing that $g_s^{CO_2}(c_a - c_i) = g_m^{CO_2}(c_i - c_c)$, where c_c is the chloroplast CO_2 molar mixing ratio ($mol\ mol^{-1}$), we get

$$385 \frac{g_s^{COS}}{g_m^{COS}} = \frac{g_s^{CO_2}}{g_m^{CO_2}} = \frac{c_i - c_c}{c_a - c_i}. \quad (A10)$$

Implementing Eq. (A10) into Eq. (A9) gives

$$LRU = \frac{1}{1.21} \left(1 - \frac{c_c}{c_a} \right)^{-1} \quad (A11)$$

$$= \frac{1}{1.21} \frac{c_a}{c_a - \Gamma^*} \left(1 - \frac{\hat{c}_c}{\hat{c}_a} \right)^{-1}. \quad (A12)$$

The CAP model predicts the optimal stomatal conductance by maximizing the rate of leaf photosynthesis A (Dewar et al.,
 390 2018). In the case that mesophyll conductance is finite and non-stomatal limitations act entirely on g_m with no effect on the
 biochemical efficiencies, A is given by

$$A = \frac{\alpha Q g_c (c_c - \Gamma^*)}{\alpha Q + g_c (c_c + \Gamma^*)}. \quad (A13)$$

This equation can be used to calculate the value of c_c :

$$\hat{c}_c \equiv c_c - \Gamma^* = \frac{\left(\frac{\alpha Q}{g_c} + 2\Gamma^* \right) A}{\alpha Q - A} \quad (A14)$$

395 into which we can then substitute the CAP solution for A . The CAP solution for stomatal conductance is given by Dewar et al. (2018) as

$$g_s = \frac{\alpha Q}{\frac{\alpha Q}{g_c} + 2\Gamma^*} \frac{x\theta}{x\beta^2 + (1-x)(xw+1)} \quad (\text{A15})$$

where

$$\theta = 1 - \frac{\psi_{soil}}{\psi_c} \quad (\text{A16})$$

$$400 \quad w = \frac{c_a - \Gamma^*}{\frac{\alpha Q}{g_c} + 2\Gamma^*} \quad (\text{A17})$$

$$x = \frac{c_i - \Gamma^*}{c_a - \Gamma^*} = \frac{1}{1 + \beta} \quad (\text{A18})$$

where ψ_{soil} is the saturated soil water potential (MPa). Substituting x as a function of β and simplifying gives

$$g_s = \frac{\alpha Q}{\frac{\alpha Q}{g_c} + 2\Gamma^*} \frac{\theta}{\beta(1 + \beta + \frac{w}{1 + \beta})}. \quad (\text{A19})$$

We then find the CAP solution for A as follows

$$405 \quad A = g_s(c_a - c_i) = g_s(\hat{c}_a - \hat{c}_i) \quad (\text{A20})$$

$$= g_s \hat{c}_a (1 - x) \quad (\text{A21})$$

$$= g_s \hat{c}_a \frac{\beta}{1 + \beta} \quad (\text{A22})$$

$$= \frac{\alpha Q \hat{c}_a}{\frac{\alpha Q}{g_c} + 2\Gamma^*} \frac{\theta}{(1 + \beta)^2 + w}. \quad (\text{A23})$$

Substituting this into Eq. (A14) and simplifying then gives

$$410 \quad \frac{\hat{c}_c}{\hat{c}_a} = \frac{\theta}{(1 + \beta)^2 + (1 - \theta)w} \quad (\text{A24})$$

$$= \frac{\theta}{(1 + \beta)^2 + (1 - \theta) \frac{g_c(c_a - \Gamma^*)}{\alpha Q + 2\Gamma^* g_c}} \quad (\text{A25})$$

that can finally be substituted into Eq. (A12) for the solution of LRU_{CAP} with finite mesophyll conductance.

Similar to LRU_{CAP} with infinite mesophyll conductance, this formulation was also fitted in terms of X and Y . In the parameterization, β and w were expressed in terms of X and Y so that

$$415 \quad \beta = \frac{1}{\sqrt{\frac{K_{sl}X}{D} \left(1 + \frac{Y}{Q}\right)}} \quad (\text{A26})$$

and

$$w = \frac{c_a - \Gamma^*}{2\Gamma^*} \frac{1}{\frac{Q}{Y} + 1} \quad (\text{A27})$$

and implemented into Eq. (A24).

Appendix B: Additional figures

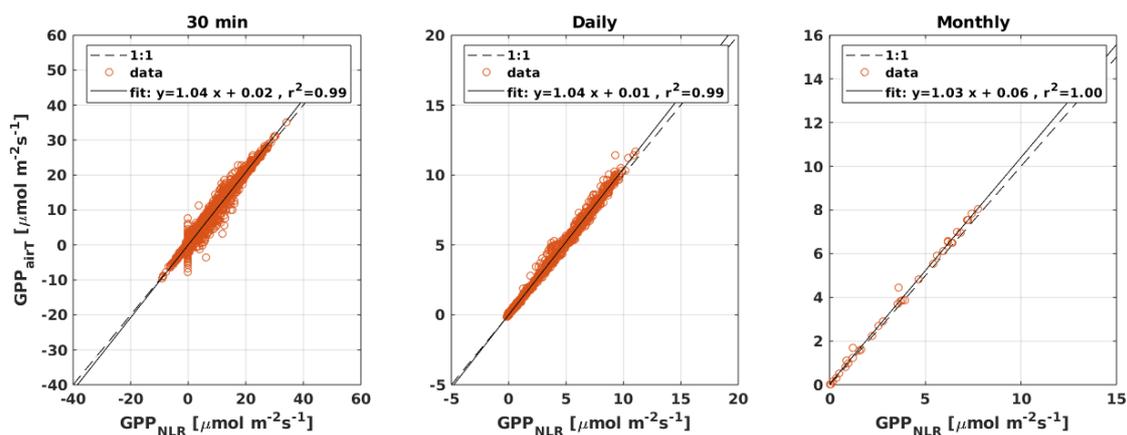

Figure B1. Scatter plots of GPP_{airT} that uses only air temperature as the driver for respiration against GPP_{NLR} that uses an average of air and soil temperatures as the respiration driver in 30 min, daily and monthly time scales. Black line is the least-squares linear fit to the data.

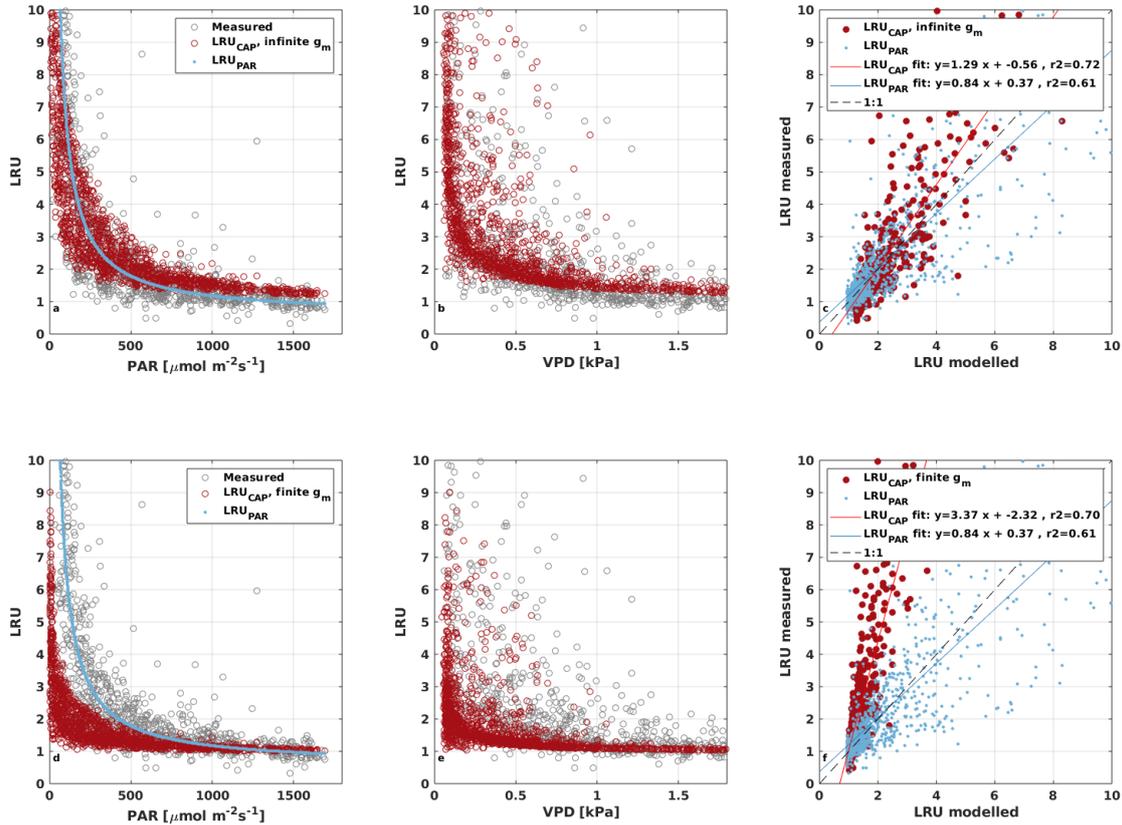

Figure B2. Measured LRU (gray) and modelled LRU_{PAR} (blue) and LRU_{CAP} (red) assuming infinite (a-c) or finite (d-f) mesophyll conductance (g_m) in LRU_{CAP} against PAR and VPD. Subplots c and d compare the measured LRU against modelled LRU_{PAR} and LRU_{CAP} .

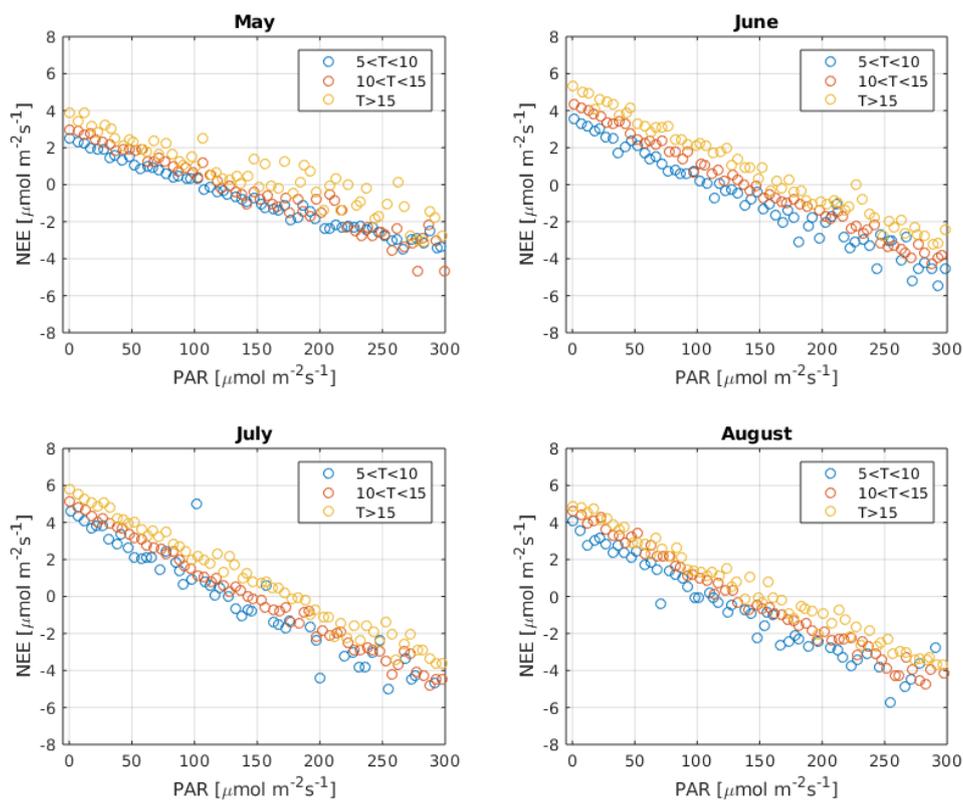

Figure B3. Net ecosystem exchange (NEE) against photosynthetically active radiation (PAR) close to the compensation point during May, June, July and August. Data are binned to different air temperature classes: $5^{\circ}\text{C} < T_a < 10^{\circ}\text{C}$ (blue), $10^{\circ}\text{C} < T_a < 15^{\circ}\text{C}$ (orange) and $T_a > 15^{\circ}\text{C}$ (yellow).

420 *Author contributions.* KMK, IM and TV designed the study. KMK, PK and LMJK performed the measurements and flux processing. RD, AM and KMK developed the new LRU formulation. GT provided the GPP estimate by artificial neural networks. All authors contributed by commenting the study design, results and the manuscript. KMK wrote the manuscript with contributions from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Special thanks to Helmi Keskinen, Sirpa Rantanen, Janne Levula, and other Hyytiälä technical staff for all their support
425 with the measurements.
