## **Abstract**

Pools are common features of peatlands and can represent from 5 to 50% of the ~~peatland's~~ peatland ecosystem's surface area. ~~They~~ Pools play an important role in the peatland carbon cycle by ~~emitting~~ releasing carbon ~~from their surfaces~~ dioxide and methane to the atmosphere. However, the origin of this carbon is not well ~~known~~ constrained. A hypothesis is that ~~the majority of the~~ carbon emitted from pools ~~is the product of~~ predominantly originates from mineralised ~~peat~~ allochthonous (i.e., plant-derived) dissolved organic matter (DOM) ~~from peat, rather than in situ primary production~~. To test this hypothesis, this study examined the ~~origins, compositions~~ origin, composition, and degradability of DOM in peat ~~porewaters~~ sporewater and ~~peat~~ pools ~~within of~~ an ombrotrophic boreal peatland in northeastern ~~Quebec~~ Quebec (Canada) for two years ~~during over~~ the growing season. The temporal ~~evolution~~ evolution of dissolved organic carbon (DOC) ~~concentrations~~ concentration, the optical properties, molecular ~~compositions~~ composition (TMH ~~composition~~ (THM-GC-MS), stable isotopic ~~signature~~ signature ( $\delta^{13}\text{C}$ -DOC), and degradability of DOM were determined. This study demonstrates that DOM ~~is a complex and, in both peat porewater and pools, presents a diverse composition, and constitutes~~ highly dynamic ~~component~~ components of peatland ecosystems. ~~If~~ The molecular ~~and isotopic~~ analyses ~~revealed~~ showed that DOM in ~~porewaters and pools share a common vegetation origin, the compositions of the pools was derived from plants. However,~~ DOM compositions in the two environments ~~are~~ were markedly different. Peat porewater DOM ~~is~~ was more aromatic, with a higher molecular weight ~~and~~ DOC:DON ratio ~~compared to pools~~. The temporal dynamics of DOC ~~concentrations~~ concentration and DOM ~~compositions~~ composition also ~~differed~~ differed. In peat ~~porewaters~~ sporewater, the DOC ~~concentrations~~ concentration followed a strong seasonal increase, starting from 9 mg L<sup>-1</sup>, ~~and~~ reaching a plateau above 20 mg L<sup>-1</sup> in summer and autumn. This ~~is best~~ was explained by seasonal peatland vegetation

productivity, which is greater than microbial DOM degradation ~~through microbial activity~~. In pools, DOC ~~concentrations~~concentration also increased but remained two times lower than in the peat porewaters at the end of the growing season ~~with an average concentration of (~10 mg L<sup>-1</sup>)~~. Those differences might be explained by a combination of physical, chemical, and biological factors. The limited hydraulic conductivity in deeper peat ~~increased the~~horizons and associated DOM residence time ~~in peat. This and~~ might ~~favour~~have favoured both DOM microbial transformation within the peat and the interaction of DOM aromatic compounds with the peat matrix, explaining part of the shift of DOM compositions between peat ~~porewaters~~porewater and pools. ~~The DOM might be even further transformed at the interface between peat and pools with the production of low molecular weight compounds.~~ This study ~~could~~did not ~~highlight~~report any photolability of DOM and only limited microbial degradability. ~~We estimate~~Thus, it is likely that the ~~carbon emissions related to DOM transformation~~DOM might have been microbially transformed at the interface between peat and pools. The combination of DOM quantitative and qualitative analysis presented in ~~peatland pools could~~this study demonstrate that most of the carbon present within and released from the pools originates from peat vegetation. These results demonstrate that pools represent from 4.2 to 8.7% of the long term apparent rate a key component of carbon accumulation. ~~the peatland ecosystem ecological and biogeochemical functioning.~~

## 1. Introduction

Northern peatlands constitute one of the most important terrestrial reservoirs of organic carbon (C) containing about  $530 \pm 160$  Pg C while only covering ~~less than~~~ 3% of the global terrestrial land surface (Yu, 2012). The ~~net~~ ecosystem carbon accumulation rates of peatlands are typically greater than the losses to the atmosphere through peat degradation and lateral transfer (Billett et al., 2006, 2012; Blodau et al., 2007; Tunaley et al., 2017). Peatlands are characterised by a mosaic of surface microforms, such as hummocks, ~~lows~~lawns, hollows, and pools (Charman, 2002). Considering peatlands as a patchwork of microforms rather than a homogeneous ecosystem is critical to accurately quantify their carbon balance and the role they play in the modern global carbon cycle. Carbon dynamics between microforms are closely related to the vegetation type and water table depth which influence the carbon dioxide (CO<sub>2</sub>) and methane (CH<sub>4</sub>) exchange with the atmosphere (Nungesser, 2003; Chaudhary et al., 2018). Among the different microforms, pools can constitute an important proportion of peatland ecosystem surface areas, ranging from 5 to 50% (White, 2011; Pelletier et al., 2014, 2015) and represent a net carbon source to the atmosphere (Pelletier et al., 2014). While most studies of peatland carbon dynamics have ~~focussed~~focused on terrestrial microforms (Nungesser, 2003; Pelletier et al., 2011; Shi et al., 2015; Chaudhary et al., 2018; Graham et al., 2020), the composition and processes of production and degradation of organic carbon in pools remain poorly documented.

The composition of dissolved organic matter (DOM) has previously been documented in peatland ~~porewaters~~porewater. A complex mixture of compounds with a diversity of ~~compositions~~composition, functional groups, and ages seem to co-exist (Tipping et al., 2010; Kaplan and Cory, 2016; Raymond and Spencer, 2015; Tiwari et al., 2018; Dean et al., 2019; Tfaily et al., 2018). The production of DOM in peat

~~porewaters~~porewater is controlled by vegetation productivity, peat temperature (Rydin et al., 2013; Kane et al., 2014), and microbial activity (Worrall et al., 2008).

75 It has also been shown that pools can represent active compartments of peatland ecosystems for DOM (Laurion and Mladenov, 2013; Deshpande et al., 2016; Payandi-Rolland et al., 2020; Folhas et al., 2020; Laurion et al., 2021) – a topic that has been less ~~well~~studied. The DOM of pools may derive from surrounding terrestrial peat (i.e., allochthonous) or be the result of their internal primary production through phytoplankton and microbial production (i.e., autochthonous). In both peat ~~porewaters~~porewater and pools, DOM is affected  
80 by biodegradation processes and by photodegradation in pools (Lapierre and del Giorgio, 2014; Vonk et al., 2015). Changes in DOC concentrations and DOM composition are commonly observed and associated with a wide range of degradation rates (Frey et al., 2016; Payandi-Rolland et al., 2020; Moody and Worrall, 2021). The composition and reactivity of DOM transferred from the terrestrial to aquatic compartments of peatlands highly depend on the hydrology and hydroclimatic context, and the biological and chemical processes  
85 occurring during their transfer (Jaffé et al., 2012; Kaplan and Cory, 2016). The DOM transfers between peatlands and aquatic ecosystems are well documented for streams (Elder et al., 2000; Billett et al., 2006, 2012; Austnes et al., 2010; Knorr, 2013; Frey et al., 2016; Buzek et al., 2019; Dean et al., 2019; Rosset et al., 2019) but more rarely for pools (Banaś, 2013; Arsenault et al., 2019; Payandi-Rolland et al., 2020).

Differences in DOM composition and ~~concentrations~~concentration between peat ~~porewaters~~porewater and  
90 pools have been observed, but the processes involved remain unclear (Schindler et al., 1997; Payandi-Rolland et al., 2020). Studies conducted in temperate peatlands have highlighted that the morphology (e.g., size, shape, depth, slope of banks) and surrounding vegetation influence the carbon ~~contents~~content and hydrochemistry in the pools (Banaś, 2013; Arsenault et al., 2018, 2019). Others have explained the changes in DOM composition in pools as the result of photodegradation and biodegradation~~in pools~~ (Laurion and  
95 Mladenov, 2013; Arsenault et al., 2019; Laurion et al., 2021). Studies investigating the changes in DOM composition in peatland ~~porewaters~~porewater and pools have mostly been focused on temperate (Banaś, 2013; Arsenault et al., 2019), subarctic, and Arctic regions (Laurion and Mladenov, 2013; Deshpande et al., 2016; Burd et al., 2020; Payandi-Rolland et al., 2020; Laurion et al., 2021; Moody and Worrall, 2021), but there is no insight about changes in DOM compositions in boreal peatlands non affected by permafrost.

100 Because DOM may derive from~~many~~ different sources and be subjected to various processes of transformation and degradation, apprehending the complexity of the ~~origins, compositions~~origin, composition, and properties of the molecules that ~~emprise~~compose the DOM is challenging. The use of complementary analytical methods is a good approach to characterise DOM and attempt to understand its ~~origins~~origin and composition (Folhas et al., 2020; Tfaily et al., 2013). The DOC:DON elementary ratio is  
105 used to estimate the extent of microbial processing of DOM (McKnight et al., 1994; Autio et al., 2016). The absorbance and fluorescence are recognised tools to estimate the average DOM molecular weight and aromaticity (Haan and Boer, 1987; Weishaar et al., 2003; Helms et al., 2008), discriminate the ~~origins~~origin of DOM between microbial and plant sources (McKnight et al., 2001; Cory et al., 2010), and highlight microbial degradation (Parlanti, 2000; Wilson and Xenopoulos, 2009). The stable carbon isotopic signature

of ~~DOM-DOC~~ ( $\delta^{13}\text{C-DOC}$ ) can be used to discriminate between terrestrial and aquatic plant-derived ~~and processed~~ DOM and also the extend of microbial processing of DOM (Elder et al., 2000; Billett et al., 2012; Buzek et al., 2019). Finally, the analysis of target molecules using TMH-GC-MS allows the definition of indicators of DOM sources and processing degradation stage (Jeanneau et al., 2014, 2015; Kaal et al., 2017, 2020).

The aim of this study is to ~~investigate~~clarify the role that pools play in the production, transfer, and transformation of organic carbon within peatland ecosystems. We identified three possible scenarios. First, pools are mineralisation hotspots that can decompose the laterally exported fresh organic matter from adjacent peat ~~porewaters~~porewater. Second, pools represent passive pipes that only collect the remaining refractory DOM laterally exported from peat ~~porewaters~~porewater. Third, pools represent a sub-ecosystem within the peatland where both primary productivity and heterotrophic respiration exist. To ~~clarify~~determine which scenario is the most accurate, we studied the spatiotemporal variability of DOM over two growing seasons- in a boreal ombrotrophic peatland. The objectives of this study were to: i) identify the differences in the origin, quantity, composition, and degradability of DOM between peat ~~porewaters~~porewater and pools; ii) understand which factors induce those differences; and iii) ~~discuss~~clarify the contribution of DOM in pools to the peatland carbon ~~budget~~cycle.

## 2. Study site

The study site is located in northeastern Quebec, Canada, within the Romaine River watershed (14,500 km<sup>2</sup>), adjacent to the Labrador border. It is located in the eastern spruce-moss bioclimatic domain of the closed boreal forest (Payette, 2001) at the limit of the coastal plain and the Highlands of the Laurentian Plateau of the Precambrian Shield (Dubois, 1980). The Bouleau peatland (unofficial name; 50°31'N, 63°12'W; alt: 108 ± 5 m) is an ombrotrophic, slightly dome-shaped bog with a total surface area of 1.518 km<sup>2</sup> (Taillardat et al., 2022). Peat accumulation was initiated at ca. 9260 cal BP and the maximum peat depth reaches 440 cm (Primeau and Garneau, 2021). The mean annual temperature is 1.5°C and the mean annual precipitation is 1011 mm, of which 590 mm falls as snow. The average monthly positive temperatures occur from May to October with 1915 growing degree days above 0°C (Havre-Saint-Pierre Meteorological Station, mean 1990-2019; Environment of Canada, 2019).

The surface microforms of the Bouleau peatland show a clear patterned surface of alternating dry hummocks, lawns, hollows, and pools. The surface vegetation varies according to the microtopography with *Sphagnum fuscum*, *S. capillifolium*, and *Cladonia rangiferina* on hummocks, *S. magellanicum*, *S. rubellum*, *S. cuspidatum*, and *Trichophorum cespitosum* on lawns, and *S. majus* and *S. pulchrum* on hollows (Primeau and Garneau, 2021). Pools cover 9% of the peatland surface area and are characterised by their elliptical morphology, steep banks, and slightly concave bottoms. Because of the steep banks, no aquatic vegetation is observed along the edges of the pools.

**Figure 1.** Aerial view of the Bouleau peatland with the location of the sampling sites (green dots = wells for peat porewater; yellow triangles = pools; blue diamond = stream outlet). The aerial photo was provided by Hydro-Québec.

### 3. Material and methods

#### 3.1. Water sampling

Sampling was performed five times during the 2018 growing season (June, July, August, September, and October) and four times in 2019 (June, August, September, and October). ~~In 2018, six pools were sampled (M1 to M6, Fig. 1) and in 2019, five additional pools were included (M11 to M15, Fig. 1). The pool sizes vary from 30 to 2065 m<sup>2</sup> with a mean depth varying between 70 and 120 cm. The pool water was sampled from the banks at the surface of the water column.~~

The peat porewater was sampled from six wells (P1 to P6, Fig. 1) located along a topographic transect from the dome to the southern edge of the peatland. Two ~~metre-~~ meters long PVC wells were perforated and covered with a nylon sock to avoid infilling by peat. They were inserted in peat to collect water in the first two meters of the peat column. This method allows collecting the fluctuating water table which moves through the peat. In 2018, six pools were chosen along a north-south axe giving a distance gradient to the stream outlet (M01 to M06, Fig. 1). ~~metres of the peat column.~~ In 2019, the pools were divided into five class sizes, and one pool was chosen into each class (M11 to M15, Fig. 1). The pool sizes varied from 30 to 2065 m<sup>2</sup> with a mean depth between 70 and 120 cm. Pools were sampled from their banks and from the surface of the water column.

The physicochemical parameters (temperature, pH, specific conductivity, and dissolved oxygen saturation) of peat porewater and pool water were measured using a multi-parameter portable meter (Multiline Multi 3620 IDS, WTW, Germany) at each sampling site and calibrated before each field visit. All water samples were collected in clean polypropylene (PP) bottles ~~(acid rinsed and pre-combusted for 4h at 450°C)~~ and filtered on pre-combusted (4h at 450°C) GF/F filters (Whatman). Samples collected during each field campaign and analyses performed are synthesized in Table SI.1.

#### 3.2. Water level and temperature monitoring

##### 3.2.1. ~~Field~~ Instrumentation

The six wells were equipped with a water-level data logger U20-001-04 in 2018 and replaced with a U201-04 in 2019 (HOBO, Onset, USA) for continuous measurements of the water table depth (WTD) and temperature from June 2018 to October 2020. Water temperature was recorded hourly in pools M11 to M15 using HOBO TMC50 probes coupled with a HOBO U12-008 data logger (Onset, USA) from June 2019 to August 2020. A water-level data logger was installed in pool M11 (Fig. 1) ~~),~~ and water-level variations were measured from May 20<sup>th</sup> to August 28<sup>th</sup> 2020. Height variations (in cm) between the peatland surface at wells P5 and P6 and adjacent pool M11 ~~werewas~~ measured using a Zip Level Pro-2000 (Technidea, USA). Those measurements allowed the water levels in the pool to be compared with those in the two wells (Fig. SI.2). An EXO2 multiparameter probe (YSI, USA) was installed at the outlet of the peatland stream to record ~~,among others,~~ water temperature hourly, from June 2018 to August 2020.

### **3.2.2. Definition of the seasons**

#### **3.2.2. Season definition**

Samples from the two studied years were pooled according to seasons. In this study, seasons were defined based on air and water temperatures measured at the site (Fig. SI.3). Spring was defined ~~from~~<sup>by</sup> the end of the seasonal thaw that occurred in May to the end of June. ~~In spring, the mean air temperature was  $12.7 \pm 2.1^{\circ}\text{C}$  while the mean water temperatures from peat porewaters and pools were  $12.3 \pm 5.2^{\circ}\text{C}$  and  $14.8 \pm 1.7^{\circ}\text{C}$ , respectively. During spring, ice lenses were still observed within some peat layers and along the pool edges with less sun exposure.~~ Summer included the months of July and August when air and water temperatures were at their warmest ~~(respectively  $17.2 \pm 1.5^{\circ}\text{C}$  in July and  $16.4 \pm 1.4^{\circ}\text{C}$  in August for air temperatures;  $16.7 \pm 3.8^{\circ}\text{C}$  and  $16.30 \pm 1.6^{\circ}\text{C}$  in peat porewaters and  $21.1 \pm 1.8^{\circ}\text{C}$  and  $23.4 \pm 3.0^{\circ}\text{C}$  in pools).~~ Finally, the autumn season corresponded to the months of September and October when air and water temperature decreased to zero. ~~September was characterised by a moderate decrease of water temperatures to  $15.7 \pm 1.0^{\circ}\text{C}$  in peat porewaters and  $17.4 \pm 1.8^{\circ}\text{C}$  in pools, but a drastic decrease in mean air temperatures with an average of  $9.5 \pm 2.5^{\circ}\text{C}$ . October was the coldest sampling period for both air temperature ( $4.3 \pm 2.1^{\circ}\text{C}$  on average) and water temperatures in peat porewaters ( $8.25 \pm 2.5^{\circ}\text{C}$ ) and in pools ( $8.10 \pm 1.8^{\circ}\text{C}$ ).~~

### **3.3. Quantitative analyses**

The filtered water samples ~~(through GF/F filters)~~ were prepared for DOC and total nitrogen (TN) analyses by acidification to pH 2 with 1M HCl and stored in ~~40mL~~<sup>40 mL</sup> glass vials. The DOC and TN concentrations were analysed using the catalytic oxidation method followed by the non-dispersive infrared (NDIR) detection of the  $\text{CO}_2$  produced (TOC analyser TOC-L, Shimadzu, Japan) with limits of quantification of  $0.1 \text{ mg C L}^{-1}$  and  $0.2 \text{ mg N L}^{-1}$ .

The samples were prepared for cation and anion analyses and stored in high-density polyethylene (HDPE) vials without acidification. ~~These~~<sup>Those</sup> ions (chloride, ammonium, nitrites, and nitrates) were analysed by high-performance liquid chromatography (HPLC) coupled with a Dionex ICS-5000+ analyser for anions (Thermo Fisher Scientific) and a Dionex DX-120 analyser for cations (Thermo Fisher Scientific).

The reference materials included ION-915 and ION 96.4 (Environment and Climate Change Canada, Canada). The analyses were performed at EcoLab (UMR 5245 CNRS – UT3 – INPT, France).

Dissolved organic nitrogen (DON) corresponds to the difference between the concentration of TN and the sum of concentration of inorganic nitrogen (ammonium, nitrites, and nitrates).

### **3.4. Qualitative analyses**

#### **3.4.1. Stable isotopic analyses**

Analyses of  $\delta^{13}\text{C}$ -DOC were realised ~~on 41 samples selected from peat porewater ( $n = 20$ ) and pools ( $n = 21$ ;~~<sup>Table SI.1)</sup> at the Jan Veizer stable isotope laboratory (University of Ottawa, Canada) following the method developed by Lalonde et al. (2014). The samples were acidified to pH 2 with 1M HCl and stored in

~~40 mL~~ 40 mL quality certified ultra-clean borosilicate glass vials. The first step involved the catalytic oxidation of DOC followed by a solid-state non-dispersive infrared (SS-NDIR) detection of the CO<sub>2</sub> produced (OI Aurora 1030C, Xylem Analytics, USA). The produced CO<sub>2</sub> was passed through a chemical trap and a Nafion trap prior to <sup>13</sup>C isotopic analyses using isotope-ratio mass spectroscopy (IRMS, Thermo Finnigan DeltaPlus XP, Thermo Electron Corporation, USA). The results were standardised with organic standards (KHP and sucrose) and the <sup>13</sup>C/<sup>12</sup>C ratios were expressed as per mil deviations from the international standard VPDB.

#### 3.4.2. Optical ~~and fluorescence~~ analyses

The samples for UV-visible spectroscopy analyses were stored at 4°C in glass vials following filtration on GF/F filters. The absorbance was measured from 180 to 900 nm with a 5 nm resolution. ~~In 2018, The absorbance analyses were performed on Ultrospec 3100 (Biochrom, United Kingdom) for 2018 samples and on Duetta (Horiba, Japan) for 2019 samples,~~ over a wavelength range from 190 to 900 nm at 2 nm intervals ~~while in 2019 they were performed on Duetta (Horiba, Japan).~~ All analyses were ~~realised~~ performed at the ~~Groupe de recherche interuniversitaire en limnologie~~ GRIL laboratory (GRIL, UQAM, Canada). For comparison, ten samples from the 2019 campaign were randomly selected and analysed on both ~~equipments~~ equipment, Duetta and Ultrospec 3100. A pairwise t-test revealed slight but significant differences between absorbance at 254 nm from the two series ( $t = -3.9013$ ,  $df = 9$ ,  $p\text{-value} = 0.0036$ ). ~~As no significant effect was observed between years on absorbance indices, no correction was performed on absorbance spectra.~~

The absorbance indices were calculated to provide information about DOM composition. Those indices were SUVA<sub>254</sub> (L mg<sup>-1</sup> m<sup>-1</sup>) which is a proxy of the of DOM's aromatic content (Weishaar et al., 2003), E2:E3 ratio, and spectral slope ratio (S<sub>R</sub>) which are proxies of the average DOM molecular weight (Haan and Boer, 1987; Helms et al., 2008).

In 2019, spectrofluorometric analyses were also conducted on Duetta (Horiba, Japan) at the GRIL laboratory. Samples were excited at a range from 230 to 450 nm (at 2 nm resolution) and fluorescence ~~was~~ were measured at a range from 240 nm to 600 nm (at a 5 nm resolution). Prior to the analyses, the samples were diluted when necessary to maintain an absorbance intensity at 254 nm below 0.6. A blank sample with MilliQ water (Merck-Millipore, Germany) was measured prior to the sample analyses. The sample spectra were obtained by subtracting the blank spectra to eliminate the Raman scatter peak. The operation was conducted automatically by the analytical equipment.

Two indices were calculated to provide qualitative information on the fluorescent fraction of the DOM: ~~1)~~ The fluorescence index (FI), lower values (FI ≈ 1.4) of which indicate a plant origin while higher values (FI ≈ 1.9) indicate a microbial origin of DOM (Cory et al., 2010; McKnight et al., 2001); ~~2)~~ The β:α index, which is known as a proxy of biological activity, and an increase in the ratio of which corresponds to an increasing proportion of ~~the~~ recently produced DOM derived from microbial activity (Parlanti, 2000; Wilson and Xenopoulos, 2009).

### 3.4.3. ~~THM-GC-MS~~Molecular analyses

Thermally assisted hydrolysis methylation-gas chromatography-mass spectrometry (THM-GC-MS) was performed on 37 samples from peat ~~porewaters~~porewater (n = 18) and pools (n = 19; Table SI.1). Those samples were selected to include summer and autumn 2018 and spring, summer, and autumn 2019. The THM-GC-MS analyses were conducted on freeze-dried samples from ~~100mL~~100 mL of water previously filtered on GF/F filters (Whatman) and followed the procedure described by Jeanneau et al. (2015). One ~~mg~~milligram of ~~the~~ sample was introduced into an 80  $\mu$ L stainless steel reactor with an excess of tetramethylammonium hydroxide (6 mg). The THM reaction was performed at 400°C using a vertical microfurnace pyrolyser PZ-2020D (Frontier Laboratories, Japan). The reaction products were injected into a gas chromatograph GC-2010 (Shimadzu, Japan) equipped with a SLB 5MS capillary column in split mode (60 m  $\times$  0.25 mm ID, 0.25  $\mu$ m film thickness). The compounds were detected with a mass spectrometer QP2010+ (Shimadzu, Japan) operating in full scan mode. Analyses were realised at the Geosciences Rennes laboratory (UMR 6118 – Univ. Rennes – CNRS, France).

For each chromatogram, the compounds were identified based on known  $m/z$  ratios (Table SI.1) through comparison with the NIST library. The area of each compound was integrated for each  $m/z$  and corrected by a mass spectra factor (MSF). The MSF corresponds to the reciprocal of the integrated fragment proportion and the entire related fragmentogram in the NIST library. The relative proportion of each compound was calculated by dividing the compound area (for all cumulated peaks) ~~with~~by the sum of total integrated compound areas and expressed as a percentage.

All compounds were classified into five groups and their relative proportions were calculated: %CAR of carbohydrates compounds (derived from both plant and microbial metabolism), %LMW\_FA for low molecular weight fatty acids (derived from microbial metabolism), ~~%SOA for small organic acids,~~ %HMW\_FA for high molecular weight fatty ~~acids,~~ %SOA for small organic acids, and %PHENOLS for phenol markers (derived from plant metabolism). The indices were calculated for each sample, derived from molecular analyses, and presented as in Jeanneau et al. (2015). The C/V ratio corresponds to the sum of coumaric and ferulic acids divided by the sum of vanillic acid, vanillaldehyde, and acetovanillone. The deoxyC6:C5 ratio is a mixing model based on the proportion of deoxyC6 carbohydrates (derived mainly from microorganisms) and the proportion of C5 carbohydrates (derived mainly from plants). Values close to 0.5 suggested a dominant contribution of plant-derived DOM while values close to 2 corresponded to the contribution of microbial-derived DOM (Rumpel and Dignac, 2006). The last index corresponds to the proportion of plant-derived markers,  $f_{\text{VEG}}$ , which is the difference between the total markers and the microbial-derived markers,  $f_{\text{MIC}}$ . The  $f_{\text{MIC}}$  corresponds to the proportion of microbial carbohydrates multiplied by the total proportion of carbohydrates, summed ~~up~~by the proportion of microbial fatty acids, and multiplied by the total proportion of fatty acids. The MIC:VEG index corresponds to the ratio of microbial-derived markers divided by the proportion of plant-derived markers.

### 3.5. Incubation of dissolved organic matter

#### 3.5.1. Experimental design

~~Dissolved organic matter from peat porewaters~~The objective of DOM incubation experiments was to test the sensitivity of DOM to biodegradation and photodegradation and how it could affect its composition. The incubation experiments were designed to test the effects of temperature (in situ versus controlled) and total organic carbon versus dissolved organic carbon on DOM degradation rates.

~~DOM from peat porewater~~ and pools was incubated during three sampling periods in 2019, from June 7<sup>th</sup> to 13<sup>th</sup>, July 31<sup>st</sup> to August 7<sup>th</sup>, and September 4<sup>th</sup> to 10<sup>th</sup>. An incubation time of six days had to be adjusted to seven days during the last campaign due to logistical constraints. Pool M11 was used to monitor the water level using a barometric pressure sensor and was also sampled for incubations. The peat porewater samples consisted of a mix of equal water volumes between five different wells ~~to avoid variability in the well water composition. This strategy was used because the water quantity in piezometers was limited and not sufficient to perform all incubation conditions.~~

The incubation experiments were performed on 100 ml of water filtered on GF/F filters (F) and in unfiltered (UF) conditions. Amber ~~glasses~~borosilicate glass vials of 125 mL were used to test biodegradation (BIO) only and transparent borosilicate vials of 125 mL were used for bio and photodegradation (BIO+PHOTO). Each condition was incubated in triplicates ~~with a headspace of 25 mL and bottles were tightly closed.~~ Considering the absence of standardised incubation media between ~~porewaters~~porewater and pools (Vonk et al., 2015), measured biodegradation rates could be dependent on the abundance and the activity of microorganisms in the samples from each environment ~~and was expected to be greater in peat porewater samples.~~

For *in situ* incubations (IS), the peat porewater samples were placed 1-2 cm below the water surface at the outlet of the peatland (Fig. 1), where water temperature was recorded hourly with the EXO2 probe. The pool samples were placed 1-2 cm below the water surface of pool M11 (Fig. 1). For controlled conditions (CC), the vials were placed in a dark room in a laboratory space at Havre-Saint-Pierre where the temperature was maintained between 18 and 20°C and controlled twice each day. Both *in situ* and controlled conditions started the same day. ~~There is no value available for F conditions in pools in August due to variability between the incubated water volume suggesting that vial caps were loose.~~

#### 3.5.2. Post-incubation analysis

In the end, samples incubated under UF conditions (n = 18) were filtered on a GF/F filter to analyse only the dissolved fraction. All samples (n = 36) were prepared for DOC, ~~TN~~ and inorganic N quantification, and absorbance analyses, before and after the incubation experiments. The apparent removal rate of dissolved organic carbon (RDOC), expressed in mg day<sup>-1</sup>, corresponds to the amount of DOC removed during incubation, reported per day, and calculated following Equation (1).

$$\text{Eq. (1)} \quad RDOC \text{ (mg day}^{-1}\text{)} = ([DOC]_{\text{pre-incubation}} - [DOC]_{\text{post-incubation}}) / \text{incubation time}$$

[DOC]<sub>pre-incubation</sub> (mg L<sup>-1</sup>): DOC concentration at the beginning of incubation

[DOC]<sub>post-incubation</sub> (mg L<sup>-1</sup>): DOC concentration at the end of incubation

The degradation rates correspond to the proportion of DOC lost per day of incubation and are expressed in %C day<sup>-1</sup> according to Equation (2).

Eq. (2) *Degradation rate* (% C.day<sup>-1</sup>) =

$$\frac{([DOC]_{pre-incubation} - [DOC]_{post-incubation})}{[DOC]_{pre-incubation}} \times 100 / \text{incubation time}$$

~~[DOC]<sub>pre-incubation</sub> (mg L<sup>-1</sup>): DOC concentration at the beginning of incubation~~

~~[DOC]<sub>post-incubation</sub> (mg L<sup>-1</sup>): DOC concentration at the end of incubation~~

Changes in the DOC:DON ratio and absorbance indices were determined in proportion to the initial values per day for the variable *i* following Equation (3).

$$\text{Eq. (3) } \Delta i \text{ (day}^{-1}\text{)} = \frac{i_{post-incubation} - i_{pre-incubation}}{i_{pre-incubation}} / \text{incubation time}$$

$\Delta i$ : change of the variable *i* during the incubation

*i*<sub>pre-incubation</sub>: initial value of the variable *i* at the beginning of incubation

*i*<sub>post-incubation</sub>: value of the variable *i* at the end of incubation

### 3.6. Statistical analyses

All statistical tests were performed on R (CRAN-Project) through the RStudio interface (RStudio inc., USA) and all figures were realised with the package ggplot2 (Wickham, 2016).

Comparisons of variance tests were performed and in the next following sections, the mention of significant differences refers to statistical tests using the following method. First, normal distribution was tested using the Shapiro and Wilk test, and normal distribution was considered true when the p-value was >0.05. If the distribution was not normal, a Kruskal and Wallis test was performed to compare the averages and significant differences were considered true when the p-value was <0.05. Dunn tests were performed as *post-hoc* pairwise comparison tests to determine which group was significantly different (when the p-value <0.05). Second, the homogeneity of variance was tested using the Levene test and was considered true when the p-value was >0.05. If the homogeneity of variance was not true, Welch ANOVA was performed, and significant differences were admitted when the p-value was <0.05. Estimated marginal means tests were performed as *post-hoc* tests to determine significantly different groups (p-value <0.05). In cases where the normal distribution and homogeneity of variances were true, an ANOVA was performed, and significant differences were true when the p-value was <0.05. When there were significant differences, the Tukey tests were performed as *post-hoc* tests to determine which groups were significantly different (when the p-value <0.05). The results of the statistical tests are summarised in Table SI.2.

Principal component analyses (PCA) were used to explore relationships between DOM qualitative variables in peat porewater and pools. The selected variables were quantitative variables as DOC concentrations and qualitative variables as the DOC:DON ratio, optical indices (SUVA<sub>254</sub>, E2:E3 ratio, and S<sub>R</sub>), and molecular indices (deoxyC6:C5, *f*VEG, *f*MIC, MIC:VEG ratio, C/V ratio, and Ac:Al(V) ratio), as well as molecular

compound proportions (%SOA, %CAR, and %CAR\_MIC, %LMW\_FA, %HMW\_FA, and %PHENOLS). Environmental and seasonal variables were used as supplementary qualitative variables. Prior to PCA, a correlation matrix was performed to identify strong correlations between the variables (Fig. SI.1). One of the correlated variables was excluded from PCA when the correlation was >0.90 or <-0.90, with p-values <0.05. Therefore, the DOC:DON ratio (DOC:DON ~ DOC, cor = 0.90, p-value <0.0001), %CAR\_MIC (%CAR-MIC ~ deoxyC6:C5 ratio, cor = 0.99, p-value <0.0001), and fMIC (fMIC ~ MIC:VEG ratio, cor = 0.98, p-value <0.0001) were excluded from the PCA ~~dataset~~data set. The PCA was performed with the package FactoMineR (Lê et al., 2008). The ellipses in the representation of the first two axes of the PCA correspond to the function addEllipses from the R package FactoMineR used to add concentration ellipses to the plot.

## 4. Results

### 4.1. Hydrodynamics and physicochemical characteristics

Pool and peat water levels followed the same seasonal trend, although the water level in the pools was always lower than in peat. Thus, the preferential water flow goes from peat ~~porewaters~~porewater to pools. The response of the water level to precipitation was slower and buffered in pools compared to peat (Fig. SI.2) and an average time lag of 13 hours was measured between the WTD peak of peat and pools.

Peat porewater temperatures were constantly lower ~~than in~~compared to pools, with  $13.4 \pm 4.4^\circ\text{C}$  in peat ~~porewaters~~porewater against  $17.1 \pm 5.5^\circ\text{C}$  in pools when averaged over the two growing seasons. In both environments, the pH was acidic with an average of  $4.9 \pm 0.7$  in peat ~~porewaters~~porewater and  $4.4 \pm 0.3$  in pools. Specific conductivity was on average almost two times higher in peat ~~porewaters~~porewater than in pools, with  $33.0 \pm 19.3 \mu\text{S cm}^{-1}$  and  $14.0 \pm 6.1 \mu\text{S cm}^{-1}$  in peat porewaters and pools, respectively. Pool waters were characterised by their constant saturation in dissolved oxygen, with  $99.9 \pm 5.2\%$  sat on average, while dissolved oxygen saturation was  $50.04 \pm 17.1\%$  sat in peat ~~porewaters~~porewater (Table 1).

**Table 1.** Peat porewater and pool seasonal average ( $\pm$ SD) of physicochemical variables (water temperature, pH, specific conductivity, and dissolved oxygen saturation), dissolved organic carbon (DOC) concentrations, and DOC to dissolved organic nitrogen (DON) ratio (DOC:DON), isotopic signature of DOC ( $\delta^{13}\text{C}$ -DOC), optical indices (SUVA<sub>254</sub>, E2:E3 ratio, and spectral slope ratio), fluorescence indices (FI and  $\beta$ : $\alpha$  index), and molecular indices (fVEG, fMIC deoxyC6:C5, and C/V ratio, %Phenols, %Carbohydrates, %Microbial Carbohydrates, %SmallOrganicAcids, %LMWFattyAcids, and %HMWFattyAcids).

#### 4.2. Evolution of DOC concentrations and DOC:DON ratios

The DOC concentrations in peat porewatersporewater were significantly higher than in pools (Fig.2.a). In both environments, the DOC concentrations showed the same seasonal trends with a significant increase from spring to summer. The DOC concentrations increased significantly in peat porewatersporewater from 9.2  $\pm$  4.2 mg L<sup>-1</sup> in spring, reaching a plateau above 20 mg L<sup>-1</sup> during summer and autumn. In pools, the DOC concentrations also increased significantly from 7.5  $\pm$  3.2 mg L<sup>-1</sup> in spring to a plateau above 10 mg L<sup>-1</sup> in summer and autumn.

Peat porewatersporewater presented a significantly higher DOC:DON ratio than pools. In both environments, the DOC:DON ratio increased significantly from spring to a plateau in summer and autumn (Fig. 2.b). In peat porewatersporewater, the DOC:DON ratio increased from 32.3  $\pm$  12.4 in spring to 52.8  $\pm$  22.5 and 56.6  $\pm$  8.2

in summer and autumn, respectively (Fig. 2.b). In pools, the DOC:DON ratio increased from  $26.2 \pm 7.7$  in spring to a plateau of  $32.0 \pm 7.5$  in summer and  $31.7 \pm 6.6$  in autumn.

**Figure 2.** Box plots (Figure 2.a to 2.b and 2.d to 2.f) and dot plot (figure 2.c and 2.g to 2.i): a) DOC concentrations, b) DOC:DON ratio, c)  $\delta^{13}\text{C}$ -DOC, d)  $\text{SUVA}_{254}$ , e) E2:E3 ratio, f) spectral slope ratio, g) fluorescence index, h)  $\beta:\alpha$  index, i)  $f\text{VEG}$ , j) deoxyC6:C5, k) C/V ratio, and l) MIC:VEG ratio. Each plot represents the evolution of variables during the growing season (SPR = spring, SUM = summer, AUT = autumn) in peat porewater and pools. Dot plots were used when  $n < 5$  for at least one season. Error bars represent standard deviations. Box plots were used when  $n > 5$  for each season. The dots represent each individual measurement, and boxes represent the lower (25<sup>th</sup> percentile) and the upper quartile (75<sup>th</sup> percentile); the median (50<sup>th</sup> percentile) is represented by the bold black horizontal bar in the boxes. Whiskers represent the interquartile range. Letters represent the significant differences between seasons. For each individual plot, conditions which share a letter does not present statistical differences.

#### 4.3. Evolution of the isotopic compositions of DOM

Different trends for  $\delta^{13}\text{C}$ -DOC were identified between peat ~~porewatersporewater~~ and pools (Fig. 2.c). In peat ~~porewatersporewater~~,  $\delta^{13}\text{C}$ -DOC decreased significantly from spring, when the ratio was  $-26.0 \pm 0.9\%$ , to autumn when the ratio dropped to  $-27.5 \pm 0.5\%$ . In pools,  $\delta^{13}\text{C}$ -DOC showed a nonsignificant increase from  $-27.5 \pm 0.3\%$  in spring to  $-26.8 \pm 0.8\%$  in autumn. In summer,  $\delta^{13}\text{C}$ -DOC was significantly different

between peat ~~porewaters and pools~~. When considering all samples, a significant negative correlation was observed between  $\delta^{13}\text{C}$ -DOC and the DOC:DON ratio, with the lower DOC stable isotopic signature corresponding to a higher DOC:DON ratio ( $\text{cor} = -0.53$ ,  $p\text{-value} = 0.0004$ , Fig. 3). ~~porewater and pools~~.

#### 4.4. Evolution of the optical and fluorescent properties of DOM

The DOM presented different optical properties between peat ~~porewatersporewater~~ and pools. Among ~~thesethose~~,  $\text{SUVA}_{254}$  was significantly higher in ~~porewatersporewater~~ than in pools during the whole growing season, indicating a higher aromaticity of peat porewater DOM (Table 1). During the growing season, there were no major changes of  $\text{SUVA}_{254}$  in peat ~~porewatersporewater~~, but a slight increase was observed in pools during the autumn ~~season~~ (Fig. 2.d).

The E2:E3 ratio was significantly higher in pools than in peat ~~porewatersporewater~~, indicative of a lower average molecular weight ~~in pools~~. As for, Compared to  $\text{SUVA}_{254}$ , the E2:E3 ratio showed no significant trends in peat ~~porewatersporewater~~, but it slightly increased in pools from  $4.02 \pm 0.11$  in spring to  $4.41 \pm 0.18$  in autumn, suggesting a decrease ~~ofin~~ the average molecular weight during the growing season (Fig. 2.e).

The lower spectral slope ratio ( $S_R$ ) of peat porewater DOM also suggested a higher molecular weight than in pool DOM. During the growing season, the  $S_R$  was steady in peat ~~porewatersporewater~~ with no significant changes between seasons, suggesting a homogeneity of the molecular weight of DOM (Fig. 2.f). In pools,  $S_R$  values increased from spring to summer and decreased in autumn. Thus, according to the  $S_R$ , the lowest average molecular weight was reached during ~~the~~ summer in pools.

The fluorescence index (FI) was significantly higher in peat ~~porewatersporewater~~ than in pools but varied within a narrow range ~~(Fig. 2.g),~~ close to typical terrestrial-derived organic matter, (Fig. 2.g). During the growing season, the index remained steady in both environments with an average of  $1.36 \pm 0.10$  in peat ~~porewatersporewater~~ against  $1.27 \pm 0.04$  in pools.

The  $\beta:\alpha$  index did not differ significantly between peat ~~porewatersporewater~~ and pools, where it was on average  $0.62 \pm 0.07$  and  $0.64 \pm 0.07$ , respectively (Fig. 2.h). During the growing season, the index remained steady in peat ~~porewatersporewater~~. In pools, the  $\beta:\alpha$  index increased significantly from spring to summer: from  $0.62 \pm 0.03$  to ~~reachreaching~~ a peak at  $0.69 \pm 0.07$ . As ~~the changes observed~~ for the FI, variations of the  $\beta:\alpha$  index were limited to a small range.

#### 4.5. Evolution of the molecular composition of DOM

Phenol markers dominated (54%) the molecular markers of DOM for both peat porewater and ~~pool DOMpools~~ (Table 1). A similar proportion of small organic acids (22% on average) was measured in both environments. Carbohydrates represented 6% of the total markers in peat ~~porewatersporewater~~ and up to 8% in pools. The distribution of fatty acids differed between the two environments. While low molecular weight fatty acids showed similar proportions in peat ~~porewatersporewater~~ (5.8%) and ~~in~~ pools (6.7%), high molecular weight fatty acids, which are associated with plant inputs, were almost three times higher in peat

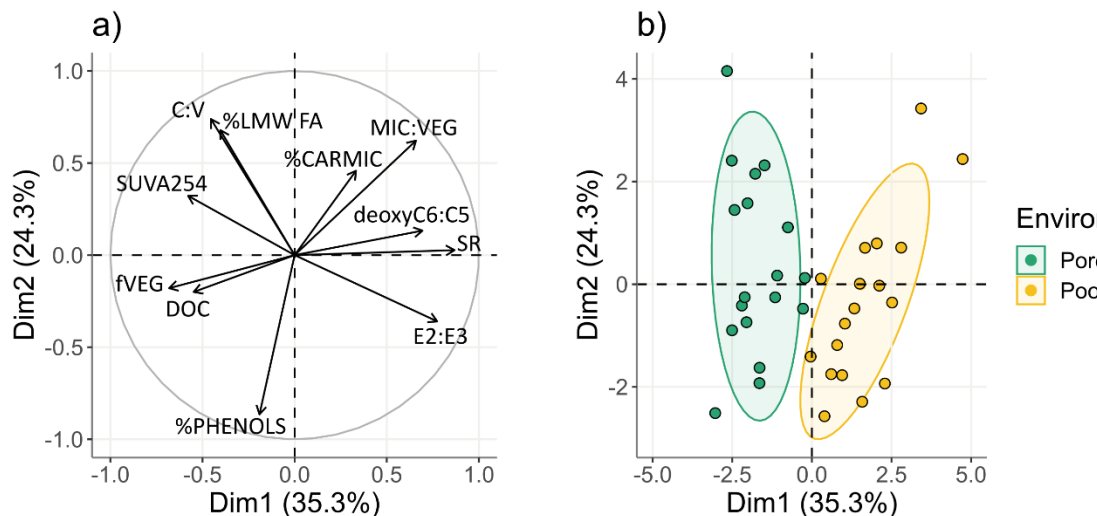

430 ~~porewatersporewater~~ (6.1%) than in pools (2.3%). ~~This represents the only significant difference in molecular class distribution between peat porewaters and pools (p-value = 0.02, Student test).~~

435 ~~Although the distribution of these five classes of compounds remained the same in peat and pools~~In addition, three modifications of the molecular composition of DOM between ~~thesethe~~ two environments must be highlighted. First, the C/V ratio (Fig. 2.i), a lignin compositional proxy, was significantly higher in peat ~~porewatersporewater~~ than in pools (p-value <0.01). While it remained almost stable in pools, it decreased in peat porewater ~~sfromfrom~~  $0.37 \pm 0.12$  during spring and summer to  $0.22 \pm 0.07$  during autumn. Secondly, the deoxyC6:C5 ratio (Fig. 2.j), a carbohydrate ratio, was significantly higher in pools ( $0.97 \pm 0.28$ ) than in peat ~~porewatersporewater~~ ( $0.57 \pm 0.20$ ) (p-value <0.0001). While it remained almost stable in peat ~~porewaters, in pools, porewater,~~ it was maximal in summer ( $1.10 \pm 0.19$ ) compared to spring ( $0.73 \pm 0.10$ ) and autumn ( $0.91 \pm 0.33$ ). ~~In pools,~~ this evolution emphasised an increase in the contribution of microbial exudates among the carbohydrate ~~poolcompounds~~ in pools. Finally, the fraction of plant-derived compounds among the identified markers, fVEG (Fig. 2.l), was always higher than 50% in both environments, highlighting the dominance of plant-derived DOM. However, fVEG was significantly higher in peat ~~porewatersporewater~~ than in pools (p-value = 0.02). ~~AsComparatively to the variations observed~~ for the C/V ratio, fVEG remained almost stable in pools, while it decreased in peat ~~porewatersporewater~~ in autumn.

#### 445 4.6. Global assessment of DOM quality in peat porewaters and pools

The PCA ~~analysesanalyse~~ of the peat porewater, and pool samples indicate that the ~~two~~-first ~~two~~ components, represented by the two axes of Figure 4.3 accounted for 56.3% of the total variance. Individuals, represented ~~onin~~ the ~~two~~-first ~~two~~ dimensions, showed a clear separation of both environments along the first dimension (Fig. 4.3). The major contributors of the first axis were S<sub>R</sub> (19.8%), E2:E3 ratio (14.4%), deoxyC6:C5 (12.8%), DOC concentration (12.7%), and finally MIC:VEG ratio (11.8%). For the second axis, the major contributors were the proportion of phenols (%PHENOLS; 20.8%), C/V ratio (18.5%), ~~and~~ high molecular weight fatty acids (%HMW FA; 17.3%), ~~and DOC:Cl ratio (10.4%).%).~~ Other variables contributed less than 10% to the ~~two~~-first ~~two~~ axes.

455 In pools, the DOM was characterised by a lower average molecular weight and aromaticity and a higher contribution of microbial-derived DOM compared to peat ~~porewatersporewater~~. Inversely, in peat ~~porewatersporewater~~, the DOC concentrations were higher, and DOM presented ~~a~~ higher aromaticity, and a higher contribution of plant-derived DOM, characterised by a higher fVEG. There was no effect of the sampling season on the variances.

**Figure 3.** Representation of the first two dimensions of principal component analysis (PCA) of a) physicochemical, quantitative, and qualitative parameters as variables and b) individuals.

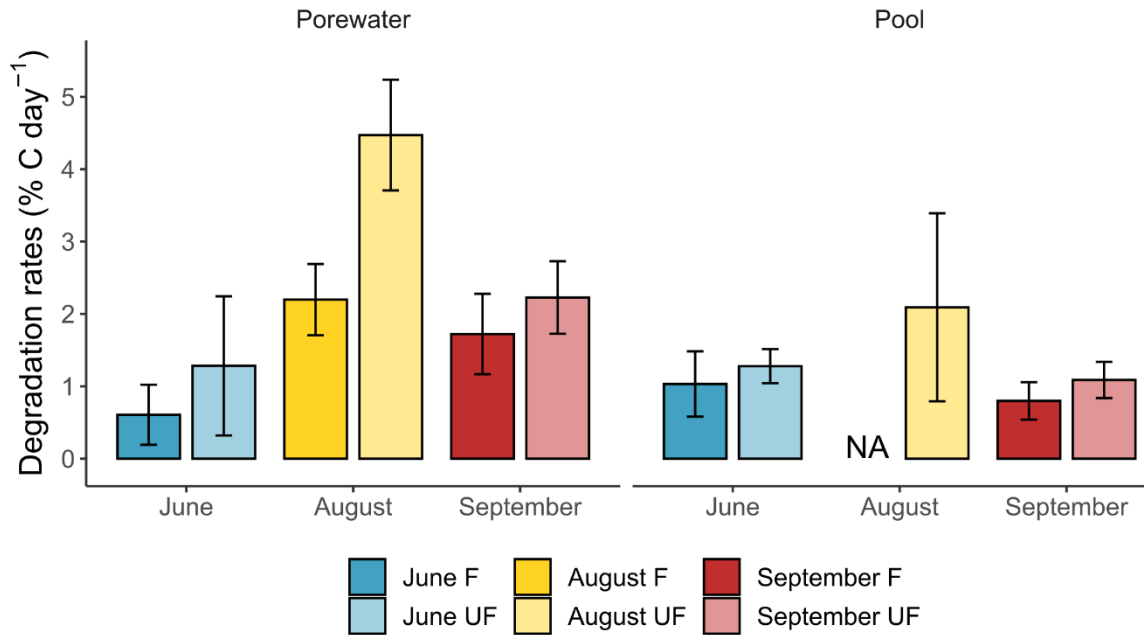

#### 4.7. Experimental degradability of peat ~~porewatersporewater~~ and pool DOM

Statistical tests revealed no significant differences in the average degradation ~~ratesrate~~ between *in situ* and controlled conditions of biodegradation (section 3.5.1). In addition, no significant differences appeared between the average degradation ~~ratesrate~~ where biodegradation only was tested and those where biodegradation and photodegradation were both tested. This suggests that temperature and sunlight had a limited effect on the DOM degradation. As a consequence, all experimental conditions (both *in situ* and controlled) ~~arewere~~ pooled in the following section. The DOM degradation rates were significantly higher for peat ~~porewatersporewater~~ than pools. ~~Statistical tests also revealed that~~The degradation rates were significantly higher for the incubation conditions of unfiltered samples (UF) compared to filtered sample (F) conditions (Fig. ~~5)-4~~).

On average, the DOC degradation rates were 1.6 times higher for incubation under unfiltered conditions ( $2.5 \pm 1.5\% \text{C day}^{-1}$ ) compared to filtered conditions ( $1.5 \pm 0.8\% \text{C day}^{-1}$ ) in peat ~~porewatersporewater~~. In pools, degradation rates were twice as high for UF ( $1.1 \pm 1.1\% \text{C day}^{-1}$ ) than for F conditions ( $0.5 \pm 0.6\% \text{C day}^{-1}$ ). In peat ~~porewatersporewater~~, the DOC degradation rates for F and UF conditions followed similar seasonal trends. The DOC degradation rates were low in June ( $0.6 \pm 0.4\% \text{C day}^{-1}$ ) and twice as high for UF conditions ( $1.3 \pm 1.0\% \text{C day}^{-1}$ ). The degradation rates reached a peak in August, with  $2.2 \pm 0.5\% \text{C day}^{-1}$  for F and  $4.5 \pm 0.8\% \text{C day}^{-1}$  for UF conditions. Then, the DOC degradation rates decreased in autumn to  $1.7 \pm 0.6\% \text{C day}^{-1}$  and  $2.2 \pm 0.5\% \text{C day}^{-1}$  for F and UF incubation conditions, respectively.

~~There is~~After excluding the UF condition of August, there was no ~~value available for~~persistent significant difference between F and UF conditions ~~in pools in August due to some technical problems~~. In June, the DOC degradation rates were similar between the F and UF conditions with rates of  $1.0 \pm 0.5\% \text{C day}^{-1}$  and  $1.3 \pm 0.2\% \text{C day}^{-1}$ , respectively. Then, an increase to  $2.1 \pm 1.3\% \text{C day}^{-1}$  was observed in August for UF

conditions which ~~was~~ were two times lower than the rate measured in peat ~~porewaters~~ porewater under the same conditions. Finally, the DOC degradation rates diminished in September, with  $0.8 \pm 0.3\% \text{C day}^{-1}$  for F and  $1.1 \pm 0.3\% \text{C day}^{-1}$  for UF incubation conditions. Those degradation rates were ~~two-timestwice~~ lower than those observed in peat ~~porewaters~~ porewater in autumn.

**Figure 4.** Seasonal degradation rates (in  $\% \text{C day}^{-1}$ ) for DOC and TOC incubation conditions in peat porewater and pools.

~~Changes in  $\text{SUVA}_{254}$  ( $\Delta \text{SUVA}_{254}$ ) during incubation experiments were linked with degradation rates. Under most of the incubation conditions,  $\text{SUVA}_{254}$  increased.~~ As observed in Figure 65,  $\Delta \text{SUVA}_{254}$  was strongly and positively correlated with degradation rates, with specific dependence in pools ( $n = 29$ ,  $\text{cor} = 0.82$ ;  $p$ -value  $< 0.0001$ ) and peat porewaters ( $n = 33$ ,  $\text{cor} = 0.65$ ;  $p$ -value  $< 0.0001$ ).

**Figure 5.** Relations between changes in  $SUVA_{254}$  ( $\Delta SUVA_{254}$ ) during incubation experiments and linear regression in peat porewater (dashed line) and pools (solid line).

## 5. Discussion

### 5.1. Differences in DOM concentrations and composition between peat porewaters and pools hidedespite a similar sourceessource

The DOM concentration and composition strongly differed between peat porewater and pools, despite a clear common plant origin. Peat porewater DOM was characterized by high DOC concentrations and a DOM composed by both recently produced and biodegraded DOM. In pools, DOC concentrations were twice lower compared to the peat porewater (Fig. 2.a). Pool DOM was characterized by a dominant contribution of allochthonous DOM (i.e., plant-derived) but also presented characteristics of microbial degraded DOM.

At our site located in the boreal ecozone, the average DOC concentration in peat porewater increased from 9.2 to 22.5 mg L<sup>-1</sup> from spring to autumn. During the growing season, DOC concentrations are in general below 20 mg L<sup>-1</sup> in boreal and subarctic regions which are lower than in temperate regions (Table SI.4). This latitudinal trend suggests that the balance between DOM production and processing in peat porewater is controlled by climate and most likely by temperature (Kane et al., 2014). At our site, both DOM production and consumption followed a strong seasonal trend in peat porewater, with DOM production being more intense, as DOC concentrations were multiplied by 2.5 during the growing season (Table 1).

DOM production by plants within peat porewater followed a strong seasonal trend. This is revealed by three observations. First, peat porewater showed a greater proportion of plant-derived DOM towards the end of the growing season as indicated by the lowest  $\delta^{13}C$ -DOC measured in the autumn. Second, the high DOC:DON

ratios measured in peat porewater at our study site - up to six times higher than those in Austnes et al. (2010), and its increase along the growing season (Fig. 2.b), - indicated a high contribution of recently produced DOM. Third, the slight decrease of  $\delta^{13}\text{C}$ -DOC (Fig. 2.c) as well as the contribution of high molecular weight fatty acids from spring to summer confirm the high contribution of plant-derived DOM. However, peat porewater DOM composition also suggested a contribution from microbial processing. First, the molecular analysis revealed the presence of microbial markers, as high as  $6.4 \pm 2.7\%$ , as expressed by  $f_{\text{MIC}}$  (Table 1). Second, the incubation experiments highlighted that the labile fraction of DOM, represented  $2.0 \pm 1.3\%$  of peat porewater DOC (Fig. 4). Third, the high  $\text{SUVA}_{254}$  values (Fig. 2d) we observed might reflect the importance of biodegradation processes of DOM in peat porewater as  $\text{SUVA}_{254}$  increase with biodegradation (Hulatt et al., 2014; Autio et al., 2016, Figure 5). The average  $\text{SUVA}_{254}$  of  $5.5 \text{ L mg}^{-1} \text{ m}^{-1}$  measured in the Bouleau peatland porewater was, in general, higher than those previously measured in peatlands from temperate regions i.e.  $<3.6 \text{ L mg}^{-1} \text{ m}^{-1}$  (Arsenault et al., 2019; Tfaily et al., 2015; Heinz and Zak, 2018), except for Austnes et al. (2010). The average DOC concentrations measured at our sites during the growing season are in agreement with the expected range of a subarctic peatland ( $13.9\text{--}28.8 \text{ mg L}^{-1}$ ). The DOC concentrations in peatland peat porewaters exhibit a latitudinal gradient, from DOC concentrations commonly lower than  $20 \text{ mg L}^{-1}$  in boreal and sub-arctic zones compared to temperate zones (Table SI.3). This observation, in line with our results, suggesting a temperature control on the balance between DOM production and processing.

The peat porewater DOM presented specific features, including high values of average molecular weight, aromaticity, and DOC:DON ratio (Fig. 2 and 4). The  $\text{SUVA}_{254}$  value of  $5.5 \text{ L mg}^{-1} \text{ m}^{-1}$  measured in the Bouleau peatland was, in general, higher than those previously measured in temperate peatlands, i.e.,  $<3.6 \text{ L mg}^{-1} \text{ m}^{-1}$ , except for who reported a similar aromaticity and average DOM molecular weight as in the Bouleau peatland. The DOC:DON ratios measured in peat porewaters at our study site were up to six times higher than in . These high ratios suggest a strong signature of plant leachates in peat porewater DOM composition.

The measured pool DOM who reported a similar aromaticity and average DOM molecular weight in a Welsh ombrotrophic peatland. These indicators of microbial degradation within the peat also showed a seasonal trend, with higher DOM biodegradability measured in summer (Fig. 4), and the lowering of the  $f_{\text{VEG}}$  at the end of the growing season. Then, most of the DOM present in peat porewater is derived from the active vegetation at the surface of the peatland but has been partially decomposed through microbial degradation. In pools, the DOM composition also presented specific features, with lower DOC concentrations, aromaticity, and average molecular weight compared to peat porewater DOM (Fig. 2). Our results highlighted a dominant contribution of allochthonous DOM in pools despite the presence of microbial-derived DOM. The DOC concentrations in pools ( $10.5 \text{ mg L}^{-1}$  in average) were similar to those previously reported in the literature (Table SI.34) which, unlike peat porewaters, do not present follow any latitudinal distribution trend. The DOC concentration remained relatively steady during the growing season, only multiplied by 1.6 compared to an increase by a factor of 2.5 in peat porewater (Table 1). The  $\text{SUVA}_{254}$  values measured in the

Bouleau peatland pools ( $3.4 \pm 0.9 \text{ L mg}^{-1} \text{ m}^{-1}$  on average; Fig. 2d) were similar to those reported from Arctic regions with values of about  $4 \text{ L mg}^{-1} \text{ m}^{-1}$  (Laurion and Mladenov, 2013; Peura et al., 2016; Gandois et al., 2019; Laurion et al., 2021) suggesting a ~~terrestrial~~-contribution of plant-derived DOM from peat at our site and supported by the high DOC:DON ratio, ~~ranged~~ ranging from 9.4 to 51.4. (Fig. 2b).

~~Our results indicate a dominant vegetation origin of DOM and support the dominant contribution in allochthonous DOM in pools. The molecular compositions of the peat porewaters and pools highlighted the dominance of phenol markers (>50% of total markers) related to plant sources. The molecular indices fVEG and deoxyC6:C5 also supported the dominance of a plant origin of DOM in both environments (Fig. 2). The stable isotopic signature of DOC from peat porewaters of  $-27.0 \pm 0.8\text{‰}$  on average varied within the same range as that observed for DOC derived from peat porewaters and peat,  $-27.9$  and  $-27.8\text{‰}$ , respectively.~~

~~The decrease of the DOC stable isotopic signature and increased DOC:DON ratio in the peat porewaters, as well as the contribution of high molecular weight fatty acids from spring to summer highlighted a greater proportion of plant derived DOM towards the end of the growing season. At the same time, the low dissolved oxygen saturation could reflect the bacterial consumption of oxygen (Table 1). This, coupled with the presence of microbial markers expressed by fMIC (Table 1) and the evidence of a labile fraction of DOM (Fig. 5) underline the importance of the microbial processing of DOM within peat porewaters. All this highlights that both DOM production and DOM microbial processing are active within peat porewaters, with DOM production being more intense, as DOC concentrations were multiplied by 2.5 during the growing season (Table 1).~~

~~Our data did not evidence any photodegradation during DOM incubation in peat porewaters and pools, suggesting that the DOM photodegradation was not sizeable by our experimental design. This contrasts with previous studies which observed DOM photodegradation and changes in DOM composition in boreal and temperate aquatic ecosystems of Eastern Canada and the United Kingdom. Because degradation processes can occur within the first days following DOM production, the already degraded DOM we sampled might not have presented any sizeable photolability. The clear pattern of the SUVA<sub>254</sub> increase observed during the incubation period was independent of the conditions where DOM was exposed to solar radiation. This is coherent with the biodegradation of non aromatic molecules leading to an increase of SUVA<sub>254</sub> while photooxidation has been shown to induce a decrease of DOM aromaticity.~~

~~How hydrological, chemical, and biological processes explain the~~ Yet, the slightly higher deoxyC6:C5 and the higher %LMW FA in pools indicate the presence of microbial markers. Microbial processing follows a seasonal trend in pools (the highest microbial activity occurred in summer), which appear to be stronger compared to peat porewater. This is revealed by the evolution of  $\delta^{13}\text{C}$ -DOC, increasing during the growing season (Fig. 2.c) and revealing an increasing proportion of processed DOM. The increase of aromaticity, from 2.9 to  $3.9 \text{ L cm}^{-1}$ , might also reflect this microbial processing and its increasing contribution during the growing season. This is supported by indices as the  $S_R$ , deoxyC6:C5, MIC:VEG ratio and  $\beta:\alpha$  index following a pronounced seasonal trend with a peak reached in summer (Fig. 2). This suggests that pool DOM is mostly derived from active vegetation in the peat but undergoes more intense microbial degradation.

## 5.2. The DOM compositional differences of DOM between peat porewatersporewater and pools are explained by hydrological, chemical, and biological processes

The observed differences in DOM ~~compositionscomposition~~ between peat porewatersporewater and pools despite similar dominant plant derived sources, can be explainedwere persistent during the growing season and under different hydroclimatic conditions. We propose that those differences were driven by a combination of hydrological, chemical, and biological factors.

~~Hydrological pathways~~Along a peatland to pool transect, both DOM concentrations and compositions remained stable within the peatland and changed sharply at the interface ~~between the peatland and an adjacent pool (Fig. SI.4).~~

~~Hydrological flow paths in the peatland and at the transitional zone~~ between peat and pools might play a role in the shift of DOC concentrations and DOM composition between porewatersporewater and pools. The two environments appear to be hydrologically connected, based on ~~the~~synchronous variations of the water levels in adjacent environments with a strong buffering of water levels in pools (Fig. SI.2). ~~TheThis~~ buffering-of water level variations in pools can be explained by the decrease of hydraulic conductivity with depth in peat which limits water exchanges (Holden et al., 2018). ~~This suggests that the preferential flow path for lateral advection occurs at shallower depths when WTD is high (Birkel et al., 2017). Alternatively, it has been shown that deep flow paths (below 2 m depth) could supply surface flow (Levy et al., 2014; Peralta-Tapia et al., 2015) and might transport deeper DOM to the surface water (Campeau et al., 2017), and could contribute to water supply in pools. The DOM composition in deep peat porewater has been reported to be relatively similar to shallow layers with high aromaticity and average molecular weight (Tfaily et al., 2018). If this process could provide DOM to pools, it could not explain the shift in DOM composition between environments.~~

~~In the Bouleau~~At our studied peatland, a decrease ~~with depth~~ in the water storage coefficient (Riahi et al., submitted) and an increase in peat density ~~was observedwith depth has been documented~~ (Primeau and Garneau, 2021), ~~limiting water circulation. This slower circulation of water induces a longer residence time of DOM with peat depth and favours interactions with microorganisms, allowing for the microbial degradation of DOM. Evidence of microbial degradation in the peat was suggested by the high SUVA<sub>254</sub> as expressed by the characteristics of degraded DOM observed through degradation experiments (Fig. 5) and the observation of microbial markers (e.g., MIC, Table 1)~~

~~The structure of peat pores also~~and should inhibit water flow movements. In addition to slower water circulation, peat pore structure stimulates interactions between DOM and partially degraded peat which can adsorb both hydrophilic and hydrophobic compounds (Kalbitz et al., 2000; Rezanezhad et al., 2016). Changes in composition between peat porewatersporewater and pools might be induced by the selective interaction ofbetween DOM aromatic compounds ~~in~~and peat during their slow transfer. As we observed SUVA<sub>254</sub> values 1.6 times higher in peat porewater compared to pools (Fig.2), those aromatic products might selectively interact with peat or at least reduced its mobility and explained the lower DOC concentration and DOM aromaticity measured in pools (Table 1), since aromatic compounds are known to constitute the

~~hydrophilic~~hydrophobic fraction of DOM (Dilling and Kaiser, 2002)-~~this process might explain the lower aromaticity measured in pools (Table 1).~~

~~Both the concentrations and compositions were~~ Then, DOM microbial processing, occurring at different rates within peat, at the interface between peat and pools and within the pool, might greatly contribute to the observed ~~to change sharply at the interface between the peat and an adjacent pool (Fig. differences SI.4).~~ This highlights that the shift in DOM composition. Peat porewater DOM composition reflects microbial degradation occurring within the peat ( $f_{MIC}$ , Table 1), and shows a greater degradation potential compared to pool DOM (Fig. 4). The slow water circulation and long residence time of DOM within peat might promote interactions with microorganisms, allowing microbial degradation of DOM (Kalbitz et al., 2000; Catalán et al., 2016)-~~and concentration was not progressive through its transfer through peat but might have been enhanced at the interface between those environments. In pools, the.~~ Yet, a significantly higher contribution of microbial-derived DOM, ~~was observed in pools, as expressed by a higher deoxyC6:C5 and higher %LMW FA and lower  $f_{VEG}$  indices, and the decrease of~~  $f_{VEG}$  in the average DOM molecular weight as shown by the higher  $S_R$  and E2:E3 ratio. The significantly lower C/V ratio measured in pools also support the higher DOM microbial processing in pools. The coumaric and ferulic acids, composing the C fraction, are preferentially biodegraded compared the vanillic acid, vanillaldehyde, and acetovanillone, composing the V fraction (Goñi and Hedges, 1992), resulting in a decrease of the C/V ratio, as observed from peat porewater to pools.

The signature of microbial-derived DOM in pools supports the hypothesis of a reactive that DOM degradation processes occur at the interface between peat porewater and pools (Fig. SI.4)-~~and within the pools.~~ A shift gradual sharp changes in physicochemical parameters between the two environments, such as the slight increase in pH and temperature, and the rise of dissolved oxygen concentrations, may favour the microbial turnover of ~~at the~~ fraction of labile peat porewater DOM exported to pools. The ~~(higher than in pool, Fig. 4; Schindler et al., 1997; Kalbitz et al., 2000; Worrall et al., 2008; Peura et al., 2016)~~potential degradation rate that was measured for peat porewater DOM suggests. Additionally, our data did not evidence any photodegradation during DOM incubation in peat porewater and pools, suggesting that a fraction of DOM the DOM photodegradation was not sizeable by our experimental design. This contrasts with previous studies which observed DOM photodegradation and changes in DOM composition in boreal and temperate aquatic ecosystems of Eastern Canada (Lapierre and del Giorgio, 2014; Ward and Cory, 2016) and the United Kingdom (Jones et al., 2016). The absence of sizeable photodegradation suggests that this process did not drive the DOM composition in pools, compared to biodegradation. The clear pattern of the  $SUVA_{254}$  increase observed during the incubation experiments was independent to the exposition of DOM with the solar radiation. This is consistent with the biodegradation of non-aromatic molecules (Spencer et al., 2008, 2015; Mann et al., 2015; Worrall et al., 2017) leading to an increase of  $SUVA_{254}$  (Hulatt et al., 2014; Autio et al., 2016) while photooxidation has been shown to induce a decrease of DOM aromaticity (Laurion and Mladenov, 2013; Ward and Cory, 2016)could be transferred to pools is labile and can actually be degraded at the interface between peat and pools. In addition to the DOM processing at the interface between peat porewaters and pools, the molecular composition of pool DOM reflected microbial activity within the pool

itself. The relative proportions of these processes (DOM transformation within the peat, at the interface, or within the pool) cannot be assessed. This is supporting the hypothesis that the peat-derived DOM biodegradation is an important driver of DOM composition in the pools.

### 5.3. Implications of the DOM ~~of~~exchange from peat to pools ~~infor~~ the peatland carbon budgetcycle

Boreal peatland pools were previously identified as a continuous source of carbon dioxide (CO<sub>2</sub>) to the atmosphere during ice-free seasons, offsetting some of the carbon uptake by the vegetation (Pelletier et al., 2014, 2015). ~~Therefore, This release of CO<sub>2</sub> was assumed to be the product of DOM mineralization through microbial processing of DOM productivity in pools is likely to generate carbon dioxide emissions~~ (Billett et al., 2004; Striegl et al., 2012; Payandi-Rolland et al., 2020). Since our results showed low ~~apparent~~ degradation rates in pools, we suggest that DOM could have been partially biodegraded within the peat and at the interface zone between peat ~~porewaters~~porewater and pools, limiting further its degradation within pools (Payandi-Rolland et al., 2020). This reactive interface could be comparable with the hyporheic zone (riparian water-saturated zone between the peat and the stream) which can be an active component of the carbon cycle through the active DOM mineralisation and CH<sub>4</sub> oxidation at this interface (Rasilo et al., 2017). ~~Incubations of DOM that included particulate organic carbon (POC) under unfiltered conditions revealed higher degradation rates than those measured for filtered conditions, indicating that POC might stimulate the degradation of DOC (Fig. 5). Indeed, POC was previously described as a hotspot of biodegradation because particulate compounds stimulate interactions between bacteria and organic substrates. Degradation rates under unfiltered conditions in pools were two times lower than for peat porewaters. This might be related to the very low levels of turbidity in pools (data not shown). This is consistent with the decrease of DOM degradability previously observed at the transition from peat to aquatic environments.~~

The long-term apparent rate of carbon accumulation (LORCA) measured in the Bouleau peatland has been estimated to be 35.5 g C m<sup>-2</sup> ~~yfy~~<sup>-1</sup> and the recent apparent rate of carbon accumulation (RERCA) 85.1 g C m<sup>-2</sup> y<sup>-1</sup> (Primeau and Garneau, 2021). Based on a total pool volume of approximately 136 350 m<sup>3</sup>, an average DOC concentration of 10.1 mg L<sup>-1</sup> (Table 1), and an average potential degradation rate between 1.9% day<sup>-1</sup> in peat ~~porewaters~~porewater and 0.9% day<sup>-1</sup> in pools (Fig. 54), the degradation of pool DOM could average between 1.5 g C m<sup>-2</sup> y<sup>-1</sup> and 3.1 g C m<sup>-2</sup> ~~yfy~~<sup>-1</sup> for our site. This is equivalent to 5.4.2% to 8.711.1% of the LORCA and 4.72.2% to 34.6% of the RERCA, ~~supporting the relatively slight effect of. Those proportions suggest that~~ the processing of DOM in pools might have a substantial impact on the peatland carbon budget. The integration of carbon exchange at the pool-atmosphere interface would tend to ultimately minimize the carbon sink capacity of peatlands often reported from studies focusing on vegetation to atmosphere exchange. It is also important to note that DOM in pools is mainly derived from the recently produced DOM in peat, and unlikely from deeper (and older) peat layers. However, DOM degradation is not the only source of carbon emissions from pools, which can also be supplied by the lateral transfer of CO<sub>2</sub> and CH<sub>4</sub> (Rasilo et al., 2017) and by CH<sub>4</sub> ebullition (Repo et al., 2007). However, the importance of the pools as a potential carbon source to the atmosphere needs to be moderate in comparison with the CO<sub>2</sub> and the CH<sub>4</sub> exported and emitted in the

headwater stream of the peatland. This flux of  $8.8 \text{ g C m}^{-2} \text{ y}^{-1}$  (Taillardat et al., 2022). ~~Also, the pools DOM seems to present characteristics of recently produced DOM transferred from peat, its biodegradation might not affect importantly old peat C stocks. The DOM sensitivity to degradation in pools as to be put in perspective with the further peatland carbon balance.~~, accounted for 22.8% of the LORCA which is between 2 and 4 times higher to the carbon potentially emitted by pools.

~~The studied site is an undisturbed~~ Results presented in this study are from a boreal peatland, without permafrost or ~~direct human pressures~~ anthropogenic disturbances that could influence the carbon production and transformation processes through the peat-pools pool complex. The morphology of pool banks and vegetation surrounding the pools may play an important role in the DOM dynamics and DOC concentrations of pools, as suggested by Arsenault et al. (2018, 2019), ~~who studied 156 pools with a range of surface and depth comparable to our study site.~~ A study conducted on ten peatland pools showed that the size of the contact surface between water and peat (influenced by pool size, depth, and the slope of the banks) influenced the concentrations and composition of ~~DOC~~ DOM (Banaś, 2013). ~~However, the pools studied by Banaś (2013) Even if the DOM of pools appeared to have a limited effect on the net carbon budget of our studied peatland since pool banks were sharp and surrounded by upland vegetation, further studies should be conducted within different peatland ecosystems to better document the spatiotemporal variability and fate of DOM under contrasting climatic regions of the northern hemisphere.~~ were up to ten times larger and deeper than in our studied peatland pools. At our site, there was no significant difference between the pools in their range of size (from 30 to 2065 m<sup>2</sup>) and depth (from 70 to 120 cm) except for SUVA<sub>254</sub> (Table SI.5). Despite the slight effect observed on SUVA<sub>254</sub>, the DOM dynamics do not seem related to the pools morphology and depth. It supports the hypothesis that DOM transfer and biodegradation from peat porewater to pools are the main driver on its dynamic and implication to the peatland carbon cycle rather than pools morphological features.

Our study suggests that peat-derived DOM degradation and release through pools could play a substantial role on the net carbon budget of our studied peatland (<10% of the LORCA). Moreover, the influence of pools in the peatland carbon cycle should be considered from the perspective of climate change. DOM production and biodegradation rates seem to be controlled by temperature (Fig. 2 and 4) during the growing season and longer ice-free seasons and higher temperatures might impact the importance of pools in the peatland carbon cycle.

6.—

## 6. Conclusion

This study ~~highlighted~~ demonstrated that DOM is a highly dynamic component of the carbon cycle in ~~boreal peatlands~~ peatland, with important ~~changes~~ differences identified in its ~~concentrations~~ concentration and composition in both peat ~~porewaters~~ porewater and pools ~~during~~. Those differences being persistent throughout the growing season ~~and different hydroclimatic conditions.~~

The strong increase of DOC concentrations in peat ~~porewaters~~porewater over the growing season highlighted the intense production of DOM in ~~peat porewaters~~. ~~Indeed, this environment~~. DOC concentrations increased by 2.5 during the growing season, ~~even with the~~ (against a DOC concentration increase by a factor of 1.7 of in pools), ~~despite~~ microbial processing of DOM occurring ~~in~~within the peat.

The molecular analysis of DOM in pools revealed ~~that peat porewater and pool DOM shared the same~~ dominant ~~contribution of allochthonous DOM derived from the peatland~~ vegetation, ~~supported by the dominance of plant makers (VEG and % Phenols) and high DOC:DON ratio~~. Despite this similar plant origin, ~~despite exhibiting~~peat porewater and pools DOM had very different concentrations, ~~compositions~~composition, and dynamics over the growing season. ~~The DOM in pools was less aromatic and showed lower molecular weight compared to peat porewater.~~

Based on our investigations, we suggest that a combination of hydrological, chemical, and biological processes ~~explains these~~explain those differences. The low hydraulic conductivity in peat might favour ~~the contact of DOM with microorganisms resulting in its degradation~~DOM microbial processing before its transfer to the aquatic compartments. Low hydraulic conductivity ~~might~~could also lead to the selective adsorption of aromatic compounds with degraded peat supporting the decrease of ~~concentrations~~concentration and the lower aromaticity of DOM observed in pools. We observed abrupt changes in DOM ~~concentrations~~concentration and ~~compositions~~composition at the interface between peat and pools, ~~which were persistent during the growing season~~. The rapid modification of physicochemical ~~parameters~~conditions (e.g., temperature and oxygen availability) between those two environments might ~~favour~~influence the biodegradation of DOM at the interface between the peat and the pools and within the poolpools. This is confirmed by the higher proportion of microbial molecular markers identified in the pool DOM. ~~Although DOM is microbially processed both at the interface and within the pool, the carbon emissions generated by these processes remain small in comparison with the carbon accumulation potential of the peatland.~~

~~Although DOM is microbially degraded both at the interface and within the pool, the carbon emissions generated by those processes could be substantial (between 5.5 and 11% of the LORCA). However, the importance of pools in the carbon cycle needs to be followed in prevision of temperatures increasing which could stimulate DOM production in peat porewater and its microbial processing in porewater and pools.~~

#### Data availability

The data sets used in this study are available online on the Pangea data repository (<https://doi.pangaea.de/10.1594/PANGAEA.945391>).
