**Abstract.** To monitor the effect of current nitrogen emissions and mitigation strategies, total atmospheric nitrogen deposition to forests is commonly estimated using chemical transport models or canopy budget models in combination with throughfall measurements. Since flux measurements of reactive nitrogen ( $N_r$ ) compounds are scarce, dry deposition process descriptions as well as the calculated flux estimates and annual budgets are subject to considerable uncertainties. In this study, we compared four different approaches to quantify annual dry deposition budgets of total reactive nitrogen ( $\Sigma N_r$ ) at a mixed forest site situated in the Bavarian Forest National Park, Germany. Dry deposition budgets were quantified based on (I) 2.5 years of eddy-covariance flux measurements with the Total Reactive Atmospheric Nitrogen Converter (TRANC), (II) an in-situ application of the bidirectional inferential resistance scheme DEPAC (Deposition of Acidifying Compounds), here called DEPAC-1D, (III) a simulation with the chemical transport model LOTOS-EUROS (Long Term Ozone Simulation – EUROpean Operational Smog) v2.0 using DEPAC as dry deposition module, and (IV) a canopy budget technique (CBT).

Averaged annual  $\Sigma N_r$  dry deposition estimates determined from TRANC measurements were  $4.7 \pm 0.2$  and  $4.3 \pm 0.4$   $\text{kg N ha}^{-1} \text{ a}^{-1}$  using DEPAC-1D only, and the Mean-Diurnal-Variation method in combination with DEPAC-1D as gap-filling approaches, respectively. DEPAC-1D modeled dry deposition, using concentrations and meteorological drivers measured at the site, was  $5.8 \pm 0.1$   $\text{kg N ha}^{-1} \text{ a}^{-1}$ . In comparison to TRANC fluxes, DEPAC-1D estimates were systematically larger during summer, and in close agreement in winter. Modeled  $\Sigma N_r$  deposition velocities ( $v_d$ ) of DEPAC-1D were found to increase with lower temperatures, higher relative humidity, and in the presence of wet leaf surfaces, in particular from May to September. This observation was in contradiction to TRANC-observed fluxes, leading to the conclusion that the parametrizations may need revision. LOTOS-EUROS modeled annual dry deposition was  $6.5 \pm 0.3$   $\text{kg N ha}^{-1} \text{ a}^{-1}$  for the site-specific weighting of land-use classes within the site's grid cell. LOTOS-EUROS showed substantial discrepancies to measured  $\Sigma N_r$  deposition during spring and winter, which was related to an overestimation of ammonia concentrations within the grid cell. LOTOS-EUROS predicted an averaged  $\Sigma N_r$  concentration of  $5.0 \pm 3.3$   $\mu\text{g N m}^{-3}$ . Ammonia ( $\text{NH}_3$ ) contributed most to modeled  $\Sigma N_r$  concentrations but the modeled  $\text{NH}_3$  concentrations were overestimated by a factor two to three compared to measured values. Annual deposition estimates were in the range of minimum and maximum estimates determined from CBT being at  $3.8 \pm 0.5$  and  $6.7 \pm 0.3$   $\text{kg N ha}^{-1} \text{ a}^{-1}$ , respectively. By adding locally measured wet-only deposition, we estimated an annual total nitrogen deposition input between  $11.5$  and  $14.8$   $\text{kg N ha}^{-1} \text{ a}^{-1}$ , which is at the upper end of the critical load ranges proposed for deciduous and coniferous forests.

In this work, we conducted one of the first comparisons of micrometeorological and ecological methods for estimating annual nitrogen dry deposition to a remote mixed forest.

## 1 Introduction

40 In the last century, global nitrogen emissions have increased significantly due to anthropogenic activities (Fowler et al., 2013). Reactive nitrogen compounds, such as ammonia ( $\text{NH}_3$ ) and nitrogen oxides ( $\text{NO}_x$ ), contribute most to the emissions. Ammonia emissions originate mostly from animal husbandry and fertilizer application (Sutton et al., 2011, 2013), whereas  $\text{NO}_x$  emissions are mainly related to combustion processes in, e.g., transport and industry (Erismann et al., 2011, 2013). Although fertilizer use and the internal combustion engine are vital for world's food security and the economy, the release of these compounds into  
45 the atmosphere has a wide range of negative effects (Krupa, 2003; Galloway et al., 2003; Erismann et al., 2013). Deposition of reactive nitrogen into ecosystems has been identified as a reduction factor for biodiversity (Bobbink et al., 1998; Krupa, 2003; Galloway et al., 2003; Sutton et al., 2011). Especially ecosystems at nutrient poor soils are highly sensitive to additional nitrogen inputs resulting in a change in plant species (Damgaard et al., 2011; Paulissen et al., 2016) and species composition in forests (Dirnböck et al., 2014, 2018; Roth et al., 2022). Critical loads are used to show at which level long term nitrogen  
50 deposition may lead to adverse impacts (Hettelingh et al., 1995). Investigations by Hettelingh et al. (2013) have shown that half of the European ecosystems receive nitrogen above the critical load level. In Germany, the fraction of ecosystems with a critical load exceedance is estimated to be about 70 % (Schaap et al., 2018).

Quantitative estimation of the total nitrogen deposition is needed to assess exceedances of critical loads and to develop  
55 successful mitigation strategies. Although wet deposition is relatively straightforward to measure, the accurate quantification of dry N deposition remains a challenge. Recent progress in fast and robust measurement techniques allowed to investigate the temporal dynamics in concentrations and dry deposition fluxes (using the eddy-covariance (EC) approach) for total reactive nitrogen ( $\Sigma\text{N}_r$ ) (Marx et al., 2012; Ammann et al., 2012; Brümmer et al., 2013, 2022; Zöll et al., 2019; Ammann et al., 2019; Wintjen et al., 2020, 2022) and its individual compounds, e.g. for  $\text{NH}_3$  (Ferrara et al., 2012, 2021; Zöll et al., 2016; Moravek  
60 et al., 2020). For  $\Sigma\text{N}_r$ , the total reactive atmospheric nitrogen converter (TRANC) (Marx et al., 2012) coupled to a chemiluminescence detector (CLD) has shown its suitability for flux measurements in various field applications (see references for  $\Sigma\text{N}_r$  above). Despite the recent progress, the number and temporal coverage of available datasets remains small. As these in-situ measurements are only valid for the ecosystem where the specific observations took place, a large-scale assessment based on observations alone is not possible.

65 Chemical transport models (CTMs) are used to assess nitrogen deposition over large regions. For Germany, the CTM LOTOS-EUROS (Wichink Kruit et al., 2012; Manders et al., 2017; van der Graaf et al., 2020) is applied for the mapping of nitrogen deposition fluxes across the country. LOTOS-EUROS predicts the dry deposition of various  $\text{N}_r$  compounds, namely nitrogen dioxide ( $\text{NO}_2$ ), nitric oxide (NO), nitric acid ( $\text{HNO}_3$ ), ammonia ( $\text{NH}_3$ ), and particulate ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ ),  
70 in each grid cell by utilizing meteorological data from the European Centre for Medium Range Weather Forecasts (ECMWF), modeled concentrations of the mentioned compounds based on their emission sources and chemical processing, as well as information about the land-use distribution within each grid cell. The deposition module DEPAC (Deposition of Acidifying Compounds) is applied for calculating dry deposition velocities of those compounds (Erismann et al., 1994). DEPAC is a dry deposition inferential scheme featuring bidirectional  $\text{NH}_3$  exchange (van Zanten et al., 2010; Wichink Kruit et al., 2012), which  
75 is also implemented in the Operational Priority Substance (OPS) model (van Jaarsveld, 2004; Sauter et al., 2020). DEPAC can be used as stand-alone model for estimating dry deposition of  $\text{N}_r$  compounds. For site-based modeling with DEPAC, decoupled from a CTM and henceforth called DEPAC-1D, only measurements of common micrometeorological variables and concentrations of the individual  $\text{N}_r$  compounds are needed. In the past, deposition estimates have often been obtained through such an inferential modeling approach (Flechard et al., 2011, 2020; Li et al., 2016; Schwede et al., 2011).

80

To evaluate modeled annual total dry deposition and seasonal patterns in modeled fluxes and deposition velocities, a careful comparative analysis to flux measurements may provide feedback on the representativeness of the input data and the bidirectional parametrizations (Wichink Kruit et al., 2010; Wichink Kruit et al., 2017). Wintjen et al. (2022) presented and analyzed novel flux measurements of  $\Sigma N_r$  and several subcomponents focussing on temporal dynamics above a remote, mixed forest site spanning a 2.5 year period. This dataset provides a unique opportunity for the evaluation of different approaches to quantify dry deposition fluxes. Such comparisons with novel measurement techniques are sparse and only available from few field campaigns (Ammann et al., 2012; Brümmer et al., 2013, 2022; Zöll et al., 2019). Since the adoption of the Geneva Convention on Long-Range Transboundary Air Pollution (CLRTAP) in 1979, throughfall measurements has been carried out at many sites of the International Cooperative Programmes of air pollution effects on Forests (ICP Forests, [www.icp-forests.net](http://www.icp-forests.net), last access: 14 March 2022) and forested catchments (ICP Integrated Monitoring, <http://www.syke.fi/nature/icpim>, last access: 14 March 2022) according to standardized protocols. Using the so-called canopy budget technique (CBT) throughfall measurements also allow to give an estimate of the annual nitrogen dry deposition (Draaijers and Erisman, 1995; de Vries et al., 2003).

In this study, we provide a comparison of four independent methods for estimating nitrogen dry deposition for a remote mixed forest site in the Bavarian Forest National Park. The comparison is made for a 2.5 year period for which novel flux measurements were available (see companion paper Wintjen et al., 2022). The aim of this measurement campaign covering the time frame from January 2016 to June 2018 was to quantify background concentration and deposition levels as well as their temporal dynamics for further improvements in modeling nitrogen deposition that may be used for further defining environmental protection guidelines. Therefore, we present modeled concentrations, deposition velocities, and fluxes of  $\Sigma N_r$  and compare them to measurements of the same variables (1), discuss the influence of micrometeorological parameters on modeled deposition velocities of  $\Sigma N_r$  and the impact of measured and modeled input parameters on modeled  $NH_3$  fluxes (2), and compare annual  $N_r$  budgets of LOTOS-EUROS with DEPAC-1D, flux measurements, and nitrogen deposition estimates based on CBT reviewing them in the context of critical loads (3).

## 2 Materials and Methods

### 2.1 Site and campaign description

The campaign took place at a remote location in the Bavarian Forest National Park (NPBW) (48° 56'N 13°25'E, 807 m a.s.l.), a natural mixed forest located close to the Czech Border in the southeast of Germany. Due to the absence of nearby anthropogenic emission hotspots in terms of intensive agriculture or industry, concentrations of air pollutants are at background concentration level (Beudert and Breit, 2010). Observations of air pollutants and micrometeorology started on a 50 m tower in the 1980s. The measurement site is located in the Forellenbach catchment (Beudert and Gietl, 2015). The Forellenbach site is part of several networks for monitoring air pollution, e.g., International Cooperative Program on Integrated Monitoring of Air pollution Effects on Ecosystems (ICP IM) within the framework of the Geneva Convention on Long-Range Transboundary Air Pollution (UNECE, 2022) and Long Term Ecological Research (LTER, 2022). The Federal Environment Agency (UBA) and the NPBW Administration are responsible for the contribution to these networks. Further details about the site can be found in Zöll et al. (2019) and Wintjen et al. (2022).

For the application of DEPAC-1D, time series of micrometeorological parameters (i.e. temperature, atmospheric pressure, relative humidity, global radiation, Obukhov length, friction velocity) and air pollutant concentrations ( $NO$ ,  $NO_2$ ,  $HNO_3$ ,  $NH_3$ ,  $NO_3^-$ ,  $NH_4^+$ , and sulphur dioxide ( $SO_2$ )) are required for the flux calculations. These concentration measurements were performed using a DELTA (DENuder for Long-Term Atmospheric sampling e.g., Sutton et al., 2001; Tang et al., 2009) system

installed at 30 m above the forest floor.  $\text{NH}_3$  was additionally collected by passive samplers of the IVL type (Ferm, 1991) at several levels from the ground to 50 m including 30 m. In addition, high resolution measurements of  $\text{NH}_3$  were made with a Quantum Cascade Laser (QCL) (model mini QC-TILDAS-76 from Aerodyne Research, Inc. (ARI, Billerica, MA, USA)). The setup was completed by the TRANC integrated in an EC system consisting of a sonic anemometer (GILL-R3, Gill Instruments, Lymington, UK) and a chemiluminescence detector (CLD 780 TR, ECO PHYSICS AG, Dürnten, Switzerland). This system allowed flux measurements of  $\Sigma\text{N}_r$  and common micrometeorological parameters. All instruments were installed at 30 m except for the CLD, which was placed in an air-conditioned box at the ground and connected to the TRANC via a 45 m opaque PTFE sampling line.  $\text{NO}$ ,  $\text{NO}_2$ , and further meteorological parameters including pressure and global radiation were observed by the NPBW at 50 m. Profile measurements of relative humidity and temperature were made at 10 m, 20 m, 40 m, and 50 m height. All devices installed at the site as well as the TRANC are described in Wintjen et al. (2022).

## 2.2 Modeling reactive nitrogen fluxes

### 2.2.1 Bidirectional resistance model DEPAC

In surface-atmosphere exchange models, fluxes are calculated by using resistance schemes. In case of gases exhibiting bidirectional exchange behavior, the flux  $F$  is defined as follows

$$F = -v_d(z - d) \cdot (\chi_a(z - d) - \chi_{\text{tot}}) \quad (1)$$

The flux is a product of the deposition velocity ( $v_d$ ) with the concentration difference between the atmospheric concentration and the compensation point of the trace gas  $\chi_a$ . Both, the dry deposition or exchange velocity as the atmospheric concentration, are height dependent and given for an aerodynamic reference height  $z - d$  where  $z$  is the geometric height and  $d$  the zero-plane displacement height. The following convention is used for the fluxes: negative values represent deposition, positive values emission. Following the conductivity-resistance analogy,  $v_d$  is the inverse of the sum of the aerodynamic resistance ( $R_a$ ), the quasi-laminar resistance ( $R_b$ ), and the canopy resistance ( $R_c$ ).

$$v_d = (R_a + R_b + R_c)^{-1} \quad (2)$$

DEPAC (van Zanten, et al., 2010) can be used to calculate the dry deposition of reactive nitrogen gases. The aerodynamic ( $R_a$ ) and laminar layer ( $R_b$ ) resistances are required by DEPAC as input variables. Hence, the module is oriented at determining  $R_c$  for  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ , and  $\text{NH}_3$ .  $R_c$  is treated differently for each  $\text{N}_r$  compound but basically as the sum of parallel resistances, which model the exchange behavior of the atmosphere and vegetation:

$$R_c^{-1} = R_w^{-1} + R_{\text{stom}}^{-1} + (R_{\text{inc}} + R_{\text{soil}})^{-1} \quad (3)$$

The stomatal resistance ( $R_{\text{stom}}$ ) is calculated following Emberson et al. (2000a, b). In this scheme, stomatal conductance is determined by vegetation type dependent on maximum conductance lowered by factors controlling stomatal opening, i.e. light intensity, ambient temperature, vapor pressure deficit, and soil water content, using well known Jarvis functions (Jarvis, 1976). For  $\text{NH}_3$  a stomatal compensation point ( $\chi_{\text{stom}}$ ) is calculated following Wichink Kruit et al. (2010, 2017). The cuticular resistance ( $R_w$ ) is described by Sutton and Fowler (1993) for  $\text{NH}_3$  and the corresponding cuticular compensation point based on the works of Wichink Kruit et al. (2010, 2017). For  $\text{NO}$  and  $\text{NO}_2$ ,  $R_w$  is set considerably high to 10000 and 2000  $\text{s m}^{-1}$ , respectively, allowing hardly any deposition on external surfaces. The in-canopy resistance ( $R_{\text{inc}}$ ) is given by van Pul and Jacobs (1994), and the soil resistance ( $R_{\text{soil}}$ ) is described following Erisman and van Pul (1994). In the current version of

DEPAC, the soil compensation point is set to zero for all surface types. In case of  $\text{HNO}_3$ , a fast uptake to any surface is assumed through a low, constant  $R_c$  of  $10 \text{ s m}^{-1}$ . The total compensation point is determined as written in van Zanten et al. (2010).

$$\chi_{\text{tot}} = \frac{R_c}{R_w} \cdot \chi_w + \frac{R_c}{R_{\text{inc}} + R_{\text{soil}}} \cdot \chi_{\text{soil}} + \frac{R_c}{R_{\text{stom}}} \cdot \chi_{\text{stom}} \quad (4)$$

For further details to the documentation of DEPAC, we refer to the publication of van Zanten et al. (2010). Following implementation in LOTOS-EUROS, the version of DEPAC used in this study differs from the one documented in van Zanten et al. (2010) in two main aspects: Firstly, the implementation of a function considering co-deposition of  $\text{SO}_2$  and  $\text{NH}_3$  (Wichink Kruit et al., 2017) in the non-stomatal pathway and secondly, the usage of a monthly moving  $\text{NH}_3$  average concentration for determining the stomatal compensation point (Wichink Kruit et al., 2017).

### 2.2.2 Modeling of $\Sigma\text{N}_r$ deposition (LOTOS-EUROS)

LOTOS-EUROS (Manders et al., 2017) simulations were performed for the entire measurement period. For this purpose, a large-scale simulation was setup for Europe in which a second domain covering northwestern Europe at  $7 \times 7 \text{ km}^2$  was nested. The simulations were forced with weather data from the European Centre for Medium range Weather Forecast (ECMWF) and the CORINE-2012 land-use classification. For the European background simulation, the CAMS-REG European emission inventory (Kuenen et al., 2021) was used. For the inner domain the emission data for Germany were replaced by the national emission inventory. Modeled concentrations were written out for a reference height of 2.5 m. The land use specific and total dry deposition were calculated by LOTOS-EUROS on hourly basis for  $\text{NH}_3$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$ . Dry deposition of particles was calculated according to Zhang et al. (2001) (see Manders-Groot et al. (2016, Sec. 5.2)). The Corine Land Cover 2012 classification of the grid cell, in which the measurement site was located, was divided into 46.0 % seminatural vegetation, 37.2 % coniferous forest, 15.9 % deciduous forest, 0.7 % water bodies, and 0.2 % grassland. However, the actual structure of the forest stand showed 81.1 % coniferous forest and 18.9 % deciduous forest within the footprint of the flux measurements during the measurement campaign. Due to differences in the distribution of vegetation types in the footprint, results from LOTOS-EUROS were calculated with the site-specific weighting of land-use classes of the flux tower's footprint. The low contribution of coniferous forest and deciduous forest within the grid cell may be related to the evaluation of older aerial photographs showing larger areas of deadwood. Finally, the dry deposition of  $\Sigma\text{N}_r$  was calculated as the sum of the individual  $\text{N}_r$  fluxes. A detailed documentation of LOTOS-EUROS is given in Manders-Groot et al. (2016) and Manders et al. (2017).

### 2.2.3 Site-based modeling of $\Sigma\text{N}_r$ deposition (DEPAC-1D)

DEPAC-1D is a stand-alone version of LOTOS-EUROS' dry deposition module DEPAC using a FORTRAN90 wrapper program to accept arbitrary input datasets. DEPAC-1D used micrometeorological variables and parameters measured at the site to estimate  $R_c$  and the compensation point of  $\text{NH}_3$ . The atmospheric resistances –  $R_a$  and  $R_b$  – and the fluxes of  $\text{NH}_3$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  were calculated outside DEPAC following Garland (1977) and Jensen and Hummelshøj (1995, 1997) with stability corrections after Webb (1970) and Paulson (1970). The deposition of particles was calculated following Zhang et al. (2001) (see also Manders-Groot et al. (2016, Sec. 5.2)) and therewith equal to LOTOS-EUROS. Note that particle deposition is strictly speaking not part of the DEPAC module and was modeled with a separate program implementing the particle deposition scheme used within LOTOS-EUROS.

For estimating fluxes with DEPAC-1D, concentration measurements on monthly and half-hourly basis were used.  $\text{NH}_3$  fluxes were mostly based on half-hourly concentration measurements of the  $\text{NH}_3$  QCL. Half-hourly gaps in the  $\text{NH}_3$  concentration time series were assigned with their monthly integrated concentration value obtained from DELTA samplers. If these measurements were not available, missing values were replaced by monthly integrated results from passive sampler

195 measurements of  $\text{NH}_3$ . During winter, the uncertainty introduced by this gap-filling approach seems to be low as suggested by  
Schrader et al. (2018). We did not superimpose gap-filled concentration values with a diurnal pattern or used monthly averages  
of half-hours to fill gaps in concentration time series, since instationarities in the  $\text{NH}_3$  concentration pattern could not be  
reproduced by a synthetic diurnal cycle or monthly averages of half-hourly values. Fluxes of  $\text{HNO}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  solely  
based on monthly DELTA measurements. Gaps in time series of these compounds and  $\text{SO}_2$  were replaced by monthly averages  
200 from adjacent years.  $\text{NO}$  and  $\text{NO}_2$  fluxes were based on half-hourly measurements routinely taken at 50 m. The difference in  
measuring height was considered in the calculation of  $R_a$ .  $\text{SO}_2$  and  $\text{NH}_3$  concentrations from gap-filled DELTA time series  
were used to determine compensation points and additional deposition corrections, similar to the use of monthly averages  
when using DEPAC within LOTOS-EUROS.

205 All micrometeorological parameters were available at half-hourly resolution. Temperature and relative humidity data  
corresponded to the average of measurements from 20 m and 40 m height above ground. Since profile measurements of  
temperature and relative humidity started in April 2016 (Wintjen et al., 2022), measurements at 50 m were used until end of  
March 2016. Pressure and global radiation measurements were taken at 50 m, too. Indicators of stability and turbulence such  
as the Obukov length and friction velocity were obtained from momentum flux measurements of the sonic anemometer. For  
210 modeling  $R_a$ , the solar zenith angle, which is calculated by using celestial mechanic equations, the roughness length ( $z_0$ ), and  
 $d$  are needed. We set  $z_0$  to 2.0 m and  $d$  to 12.933 for coniferous forest and to 11.60 m for deciduous forest, corresponding to  
LOTOS-EUROS defaults for these land-use classes. Leaf area index (LAI) was modeled as described by van Zanten et al.  
(2010). The LAI determined from the site-specific land-use class weighting ranged between 4.1 and 4.8.

215 The calculation of the dry deposition was made for  $\text{NH}_3$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  with the mentioned input data on  
half-hourly basis. Results from DEPAC-1D were weighted with the site-specific land-use distribution within the flux  
measurement's footprint (81.1 % coniferous forest and 18.9 % deciduous forest). We compared them to dry deposition fluxes  
of LOTOS-EUROS as well as the measured  $\Sigma\text{N}_r$  fluxes estimated with the EC method from TRANC measurements (Wintjen,  
et al. 2022). In order to compare the results from modeling to TRANC measurements, we filled gaps in the TRANC flux data  
220 given by Wintjen et al. (2022) with results from DEPAC-1D. Those gaps were related to insufficient turbulence mostly  
occurring during nighttime, performance issues of the instruments, etc. Gaps in DEPAC-1D were mostly related to power  
outages causing gaps in micrometeorological data and issues in the measurements of  $\text{N}_r$  compounds. Respective half-hourly  
values in the flux time series of each gas (approx. 3.4% for  $\text{NH}_3$ ,  $\text{HNO}_3$ ,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$  and 9.3% for  $\text{NO}$  and  $\text{NO}_2$ ) were filled  
with results from LOTOS-EUROS. We further made a combination of Mean-Diurnal-Variation (MDV) approach (Falge et al.,  
225 2001) and DEPAC-1D. Analogous to Wintjen et al. (2022), MDV was applied to short-term gaps (less than 3 days), but instead  
of using monthly diurnal averages of specific half-hours to replace missing values in long-term gaps we used DEPAC-1D. The  
window for filling a gap with MDV was set to  $\pm 5$  days, gaps spanning time frames of more than 3 days were treated as long-  
term. Both approaches, DEPAC-1D alone and the combination of DEPAC-1D and MDV, were able to fill all gaps in flux  
time series. Uncertainties of the gap-filled fluxes determined by MDV were calculated as the standard error of the mean.  
230 Cumulative uncertainties of TRANC fluxes solely based on the uncertainty of the gap-filling and were calculated according to  
Eq. (3) of Wintjen et al. (2022). The error calculation scheme proposed by Brümmer et al. (2022) (Eq. (1)) was applied to  
fluxes filled with DEPAC-1D. Flux uncertainty of those half-hours was given as

$$F_{\text{unc,DEPAC-1D}} = \frac{\tilde{X}}{F_{\text{DEPAC-1D}}} ; \text{ with } \tilde{X} = \frac{F_{\text{unc,meas}}}{F_{\text{meas}}} \quad (5)$$

where  $\tilde{X}$  represents the median of the ratio of the uncertainty of the measured fluxes ( $F_{\text{unc,meas}}$ ) to their corresponding flux  
values ( $F_{\text{meas}}$ ). The uncertainty of the measured fluxes was given by Finkelstein and Sims (2001). Systematic uncertainties  
235 were not accounted in the error calculation. A discussion on systematic uncertainties is given in Wintjen et al. (2022).

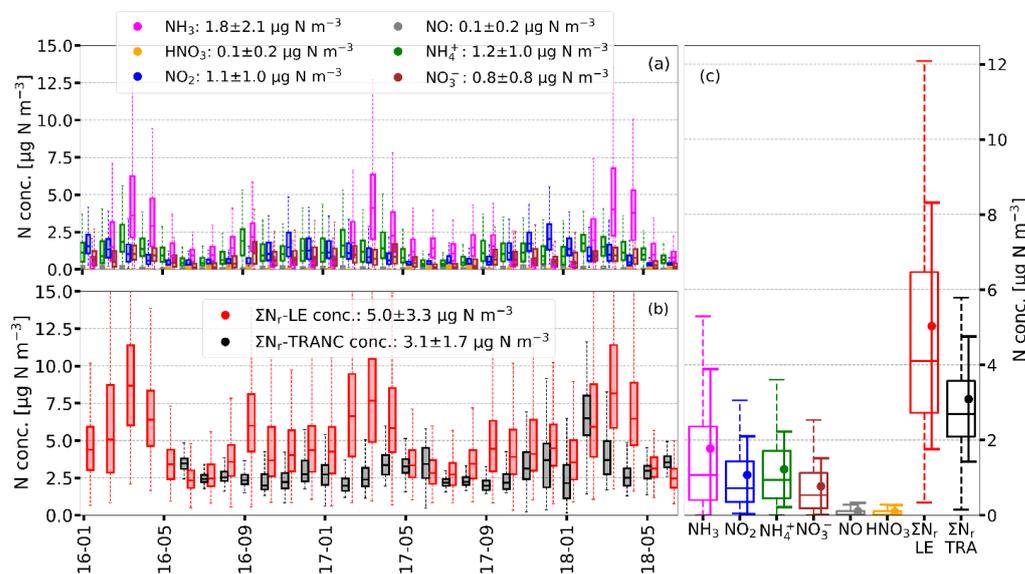

### 2.3 Measuring nitrogen outflow from the canopy using the Canopy Budget technique (CBT)

The canopy budget technique (CBT) is the most common method for estimating total and dry nitrogen deposition in ecological field research based on inorganic nitrogen fluxes ( $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ) only (see Staelens et al., 2008, Table 1). Total deposition of dissolved inorganic nitrogen ( $\text{DIN}_i$ ) was estimated on yearly basis after the CBT approach of Draaijers and Erisman (1995) and de Vries et al. (2003) whose results differed only marginally and were therefore averaged. The biological conversion of deposited inorganic nitrogen into dissolved organic nitrogen (DON) in the canopy, which is not addressed in CBT was estimated by the difference of DON fluxes between throughfall and bulk deposition ( $\Delta\text{DON}$ ). Adding  $\Delta\text{DON}$  to throughfall  $\text{DIN}$  or to  $\text{DIN}_i$  reveals a frame of lower and upper estimates of total nitrogen deposition ( $\text{N}_t$ ) and, by subtracting  $\text{DIN}$  deposition at an open land site from these  $\text{N}_t$ , of lower and upper estimates of dry deposition (Beudert and Breit, 2014).

## 3 Results

### 3.1 Comparison of modeled and measured concentrations

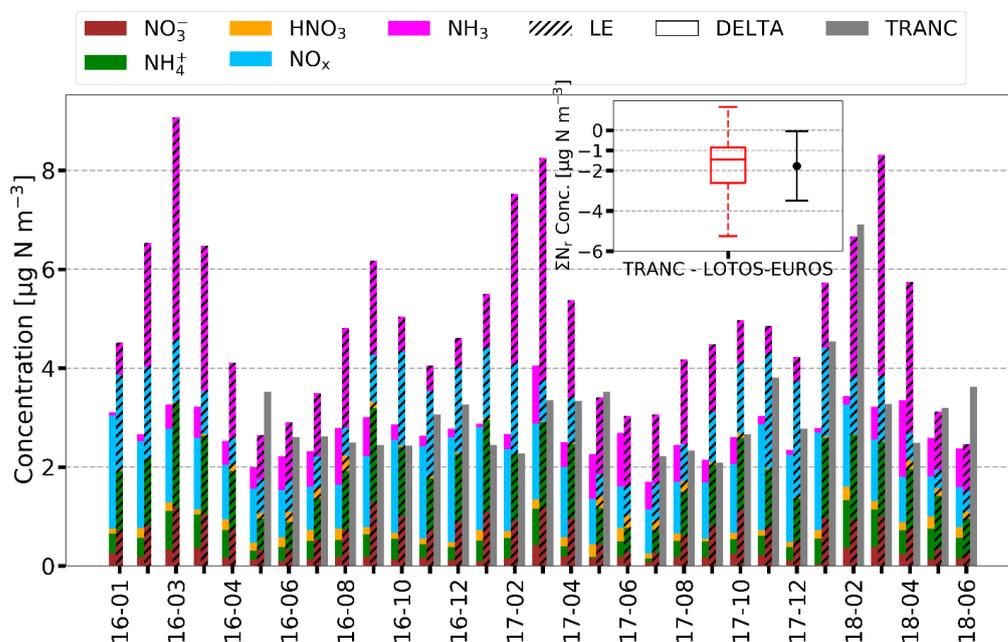

Figure 1 shows the modeled concentrations of LOTOS-EUROS for each  $\text{N}_r$  compound and their sum in comparison to the TRANC measurements. Looking at concentrations and patterns of each of the individually modeled compounds, reveals that  $\text{NH}_3$  had the highest concentrations, in particular in spring and partially in autumn with values close to zero in winter. On average, LOTOS-EUROS predicted an average  $\text{NH}_3$  concentration of  $1.8 \mu\text{g N m}^{-3}$ . During spring, modeled concentrations exceeded  $10 \mu\text{g N m}^{-3}$ . Such high concentration levels were not reached by the other  $\text{N}_r$  compounds. In winter,  $\text{NO}_2$  concentrations reached up to  $5 \mu\text{g N m}^{-3}$ , whereas concentrations were negligibly small in summer. The concentrations of  $\text{NO}$  and  $\text{HNO}_3$  were close to zero during the entire measurement campaign. Only during summer  $\text{HNO}_3$ , showed slight variations. Average concentrations of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were similar to  $\text{NO}_2$ . Particle concentrations were lowest in summer and reached values up to  $5 \mu\text{g N m}^{-3}$  in spring. The comparison of measured and modeled  $\Sigma\text{N}_r$  revealed significant discrepancies in concentration values. Except for the summer, modeled half-hourly concentrations were two to three times higher than the measured values. Average  $\Sigma\text{N}_r$  concentration modeled with LOTOS-EUROS was  $5.0 \mu\text{g N m}^{-3}$ , whereas the average measured concentration with the TRANC was  $3.1 \mu\text{g N m}^{-3}$ . The discrepancy being largest during spring clearly correlates with the modeled ammonia concentrations.

**Figure 1.** Concentrations of  $\text{NH}_3$  (fuchsia),  $\text{NO}_2$  (blue),  $\text{NO}$  (grey),  $\text{HNO}_3$  (orange),  $\text{NH}_4^+$  (green),  $\text{NO}_3^-$  (brown), and their corresponding sum (red) predicted by LOTOS-EUROS (LE) compared to  $\Sigma\text{N}_r$  (black) obtained from TRANC measurements represented as box-and-whisker plots (box frame = 25 % to 75 % interquartile range (IQR), bold line = median, whisker =  $1.5 \times \text{IQR}$ ) on monthly basis ((a) and (b)) and for the entire duration of the campaign (January 2016 to end of June 2018) (c) in  $\mu\text{g N m}^{-3}$ . In the legends, averages and standard deviations referring to the entire campaign for  $\Sigma\text{N}_r$  and its individual compounds are shown.

The large modeled  $\text{NH}_3$  concentrations by LOTOS-EUROS could not be verified by the observed levels of the passive samplers, the DELTA system, and the QCL. Figure S1 shows a comparison of these measurement techniques with  $\text{NH}_3$  concentrations predicted by LOTOS-EUROS. A two- to threefold overestimation of  $\text{NH}_3$  concentrations by LOTOS-EUROS is visible. In addition, the modeled seasonal pattern was not in agreement with the measurements, for example, the increase in  $\text{NH}_3$  during autumn was not observed by the instruments.

A comparison of the individual measured  $\text{N}_r$  compounds by DELTA to LOTOS-EUROS is displayed in Fig. 2. The discrepancy in the seasonal pattern of  $\text{NH}_3$  is obvious. The distinct peaks occurring in February, March, April, September, and October were not found by DELTA.  $\Sigma\text{N}_r$  values of DELTA and TRANC showed a reasonable agreement and  $\Sigma\text{N}_r$  concentrations showed only small seasonal differences whereas LOTOS-EUROS overestimated  $\Sigma\text{N}_r$  of the TRANC by ca.  $2 \mu\text{g N m}^{-3}$ . The high  $\Sigma\text{N}_r$  concentrations of LOTOS-EUROS were mainly related to  $\text{NH}_3$ . In addition,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were not in agreement with values determined by DELTA. Considering the entire campaign, median differences to DELTA were 0.57, 0.77, and 0.87  $\mu\text{g N m}^{-3}$  for  $\text{NH}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$ , respectively (see Fig. S2).  $\text{HNO}_3$  concentrations agreed well ( $0.08 \mu\text{g N m}^{-3}$ ), and  $\text{NO}_x$  was slightly lower in the LOTOS-EUROS simulations ( $0.32 \mu\text{g N m}^{-3}$ ) (Fig. S2).

**Figure 2.** Monthly stacked concentration of LOTOS-EUROS (LE) (hatched), TRANC (grey), DELTA, and  $\text{NO}_x$  in  $\mu\text{g N m}^{-3}$  for the entire measurement campaign. Gaps in the  $\text{NH}_3$  timeseries caused by a low pump flow of the denuder pump were filled with passive sampler values from 30 m. This procedure was done for December 2016 and 2017, March 2018, and April 2018. Remaining gaps in the time series of  $\text{HNO}_3$ ,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$  were replaced by monthly averages estimated from other years if available. In case of  $\text{NH}_3$ , the procedure was applied to January 2017. For the other compounds, the gap-filling was done for December 2017, March 2018, and April 2018. Results from LOTOS-EUROS, TRANC, and  $\text{NO}_x$  measurements were averaged to the exposure periods of the DELTA samplers. In the small panel, the difference in the monthly  $\Sigma\text{N}_r$  concentrations of TRANC and LOTOS-EUROS is shown represented as box-whisker-plot (box frame = 25 % to 75 % interquartile range (IQR), bold line = median, whisker =  $1.5 \cdot \text{IQR}$ ) (red) and average with error bars indicating the standard deviation (black) for the entire measurement campaign.

Since  $\text{NH}_3$  contributed most to  $\Sigma\text{N}_r$  in LOTOS-EUROS, seasonal contributions of the  $\text{N}_r$  compounds were different to results determined from DELTA and  $\text{NO}_x$  measurements. Wintjen et al. (2022) determined  $\text{NO}_x$  as predominant compound in the  $\Sigma\text{N}_r$  concentrations. LOTOS-EUROS states the  $\text{NH}_3$  as the most important compound contributing to  $\Sigma\text{N}_r$  as shown by Fig. S3. By comparing Fig. S3 and Fig. 2, we examined that LOTOS-EUROS and DELTA found seasonal changes for  $\text{NH}_3$  with the highest contribution in spring and lowest in winter. However, the contribution of  $\text{NH}_3$  to  $\Sigma\text{N}_r$  was surprisingly high (29 %) compared to the observations (4.9 %) during winter. As expected from Fig. 2,  $\text{HNO}_3$  contributions were comparable between LOTOS-EUROS and DELTA. Particle contribution was higher in the model, and their contributions and concentrations were invariant to seasonal changes except for spring.

### 3.2 Modeled $\text{N}_r$ deposition velocities and fluxes of DEPAC-1D

The comparison of the deposition velocities and fluxes for each  $\text{N}_r$  compound modeled by DEPAC-1D is shown in Fig. S4 and S5 displayed as monthly box-and-whisker plots, respectively. For the data description, medians were preferred to reduce the influence of outliers on reported deposition velocities and fluxes.

In case of  $\text{HNO}_3$ , a median  $v_d$  of  $1.56 \text{ cm s}^{-1}$  was determined by DEPAC-1D. During the entire campaign, IQR and positions of the whiskers showed less interseasonal variations with largest values of  $4.27 \text{ cm s}^{-1}$ . From May to September, the flux median was  $-3.35 \text{ ng N m}^{-2} \text{ s}^{-1}$  whereas  $-2.04 \text{ ng N m}^{-2} \text{ s}^{-1}$  was determined for the other months. Largest fluxes were found for May and June with values close to  $10.0 \text{ ng N m}^{-2} \text{ s}^{-1}$  caused by slightly higher concentrations compared to the rest of the year.

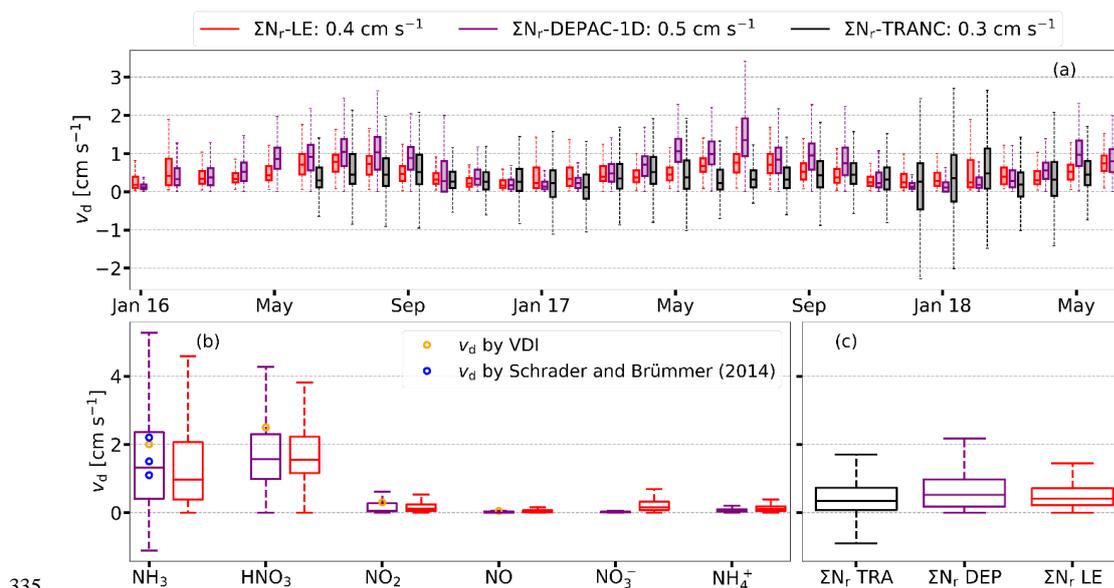

Deposition velocities of  $\text{NO}_2$  were close to zero in winter. From April to October, monthly median deposition velocities ranged between  $0.07$  and  $0.35 \text{ cm s}^{-1}$  with largest values ( $1.5 \times \text{IQR}$ ; see Fig. S4) close to  $1.0 \text{ cm s}^{-1}$ . The seasonal pattern in  $v_d$  is transferable to the predicted fluxes. Fluxes were enlarged from April to October, but flux medians showed hardly any monthly variations, and flux median was at  $-1.57 \text{ ng N m}^{-2} \text{ s}^{-1}$ . Similar to  $\text{HNO}_3$ , largest fluxes ( $1.5 \times \text{IQR}$ ; see Fig. S5) reached up to  $-10.0 \text{ ng N m}^{-2} \text{ s}^{-1}$ . Modeled deposition velocities of and fluxes of  $\text{NO}$  were the lowest in DEPAC-1D and negligible compared to the other compounds

Only during winter, monthly median deposition velocities of  $\text{NH}_3$  were close to zero. From March to August, deposition velocities were larger, and monthly medians ranged between  $0.55$  and  $2.17 \text{ cm s}^{-1}$  but extensions of the IQR and whiskers in the boxplots were similar (Fig. S4). Overall, the median  $\text{NH}_3$  deposition was  $7.87 \text{ ng N m}^{-2} \text{ s}^{-1}$  for DEPAC-1D. From the seasonal point of view, hardly any deposition was predicted for winter, and a median deposition of  $10.52 \text{ ng N m}^{-2} \text{ s}^{-1}$  was found during spring.

Monthly median deposition velocities of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  followed the same temporal pattern with lower values lowest in summer and higher in winter. During summer, monthly median deposition velocities were close to zero. Median  $v_d$  was  $0.01$  and  $0.05 \text{ cm s}^{-1}$  for  $\text{NO}_3^-$  and  $\text{NH}_4^+$  during winter, respectively. Only in February 2018, whiskers of DEPAC-1D extended up to  $0.37$  and  $1.27 \text{ cm s}^{-1}$  for  $\text{NO}_3^-$  and  $\text{NH}_4^+$ , respectively. For the entire campaign, DEPAC-1D monthly flux medians of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were lower than  $-0.05$  and  $-0.60 \text{ ng N m}^{-2} \text{ s}^{-1}$ . In February 2018, whiskers for DEPAC-1D extended to  $-11.0$  and  $-1.0 \text{ ng N m}^{-2} \text{ s}^{-1}$  for  $\text{NH}_4^+$  and  $\text{NO}_3^-$ , respectively (see Fig. S5).

A comparison of the modeled and measured  $v_d$  for the  $\Sigma \text{N}_r$  flux is provided in Fig. 3. The modeled total nitrogen dry deposition velocities were obtained by dividing the modeled dry deposition flux for all compounds by the modeled total nitrogen concentrations in ambient air. Differences between the median modeled and measured  $v_d$  typically ranged between  $-0.3$  and  $1.0 \text{ cm s}^{-1}$ . Especially during the summer months, an overestimation of the modeled values was observed for the DEPAC-1D results. The modeled median values and diurnal cycles for winter months were quite comparable to the measured values.

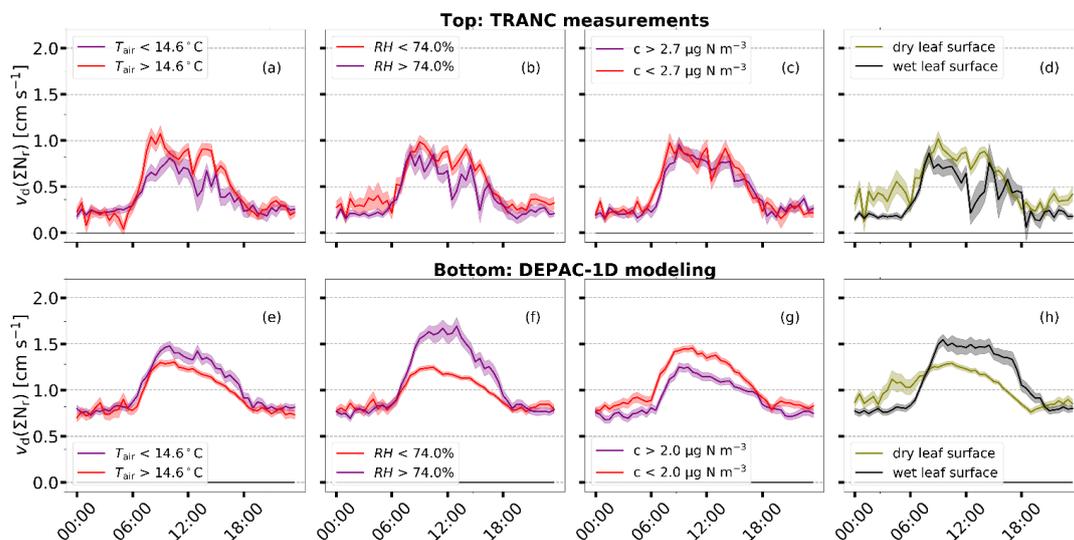

**Figure 3.** Monthly  $v_d$  of  $\Sigma \text{N}_r$  determined from TRANC (purple) measurements, DEPAC-1D (black), and LOTOS-EUROS (red) with the corrected land-use weighting in  $\text{cm s}^{-1}$  represented as box-and-whisker plots in the upper panel (a). In the corresponding legend median  $v_d$  related to the entire campaign are given. In the lower panels ((b) and (c)), box-and-whisker plots of  $v_d$  for each  $\text{N}_r$  compound and  $\Sigma \text{N}_r$  are shown based on the entire campaign (TRA=TRANC, DEP=DEPAC-1D, LE= LOTOS-EUROS). Blue circles are referring to  $\text{NH}_3$  deposition

340 velocities reported by Schrader and Brümmner (2014) for deciduous forest, mixed forest, and spruce forest (from low to high), orange circles show deposition velocities proposed by VDI (2006).

As the DEPAC-1D was fed with measured concentration data, the comparison for the modeled  $\Sigma N_r$  fluxes shows a large degree of similarity to the results for the deposition velocity, see Fig. 6. The  $\Sigma N_r$  exchange of DEPAC-1D is close to zero during the entire winter, and thus the difference to measured deposition was lowest during that time. During summer, a systematic overestimation of DEPAC-1D compared to measured fluxes was observed. Inspection of the diurnal cycles for May to September shows that both, the DEPAC-1D and measured data, exhibit a clear diurnal pattern with lowest deposition during the night and highest values around noon. However, where the measured data are close to zero during the night, the modeled flux show considerable nighttime fluxes. The latter may be due to the assumption of constant  $\text{HNO}_3$  concentrations as input to DEPAC-1D, whereas in reality the concentrations are low at night and maximize during the day. Note that improving this issue would result in an even larger overestimation of the flux during daytime.

To further examine the reasons behind these discrepancies, we show the diurnal cycles of  $v_d$  after classifying the  $\Sigma N_r$  deposition velocities for half-hours without precipitation during May-September in two groups being below or above the median temperature ( $T_{\text{air}} = 14.6^\circ\text{C}$ ), relative humidity ( $RH = 74.0\%$ ) and total  $\Sigma N_r$  concentration ( $c(\Sigma N_r) = 2.7 \mu\text{g N m}^{-3}$ ). In addition, we separated dry and wet leaf surfaces following the calculation scheme by Wintjen et al. (2022). The diurnal cycles illustrate the same diurnal biases as discussed above. Figure 4 shows that DEPAC-1D results indicate that lower temperatures, higher relative humidity, and wet leaf surfaces enhance the  $\Sigma N_r$  dry deposition velocity. This behavior was expected based on the models' parameterization, but it is in contradiction to the TRANC measurements. Especially, the differences for the relative humidity regimes are remarkable. Smaller differences are observed for the dependency on temperature and the  $\Sigma N_r$  concentration, although both have a stronger influence in the model than on their measured counterpart.

365 **Figure 4.** Averaged diurnal cycles of  $\Sigma N_r v_d$  for low and high temperature, relative humidity, concentration during the time frame May to September. The top row refers to TRANC measurements ((a) to (d)), the bottom row refers to DEPAC-1D modeling ((e) to (h)). Data was stratified after their median calculated for the entire period. Dry and wet leaf surfaces (Panel (d) and (h)) were identified following the calculation scheme of Wintjen et al. (2022). Shaded areas represent the standard error of the mean.

### 3.3 Modeled $N_r$ deposition velocities and fluxes of LOTOS-EUROS

Inspection of the dry deposition velocity for  $\text{HNO}_3$  as calculated by LOTOS-EUROS (Fig. S4) showed a striking feature with unrealistically high values modeled for November 2017 to February 2018. Monthly median deposition velocities of LOTOS-

370 EUROS were higher than  $1.90 \text{ cm s}^{-1}$  and values of more than  $10 \text{ cm s}^{-1}$  were reached. As  $v_d$  depends mostly on the aerodynamic resistance, a maximum is expected during summer and normally present. The periods with high  $v_d$  in winter are characterized by snow cover. An error in the stability parametrization was found and will be corrected for after this study. The high  $v_d$  values during snow cover were present for all components for which subsequent resistances are small as well, i.e.  $\text{HNO}_3$ ,  $\text{NH}_3$ , and nitrogen aerosols. The impact is also visible in the total nitrogen flux estimates, although not for all compounds. For example, 375 the  $\text{HNO}_3$  flux in winter is near to zero as nitric acid is almost not present. Also, for  $\text{NH}_3$  the impact is small. The main impact is through the deposition of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  particles, which we will later correct for.

The deposition velocities of  $\text{NH}_3$  of LOTOS-EUROS showed a seasonal pattern comparable to DEPAC-1D but deviations in absolute values were found. From April to August, we determined monthly medians ranging from  $0.43$  to  $1.76 \text{ cm s}^{-1}$ . Except 380 for autumn, deposition velocities covered a wider range compared to DEPAC-1D. During that season, large values of up to  $10.0 \text{ cm s}^{-1}$  were reached. Differences in  $v_d$  of  $\text{NO}_2$  to DEPAC-1D were negligible. From April to October, monthly median deposition velocities of LOTOS-EUROS were between  $0.11$  and  $0.30 \text{ cm s}^{-1}$  and close to zero in winter. Analogous to DEPAC-1D, deposition of  $\text{NO}$  did not play a role in the LOTOS-EUROS modeling. Deposition velocities of aerosol  $\text{NO}_3^-$  and  $\text{NH}_4^+$  exhibited the same seasonal pattern. We determined a median  $v_d$  of  $0.11 \text{ cm s}^{-1}$  for  $\text{NH}_4^+$  and  $0.15 \text{ cm s}^{-1}$  for  $\text{NO}_3^-$ .

385 From October to April, deposition fluxes of  $\text{HNO}_3$  were nearly zero in LOTOS-EUROS but enlarged from May to September with a flux median of  $-1.56 \text{ ng N m}^{-2} \text{ s}^{-1}$  and maximum values close to  $10.0 \text{ ng N m}^{-2} \text{ s}^{-1}$  (Fig. S5). Still, LOTOS-EUROS fluxes were generally lower than DEPAC-1D as represented by their monthly flux medians.

In case of  $\text{NH}_3$ , a median deposition of  $10.44 \text{ ng N m}^{-2} \text{ s}^{-1}$  was predicted by LOTOS-EUROS. Compared to DEPAC-1D, 390 LOTOS-EUROS monthly flux medians differed from zero during winter and extreme values in the order of  $15.0 \text{ ng N m}^{-2} \text{ s}^{-1}$  were written out. Outside the snow-covered period, large discrepancies were recorded in February, March, and April. Medians of LOTOS-EUROS were higher by about  $7.30 \text{ ng N m}^{-2} \text{ s}^{-1}$ . During spring,  $14.58 \text{ ng N m}^{-2} \text{ s}^{-1}$  were modeled with LOTOS-EUROS as median deposition.

In the LOTOS-EUROS simulations,  $\text{NO}_2$  fluxes were generally lower and seasonal differences were less pronounced compared 395 to DEPAC-1D. From April to October, a median flux of  $-0.96 \text{ ng N m}^{-2} \text{ s}^{-1}$  was determined whereas  $-0.78 \text{ ng N m}^{-2} \text{ s}^{-1}$  was calculated during the rest of the year. During winter, median depositions of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were  $1.40$  and  $1.76 \text{ ng N m}^{-2} \text{ s}^{-1}$ , respectively, with values higher than  $10.0 \text{ ng N m}^{-2} \text{ s}^{-1}$ . During the rest of the year, median depositions of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were approximately  $0.65$  and  $0.78 \text{ ng N m}^{-2} \text{ s}^{-1}$ , respectively.

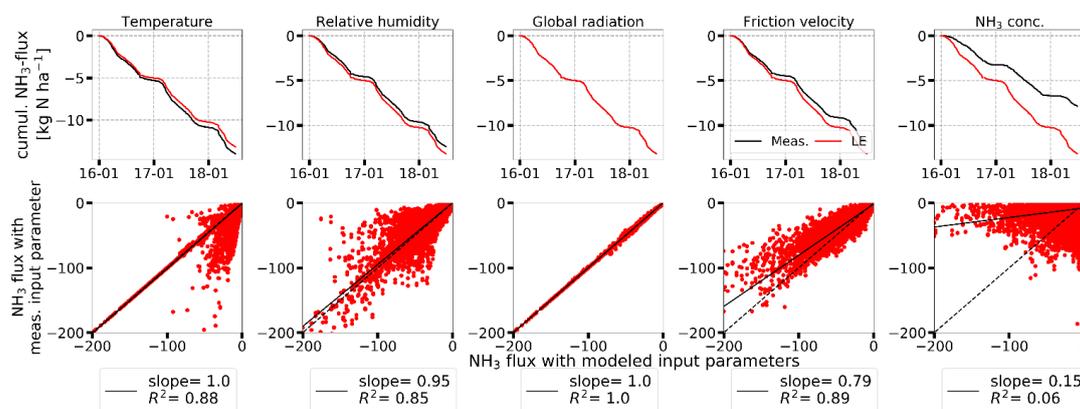

400 Overall, the modeled and measured total nitrogen dry deposition velocities of LOTOS-EUROS and TRANC showed a slightly better agreement compared to DEPAC-1D, but  $v_d$  of LOTOS-EUROS were still higher during summer and substantially high in winter due to the influence of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  (see Fig. 3). Generally, deviations to the results of  $v_d$  for the  $\Sigma \text{N}_r$  flux were related to the input data of LOTOS-EUROS. The disagreements to measured concentrations were elaborated in Sect. 3.1, especially for  $\text{NH}_3$ , but also for nitrogen aerosols (see Fig. 2 and S2) leading to discrepancies to TRANC fluxes in spring and 405 winter (Fig. 6).

To further investigate the impacts of the input data used in the LOTOS-EUROS simulations, we made a comparison of the measured and modeled input parameters used for the dry deposition modeling of  $\text{NH}_3$  in LOTOS-EUROS (Fig. S6). The agreement of temperature and global radiation in terms of their coefficient of determination  $R^2$  was good. We found marginal 410 differences of approximately  $1.5^\circ\text{C}$  and  $-6.13 \text{ W m}^{-2}$  to measured values on average. High  $R^2$  values were determined, namely  $0.97$  for temperature and  $0.78$  for global radiation. A slight difference was found for relative humidity during the first half of 2016. However, modeled values were higher by only  $2.4 \%$  on average, and the  $R^2$  was still  $0.67$ . In case of  $u^*$ , we found a

systematic difference, and the seasonal pattern did not agree well resulting in a lower  $R^2$  of 0.43 compared to the other micrometeorological parameters. Modeled values were higher by  $0.09 \text{ m s}^{-1}$ . In particular from November 2017 to February 2018, the difference between modeled and measured  $u^*$  values was enlarged due to the snow cover effect. An increase in  $u^*$  reduces turbulent resistances leading to large deposition velocities and fluxes for compounds like  $\text{HNO}_3$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  which are not or hardly affected by  $R_c$ .

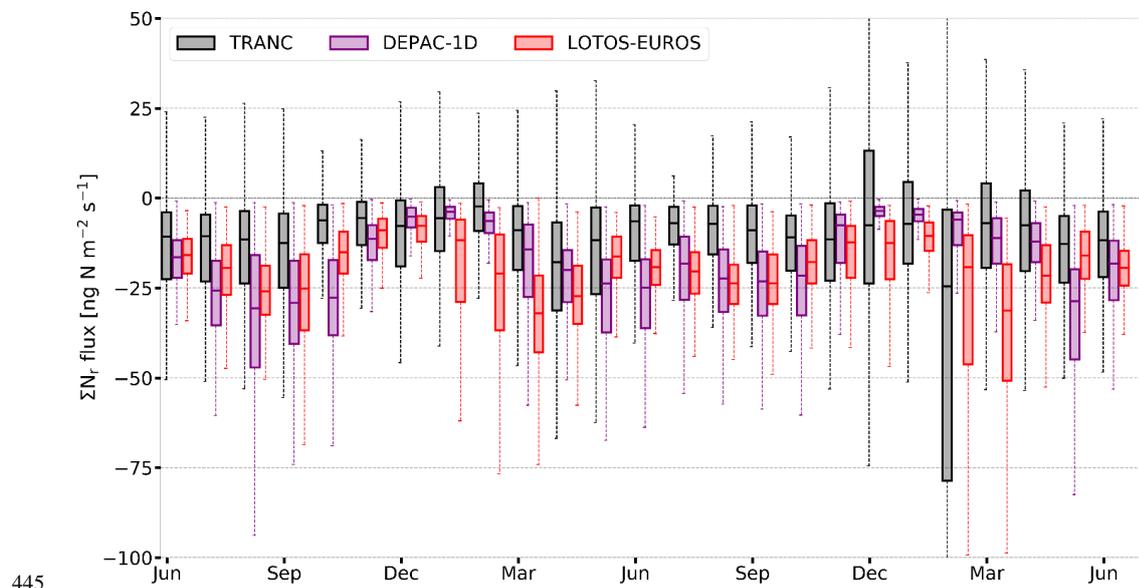

The largest discrepancy was found for  $\text{NH}_3$  concentration as illustrated by Fig. 2 and S1 in detail. All of these parameters play an important role in the modeling of the  $\text{NH}_3$  exchange. In order to determine the impact of these parameters on modeled  $\text{NH}_3$  fluxes, we calculated  $\text{NH}_3$  fluxes for the land-use class spruce forest with DEPAC-1D by replacing a certain input parameter by its measured counterpart while all other input data were from LOTOS-EUROS. Figure 5 illustrates the results of this comparison. Since modeled temperature and global radiation agreed well with their measured counterpart, deposition of  $\text{NH}_3$  is only marginally reduced if measured values were used. Relative humidity led to an increase in deposition, but the effect is constrained to approximately 6 %. We found significant differences in  $u^*$ , but considering measured values in the flux calculation leads only to a reduction of 10 %. As expected from the analysis of Fig. S6,  $\text{NH}_3$  concentration had the largest impact on deposition. Using measured  $\text{NH}_3$  concentration reduced the deposition substantially by 42 % compared to the modeled deposition. As indicated by the lower panel, the largest discrepancy in fluxes was observed for the concentration case.

**Figure 5.** Comparison  $\text{NH}_3$  fluxes calculated with DEPAC-1D for the land-use class spruce forest based on measured (black) and modeled input data (red). The comparison was made for temperature, relative humidity, global radiation, friction velocity, and  $\text{NH}_3$  concentrations. In the first row,  $\text{NH}_3$  fluxes are shown as cumulative sums in  $\text{kg N ha}^{-1}$ . In the second row, scatter plots of  $\text{NH}_3$  fluxes in  $\text{ng N m}^{-2} \text{ s}^{-1}$  are given. Linear regressions are shown as black, solid lines, black, dashed lines represent 1:1 lines.

### 3.4 Comparison of modeled and measured $\Sigma\text{N}_r$ deposition fluxes

The comparison of modeled  $\Sigma\text{N}_r$  fluxes with TRANC fluxes is presented in Fig. 6. Only periods during which high quality flux measurements were available were considered for the analysis. Models were basically able to capture the seasonal pattern of the  $\Sigma\text{N}_r$  fluxes well, but generally overestimated the measured flux amplitude. The  $\Sigma\text{N}_r$  exchange of DEPAC-1D is near zero during the entire winter, and thus the difference to measured deposition was nearly zero. During summer, a systematic overestimation of DEPAC-1D to measured fluxes was observed. Modeled deposition of LOTOS-EUROS was slightly lower than DEPAC-1D during summer and consequentially closer to measured fluxes. However, during autumn and spring predicted deposition of LOTOS-EUROS was significantly higher than deposition determined by DEPAC-1D and TRANC measurements due to the overestimated  $\text{NH}_3$  concentrations. Similar observations were made during winter whereas median  $\Sigma\text{N}_r$  deposition of DEPAC-1D and TRANC was close to zero. Note that during February 2018 large aerosol concentrations were predicted and observed. The TRANC flux data also show the impact of the aerosol deposition, but to a larger extend as LOTOS-EUROS.

445

**Figure 6.** Fluxes of DEPAC-1D (purple), LOTOS-EUROS (red), and TRANC (black) from June 2016 to June 2018 shown as box-and-whisker plots. Whiskers of TRANC fluxes cover the range from -191 to 105 ng N m<sup>-2</sup> s<sup>-1</sup> in February 2018; the upper whisker of December 2017 reached 69 ng N m<sup>-2</sup> s<sup>-1</sup>.

Figure S7 shows exemplarily monthly diurnal cycles of  $\Sigma N_r$  based on TRANC, DEPAC-1D, and LOTOS-EUROS. As previously written, during winter LOTOS-EUROS overestimated deposition whereas measurements showed near-zero exchange with emission phases. From May to September/October, DEPAC-1D exhibited a clear diurnal pattern with lowest deposition during the night and highest values around noon, which was in line with results from TRANC measurements. However, fluxes were systematically overestimated as indicated by Fig. 6 and Fig. S7 during those months. During the same period,  $\Sigma N_r$  deposition of LOTOS-EUROS was lower but still higher than TRANC fluxes except for September. During that month, LOTOS-EUROS was similar to DEPAC-1D. Generally, the diurnal deposition pattern of LOTOS-EUROS did not agree well with DEPAC-1D and TRANC. Compared to DEPAC-1D and TRANC measurements, deposition showed fewer diurnal variations resulting in a smaller daily amplitude.

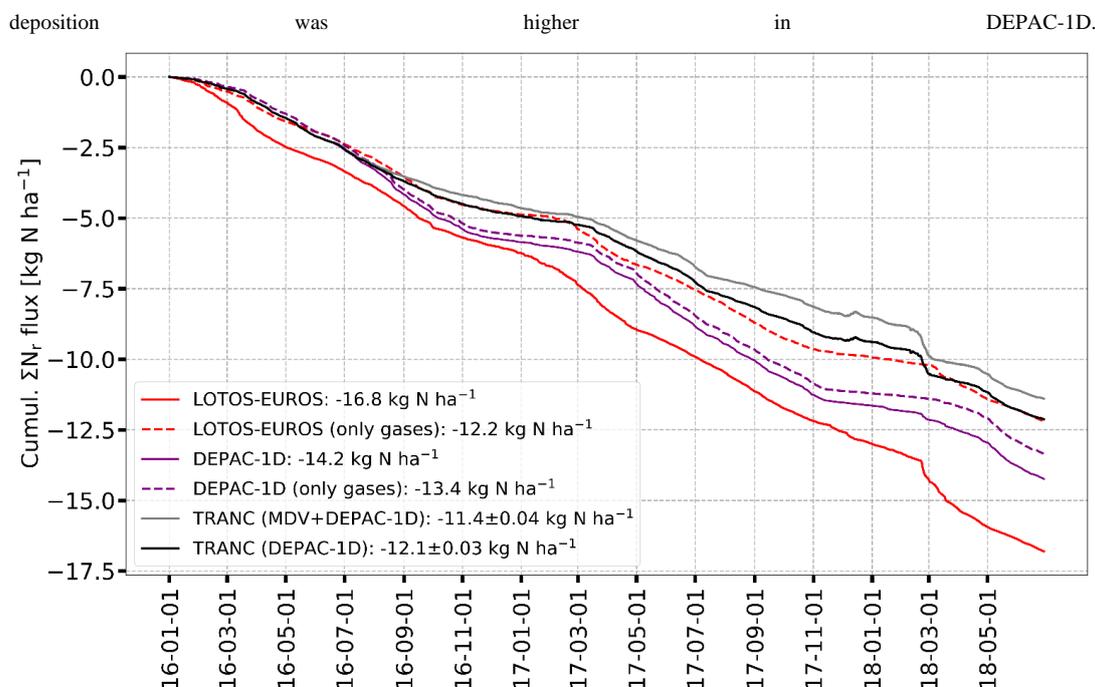

455

### 3.5 Cumulative N exchange and method comparison

To derive annual deposition numbers the gap-filling procedures were applied to the time series of the TRANC and DEPAC-1D (see Sect. 2.2.3). Figure 7 shows the cumulative  $\Sigma N_r$  dry deposition of each method from January 2016 to end of June 2018. The contributions of the individual components to the dry  $\Sigma N_r$  deposition of DEPAC-1D were: 67.9 % NH<sub>3</sub>, 15.3 % HNO<sub>3</sub>, 10.4 % NO<sub>2</sub>, 5.2 % NH<sub>4</sub><sup>+</sup>, 1.0 % NO<sub>3</sub><sup>-</sup>, and 0.1 % NO showing that modeled deposition was clearly driven by NH<sub>3</sub>. Since emission processes could only be treated for NH<sub>3</sub>, the observed emission of  $\Sigma N_r$ , for example deduced for December 2017 (Wintjen et al., 2022), could not be sufficiently modeled. Total compensation point (Eq. 4) was on average at 0.024 μg N m<sup>-3</sup>. Figure S8 shows the difference of ambient concentration and total compensation point for each month as boxplot. As seen by the whiskers, emission of NH<sub>3</sub> was possible only for certain periods in winter. Since NH<sub>3</sub> exchange was close to zero in winter, NH<sub>3</sub> emissions had hardly any influence on modeled total deposition of NH<sub>3</sub>. The disagreement to TRANC deposition estimates was mainly related to the overestimation of  $\Sigma N_r$  fluxes in summer. Since the  $\Sigma N_r$  exchange was close to zero in winter, the difference to flux measurements was lower. As expected from the results above, LOTOS-EUROS exhibited a larger discrepancy to flux measurements. Still, modeled  $\Sigma N_r$  deposition was lower than by using DEPAC-1D in summer, but in relation to flux measurements relatively high in winter and spring as indicated by the slope of their cumulative curves and in Fig. 6 and Fig. S7. Due to the snow cover effect, particle deposition was higher in LOTOS-EUROS, whereas gaseous

465

470

475 **Figure 7.** Comparison of measured and modeled cumulative  $\Sigma N_r$  dry deposition after gap-filling for the entire measurement campaign. Colors indicate different methods: TRANC+DEPAC-1D (black), TRANC+MDV+DEPAC-1D (grey), DEPAC-1D (purple), and LOTOS-EUROS (red). Dashed lines refer to cumulative dry deposition considering only gases. Number shown in the legend represent dry deposition and uncertainties after 2.5 years.

480 Both gap-filling strategies resulted in similar deposition estimates. After 2.5 years, the difference was estimated to be in the order of  $700 \text{ g N ha}^{-1}$ . Uncertainties related to gap-filling were negligible. Explicit differences in cumulative fluxes were found from June to September 2017 due to higher deposition fluxes in DEPAC-1D during those months. In February 2018, difference in measured deposition estimates was reduced since measured fluxes were larger than modeled fluxes of DEPAC-1D. Since all cumulative curves exhibit generally the same shape, we conclude that the variability in fluxes is reproduced by DEPAC-1D and LOTOS-EUROS well, although the amplitude and duration of certain deposition events is different. In Fig. 8, a comparison of the  $\Sigma N_r$  dry deposition separated by methods and measurement years is shown. Corresponding values of the dry deposition estimates are given in Table 1.

490 **Table 1**  $\Sigma N_r$  dry deposition of TRANC, DEPAC-1D, LOTOS-EUROS, and CBT for the entire measurement campaign, i.e., January 2016 to June 2018. Results from CBT were weighted according to the measured land-use weighting. For a visualization of the annual dry deposition see Fig. 8.

| Method               | 2016 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] | 2017 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] | until June 2018 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] |
|----------------------|---|---|--|
| TRANC (MDV+DEPAC-1D) | 4.6   | 3.9   | 2.9  |
| TRANC (DEPAC-1D)     | 4.9   | 4.5   | 2.7  |
| DEPAC-1D             | 5.8   | 5.8   | 2.6  |
| LOTOS-EUROS          | 6.2   | 6.8   | 3.8  |
| CBT (lower estimate) | 3.3   | 4.3   |  |
| CBT (upper estimate) | 6.4   | 7.0   |  |

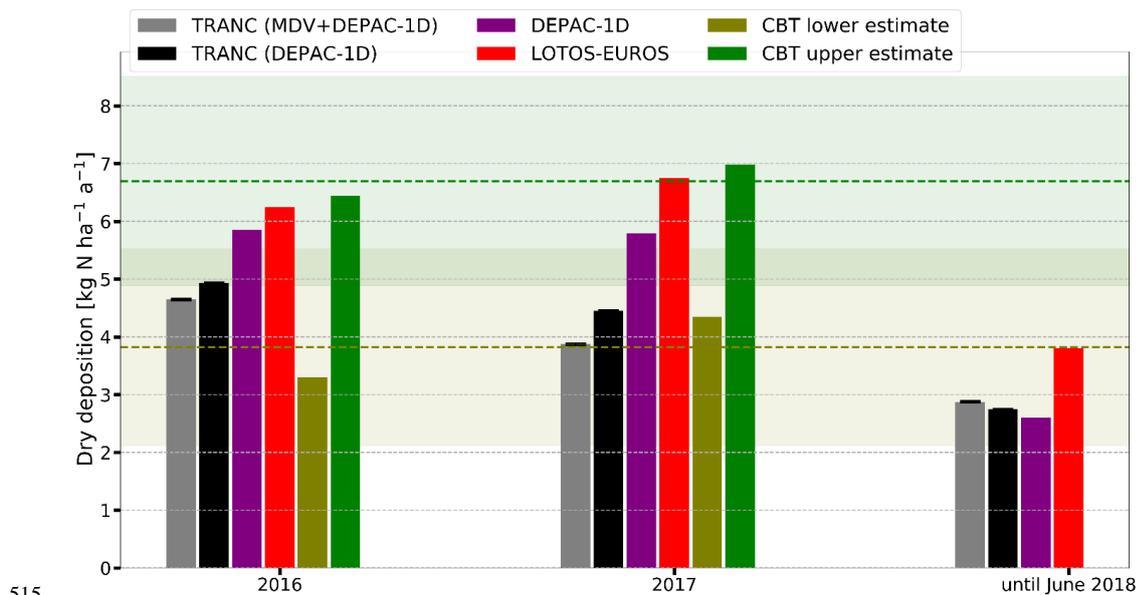

In 2016, annual TRANC deposition was higher than in 2017. Using only DEPAC-1D as gap-filling technique, resulted in slightly higher dry deposition estimates. However, differences were negligible compared to their total dry deposition estimates.

495 Until June 2018, measured deposition was higher than the half of the previous years. DEPAC-1D deposition was nearly identical for 2016 and 2017, but lower than measured deposition until June 2018. The difference to TRANC estimates until June 2018 was caused by the deposition fluxes in February 2018, which had an influence on the MDV method leading to significantly larger gap-filled fluxes.

500 TRANC deposition was closer to the lower estimate of CBT, whereas DEPAC-1D predictions were within the standard deviation range of the CBT estimates. LOTOS-EUROS exhibited values close to the upper estimates of CBT. If we assume that the deposition from June to December 2018 would have been similar to the average of the previous measurement years (2.0, 2.3, 3.1, and 3.0 kg N ha<sup>-1</sup> a<sup>-1</sup> for TRANC (MDV+DEPAC-1D), TRANC (DEPAC-1D), DEPAC-1D, and LOTOS-EUROS, respectively), we would get dry deposition estimates similar to the previous years in case of TRANC and LOTOS-EUROS.

505 DEPAC-1D estimates would be lower than 2016 and 2017. Annual dry deposition estimated by CBT were close to each other for 2016 and 2017 and in the range of the long-term averages estimated from 2010 to 2018 (3.8 kg N ha<sup>-1</sup> a<sup>-1</sup> as lower estimate and 6.7 kg N ha<sup>-1</sup> a<sup>-1</sup> as upper estimate).

Averaging of the annual sums of each method for 2016 and 2017 resulted in a TRANC dry deposition of 4.3±0.4 and 4.7±0.2 kg N ha<sup>-1</sup> a<sup>-1</sup> depending on the gap-filling approach. DEPAC-1D showed 5.8±0.1 kg N ha<sup>-1</sup> a<sup>-1</sup>, LOTOS-EUROS predicted 6.5±0.3 kg N ha<sup>-1</sup> a<sup>-1</sup>. We determined 6.7±0.3 kg N ha<sup>-1</sup> a<sup>-1</sup> with CBT as averaged upper estimate, and 3.8±0.5 kg N ha<sup>-1</sup> a<sup>-1</sup> as averaged lower estimate. It shows that dry deposition estimated by TRANC, DEPAC-1D, and LOTOS-EUROS were within the minimum and maximum deposition estimated by CBT but generally closer to the lower estimate of CBT except for LOTOS-EUROS.

515 **Figure 8.** ΣN<sub>r</sub> dry deposition for the years 2016 and 2017 and from January to June 2018 shown as bar chart. Colors indicate different methods: TRANC+DEPAC-1D (black), TRANC+MDV+DEPAC-1D (grey), DEPAC-1D (purple), LOTOS-EUROS (red), and canopy budget technique (olive and green). Data from TRANC, DEPAC-1D, and LOTOS-EUROS range from January 2016 to June 2018. CBTs' lower and upper estimates weighted according to the measured land use. The colored dashed lines indicate the averaged dry deposition of the lower and upper estimates (dashed, brown line and dashed, olive line, respectively) were from 2010 to 2018, the shaded areas represent their standard deviation.

520

## 4 Discussion

### 4.1 Comparison of concentrations, fluxes, and annual budgets

525 The comparison to concentration measurements of NO, NO<sub>2</sub>, and NH<sub>3</sub> conducted by Wintjen et al. (2022) revealed that NH<sub>3</sub>  
concentrations were systematically overestimated by LOTOS-EUROS during the entire campaign as described in Sec. 3.1 in  
detail. Modeled NO<sub>x</sub> concentrations were similar or even lower than their measured values. Modeled seasonal patterns of NO<sub>x</sub>  
and NH<sub>3</sub> agreed partly with their observed counterparts. In case of NO<sub>x</sub>, model and measurements reported highest values in  
winter and lowest values in summer mostly related to differences in emissions from enhanced heating and combustion  
530 processes. In case of NH<sub>3</sub>, a peak in the LOTOS-EUROS concentrations was found during spring. However, the predicted  
increase in NH<sub>3</sub> during autumn was not confirmed by the observations. Elevated NH<sub>3</sub> concentrations were most likely related  
to emissions from agriculture, in particular to the application of fertilizer during these times. Thus, the low pollution climate  
at the site could not be modeled well by LOTOS-EUROS.

Compared to other forest ecosystems, modeled concentrations of LOTOS-EUROS were closer to reported concentrations, e.g  
535 for HNO<sub>3</sub> (Farmer et al., 2006; Horii et al., 2006; Farmer and Cohen, 2008), for NH<sub>3</sub> (Wyers and Erisman, 1998; Hansen et  
al., 2013, 2015), for NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> (Wolff et al., 2010; Gordon et al. 2011; Farmer et al. 2011, 2013), and NO<sub>2</sub> (Horii et al.,  
2004; Farmer and Cohen, 2006).

Modeled NH<sub>3</sub> fluxes were similar to observations of Hansen et al. (2015) ranging from -60 to 120 ng N m<sup>-2</sup> s<sup>-1</sup> above a  
540 deciduous forest. The emission fluxes observed by Hansen et al. (2015) were probably caused by the decay of fallen leaves  
(Hansen et al., 2013) leading to less deposition during late summer and autumn compared to our site. During spring, Pryor et  
al. (2001) reported a daily deposition of 15 ng N m<sup>-2</sup> s<sup>-1</sup> for NH<sub>3</sub>, which was comparable to predicted median depositions of  
DEPAC-1D and LOTOS-EUROS in the same season although ambient NH<sub>3</sub> concentrations were different. The high  
contribution of emission fluxes observed by Hansen et al. (2015) was not reproduced by the model applications at our site,  
545 which was probably related to the negligible compensation point of NH<sub>3</sub>. Since no compensation point is implemented for  
other N<sub>r</sub> compounds, only deposition fluxes could be modeled for those compounds. In addition, their flux amplitude was  
significantly lower than for NH<sub>3</sub>. Thus, the combined ΣN<sub>r</sub> flux was mainly controlled by the NH<sub>3</sub> flux pattern.

Unlike NH<sub>3</sub>, modeled NO fluxes had an insignificant contribution to the ΣN<sub>r</sub> flux. Geddes and Murphy (2014) found that NO  
550 fluxes were mostly downward with a maximum deposition of -2.9 ng N m<sup>-2</sup> s<sup>-1</sup> during daytime. The diurnal cycle of NO was  
reversed to NO<sub>2</sub> during the day and was nearly zero with a tendency of slight emission during the night (Horii et al., 2004;  
Geddes and Murphy, 2014). Thus, they observed emission of NO<sub>2</sub> during the day peaking at approximately 2.8 ng N m<sup>-2</sup> s<sup>-1</sup>.  
As a result, NO<sub>x</sub> fluxes were slightly different from zero. Horii et al. (2004) found NO<sub>2</sub> deposition at concentrations higher  
than 1.1 μg N m<sup>-3</sup> and emission fluxes in the opposite case. They further identified non-stomatal deposition as the strongest  
555 contributor to the flux. Min et al. (2014) observed emission fluxes for NO and NO<sub>2</sub> during daytime but with even lower flux  
amplitude. Besides the emission fluxes, modeled deposition fluxes of NO<sub>2</sub> and NO were within the range of the reported  
values.

The contribution of NO to total modeled ΣN<sub>r</sub> dry deposition was negligible due to the high canopy resistance implemented in  
560 DEPAC. In general, NO is mainly observed as emission from soil if it is produced through (de)nitritication processes  
(Butterbach-Bahl et al., 1997; Rosenkranz et al., 2006). Most of the NO is rapidly converted to NO<sub>2</sub> in the presence of ozone  
(O<sub>3</sub>) within the forest canopy, especially close to the ground (Rummel et al., 2002; Geddes and Murphy, 2014). Thus, NO  
fluxes were assumed to be close to zero in DEPAC at the reference height due to fast conversion processes within the forest

565 canopy and uptake possibilities like leaf surfaces for  $N_r$  compounds (e.g., Wyers and Erismann, 1998; Rummel et al., 2002; Sparks et al., 2001; Gordon et al., 2011; Geddes and Murphy, 2014; Min et al., 2014; Wentworth et al., 2016).

570 It has to be considered that  $NO_2$  is removed from the atmosphere by the reaction with  $O_3$ . During the night,  $NO_3$  reacts with  $NO_2$  to dinitrogen pentoxide ( $N_2O_5$ ). The latter can react with  $H_2O$  to  $HNO_3$ .  $HNO_3$  as well as peroxyacetyl nitrates (PANs) (Min et al. 2014) are effective sinks for  $NO_2$ , and  $HNO_3$  has a significant impact on the measured deposition flux (Munger et al., 1996). Modeled  $HNO_3$  fluxes had a similar flux magnitude as the  $NO_2$  fluxes. Comparing predicted  $HNO_3$  fluxes with values reported for different forest sites shows that  $HNO_3$  was predominantly deposited at selected sites (see Walker et al., 2020, Table 1) with values ranging from 1.4 to 40  $ng\ N\ m^{-2}\ s^{-1}$  depending on forest types and time of the year. Modeled  $HNO_3$  fluxes were at the lower end of published values.

575 Horii et al. (2006) reported inferred  $HNO_3$  fluxes almost as high as the measured total  $NO_y$  fluxes.  $NO_y$  corresponds to the sum of all oxidized nitrogen compounds, for example,  $NO$ ,  $NO_2$ , particulate  $NO_3^-$ ,  $HNO_3$ ,  $N_2O_5$ , PAN, and other organic nitrates. Their measured  $NO_y$  deposition ranged between 0 and 80  $ng\ N\ m^{-2}\ s^{-1}$ . Comparing the values of  $NO_y$  and  $HNO_3$  summarized by Walker et al. (2020) shows that  $HNO_3$  fluxes were almost as high as the  $NO_y$  fluxes highlighting their relevance in the  $NO_y$  flux budget.

580 Modeled  $NO_3^-$  and  $NH_4^+$  deposition fluxes were similar in magnitude and their absolute flux values were mostly below 1  $ng\ N\ m^{-2}\ s^{-1}$  considering their flux medians.  $NH_4^+$  fluxes were similar to values reported by Farmer et al. (2011), who observed  $NH_4^+$  deposition with 1  $ng\ N\ m^{-2}\ s^{-1}$  at maximum for a coniferous forest during midday. Gordon et al. (2011) found an average  $NO_3^-$  flux of -0.8  $ng\ N\ m^{-2}\ s^{-1}$  with a standard deviation of 1.5  $ng\ N\ m^{-2}\ s^{-1}$ . Wolff et al. (2010) conducted measurements of total ammonium ( $NH_3$  and  $NH_4^+$ ) and total nitrate ( $HNO_3$  and  $NO_3^-$ ) above a spruce forest. They determined mean fluxes of -66  $ng\ N\ m^{-2}\ s^{-1}$  and -41  $ng\ N\ m^{-2}\ s^{-1}$  for tot- $NH_4^+$  and tot- $NO_3^-$ , respectively. Modeled tot- $NH_4^+$  and tot- $NO_3^-$  of LOTOS-EUROS were significantly lower. Monthly medians ranged between -2.9 and -26.3  $ng\ N\ m^{-2}\ s^{-1}$  and between -0.74 and -4.0  $ng\ N\ m^{-2}\ s^{-1}$  for tot- $NH_4^+$  and tot- $NO_3^-$ , respectively. Similar values were calculated for DEPAC-1D.

590 In conclusion, modeled deposition fluxes are comparable to flux measurements conducted at various forest ecosystems. However, comparison possibilities to flux measurements of  $N_r$  compounds, e.g.,  $NH_3$  and particles (Walker et al., 2020), above forests are still sparse. In addition, most of the studies were carried out for a limited time of the year. The comparison revealed that emission fluxes were observed for  $NH_3$  and  $NO_2$  due to the existence of a compensation point, the alternation of day and night, or changes in surface properties or micrometeorology.

595 The comparison to TRANC fluxes indicated an overestimation of modeled  $\Sigma N_r$ . Predicted  $\Sigma N_r$  fluxes of DEPAC-1D were systematically higher in summer, and LOTOS-EUROS  $\Sigma N_r$  deposition was suspiciously high in winter whereas measured and site-based fluxes were close to zero. Median  $\Sigma N_r\ v_d$  of TRANC and LOTOS-EUROS were close to each other and lower than DEPAC-1D for the entire campaign. Except for  $NH_3$  and nitrogen aerosols, LOTOS-EUROS and DEPAC-1D gave similar values for each compound (Fig. 3). In case of TRANC measurements, significant emission fluxes were found in winter as discussed in Wintjen et al. (2022) for December 2017. Generally, emissions could not be sufficiently reproduced by the models since emissions from soil are currently not included in DEPAC. The observed large deposition fluxes in February 2018 were reproduced in the model simulations although the modeled flux amplitude was smaller. During that time, modeled concentrations and fluxes of particulate  $N_r$  were the largest contributor to total  $\Sigma N_r$ , leading to the assumption of particle driven  
600  $\Sigma N_r$  deposition. DELTA measurements suggested that particulate  $NH_4^+$  was most likely responsible for the measured  $\Sigma N_r$  deposition (Wintjen et al., 2022). Modeled and measured  $NH_4^+$  concentrations differed only by 0.75  $\mu g\ N\ m^{-3}$  whereas a

significant disagreement was found between  $\text{NH}_3$  measurements and LOTOS-EUROS (approx.  $2.7 \mu\text{g N m}^{-3}$ ). According to DELTA measurements, the  $\text{NH}_3$  concentration was approximately  $0.17 \mu\text{g N m}^{-3}$ . The averaged  $\text{SO}_2$  concentration obtained from LOTOS-EUROS and DELTA were comparable during the exposure period of the samplers ( $1.5$  and  $2.0 \mu\text{g m}^{-3}$ , respectively). In case of the LOTOS-EUROS simulations, the dominant aerosol could have been  $\text{NH}_4\text{NO}_3$  due to the high  $\text{NH}_3/\text{SO}_2$  ratio (Trebs et al., 2005). In conclusion, the high deposition fluxes seem to be driven by particulate  $\text{NH}_4^+$  compounds, ammonium sulfate and ammonium nitrate. DELTA measurements revealed a slightly lower concentration of the  $\text{SO}_4^{2-}$  than the  $\text{NO}_3^-$  aerosol,  $1.28$  and  $1.63 \mu\text{g m}^{-3}$ , respectively, suggesting  $\text{NH}_4\text{NO}_3$  as the aerosol likely responsible for the measured  $\Sigma\text{N}_r$  deposition. Still, the dominant aerosol is not fully known due to missing high-resolution measurements of nitrogen aerosols.

The annual dry deposition estimates of all methods were in the same range considering uncertainties of measured fluxes and model applications (see Sect. 4.2 and 4.3). Annual estimates from TRANC were lower than the results from DEPAC-1D and LOTOS-EUROS. The reasons for the differences to the modeling approaches were elaborated in the previous sections. Possible uncertainties regarding model applications are described in the subsequent sections. Uncertainties in TRANC measurements were discussed in Sect. 4.3 of Wintjen et al. (2022). At the measurement site, both gap-filling methods led to similar dry deposition estimates. During summer, we found differences in the gap-filled fluxes due to the systematic overestimation of DEPAC-1D. It should be kept in mind that  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{HNO}_3$  were measured by long-term samplers and monthly concentration estimates may not be fully representative of local events. Saylor et al. (2019) noted that  $v_d$  of particles for forest are highly uncertain. Thus, differences to measurements could be expected. Besides missing emission fluxes in DEPAC-1D, the agreement of the dry deposition estimates was reasonable showing an inferential model like DEPAC-1D as an alternative gap-filling tool at sites or seasons with predominant N deposition.

Annual dry deposition estimates from TRANC, LOTOS-EUROS, and DEPAC-1D were found to be within the range of the lower and upper estimates of the CBT approach. Adding the wet-only deposition results reported in Wintjen et al. (2022) to determined dry depositions, we calculated annual total depositions ranging between  $11.5$  and  $14.8 \text{ kg N ha}^{-1} \text{ a}^{-1}$  noted in Table 2 for each year.

**Table 2** Annual  $\Sigma\text{N}_r$  deposition of TRANC, DEPAC-1D, LOTOS-EUROS, and CBT for 2016, 2017, and from January to June 2018 in  $\text{kg N ha}^{-1} \text{ a}^{-1}$ . Wet-only depositions of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and DON were adapted from Wintjen et al. (2022).

| Method               | 2016 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] | 2017 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] | Until June 2018 [ $\text{kg N ha}^{-1} \text{ a}^{-1}$ ] |
|----------------------|---|---|--|
| TRANC (MDV+DEPAC-1D) | 12.9  | 11.7  | 6.3  |
| TRANC (DEPAC-1D)     | 13.1  | 12.3  | 6.2  |
| DEPAC-1D             | 14.1  | 13.6  | 6.1  |
| LOTOS-EUROS          | 14.4  | 14.6  | 7.3  |
| CBT (upper estimate) | 11.5  | 12.2  |  |
| CBT (lower estimate) | 14.6  | 14.8  |  |

Comparing the results obtained from the measurement site to results obtained for other forest ecosystems using a similar validation procedure is rather difficult due to a large temporal and spatial variability in  $\text{N}_r$  compounds contributing to  $\Sigma\text{N}_r$ . Additionally, micrometeorological measurements as carried out in this study require substantial effort in maintenance and processing of the acquired data. Thus, most currently available EC measurements are limited to time periods covering a few weeks or months and are only available for certain locations.

Recently, Ahrends et al. (2020) compared deposition estimates of a CBT approach, an inferential method, and LOTOS-EUROS for several forest ecosystems. However, their CBT based on the variant suggested by Ulrich (1994), which is different to the

version used in this study, and their inferential method (IFM) was only applied to NO<sub>2</sub> and NH<sub>3</sub> due to the limited availability of ambient concentration measurements for other N<sub>r</sub> compounds. In addition, deposition velocities for NO<sub>2</sub> and NH<sub>3</sub> were  
645 calculated based on literature research for different forest types accompanied by various correction factors. They reported similar annual dry deposition estimates for CBT and IFM, which were found to be 12.6 and 12.9 kg N ha<sup>-1</sup> a<sup>-1</sup>, respectively. Minimum deposition was 3.8 kg N ha<sup>-1</sup> a<sup>-1</sup> for CBT and 1.0 kg N ha<sup>-1</sup> a<sup>-1</sup> for IFM. The lowest average deposition was 9.3 kg N ha<sup>-1</sup> a<sup>-1</sup> given by LOTOS-EUROS but minimum deposition was highest 6.3 kg N ha<sup>-1</sup> a<sup>-1</sup>. Since we measured N deposition in a low-polluted environment, the agreement to the minimum deposition estimates of Ahrends et al. (2020) seems reasonable.

650

In the consideration of critical loads, total nitrogen deposition is close to the proposed limits. Critical loads ranging from 10 to 15 kg N ha<sup>-1</sup> a<sup>-1</sup> and 10 to 20 kg N ha<sup>-1</sup> a<sup>-1</sup> were defined by Bobbink and Hettelingh (2011) for *Picea abies* and *Fagus sylvatica*, respectively. Since *Picea abies* was the prevailing tree species in the flux footprint (approx. 80%), the critical load of the investigated forest ecosystem is probably closer to the limits of *Picea abies*. Thus, the investigated forest ecosystem is in a  
655 potentially endangered state. It should be kept in mind that this result refers to the current climatic situation and concentration level of various N<sub>r</sub> compounds. Additionally, nitrogen input to the atmosphere on a broader scale will probably increase due to a growing population for which food security needs to be ensured. However, if proposed mitigation strategies on air pollutants, e.g., O<sub>3</sub> and NO<sub>2</sub> are successfully implemented in Europe, reductions in these gases could be still achieved even if global temperatures will rise by 2°C (Watson et al., 2016). Recently, van Damme et al. (2021) found that atmospheric NH<sub>3</sub>  
660 concentrations increased on different continents considering the years 2008 to 2018. Exceedances of critical loads could be still possible for forest ecosystems even at remote locations in the future.

#### 4.2 Uncertainties in DEPAC-1D

We identified wet leaf surfaces, high relative humidity, and lower temperatures as conditions enhancing ΣN<sub>r</sub> deposition from  
665 May to September. Wet conditions hold an important role in the deposition of NH<sub>3</sub> (Wentworth et al., 2016) and cuticular deposition was identified as a larger sink for NH<sub>3</sub> than stomatal deposition (Wyers and Erisman, 1998). However, the results from TRANC measurements highlighted higher temperatures, lower relative humidity, and dry leaf surfaces as important factors enhancing ΣN<sub>r</sub> deposition (Wintjen et al., 2022). Wet conditions, likely enhancing cuticular deposition of NH<sub>3</sub>, seemed to be most responsible for the ΣN<sub>r</sub> deposition at the measurement site as suggested by the models. The contradiction in wet  
670 and dry conditions lead to the assumption that the current implementation of the NH<sub>3</sub> exchange pathways in DEPAC was not fully suited for predicting NH<sub>3</sub> deposition correctly under all site characteristics and situations and needs further investigation. It should be kept in mind that we measured ΣN<sub>r</sub> exchange at low-polluted, mixed forest site (Beudert and Breit, 2010; Wintjen et al., 2022). Sites with different micrometeorology, vegetation, and pollution climate may exhibit other parameters like surface wetness, canopy temperature, and ambient concentration responsible for the ΣN<sub>r</sub> exchange as found by Milford et al. (2001).  
675 Further comparisons to flux measurements of ΣN<sub>r</sub> and NH<sub>3</sub> are needed to investigate the role of stomatal and cuticular deposition.

Schrader et al. (2016) discovered problems in the calculation of the cuticular NH<sub>3</sub> compensation point under high ambient NH<sub>3</sub> concentrations and high temperatures, for instance during summer. The current implementation of Wichink Kruit et al. (2010)  
680 in DEPAC likely underestimates the cuticular compensation point at high temperatures. This issue is not solved yet and could not be verified for our measurement site due to generally low NH<sub>3</sub> concentrations and the implementation of monthly averaged NH<sub>3</sub> concentration instead of half-hourly values in the concentration time series of NH<sub>3</sub> to some extent. However, NH<sub>3</sub> concentration were rather low at the measurement site, and the cuticular emission potential was estimated from monthly averaged concentrations in LOTOS-EUROS and DEPAC-1D, instead of instantaneous values as in the original

685 parameterization of Wichink Kruit et al. (2010), likely somewhat alleviating the issue discussed in Schrader et al. (2016). Thus,  
this issue could be not the main reason for the difference to flux measurements at our site. Unfortunately,  $\text{NH}_3$  flux calculation  
with the EC method was not possible at the measurement site. No distinct time lag was found during the entire measurement  
campaign. Presumably, variability in measured raw concentrations of  $\text{NH}_3$  could not be adequately identified by the  $\text{NH}_3$  QCL  
(Ferrara et al., 2021; Wintjen et al., 2022).

690

In case of  $\text{HNO}_3$ , a constantly, low  $R_c$  is assumed leading to a median  $v_d$  similar to  $\text{NH}_3$  since median  $R_c$  of  $\text{NH}_3$  was about  $15$   
 $\text{s m}^{-1}$  for the entire campaign. In general, deposition velocities of  $\text{NH}_3$ ,  $\text{HNO}_3$ ,  $\text{NO}_2$ , and  $\text{NO}$  proposed by the Association of  
German Engineers (VDI, 2006) were generally larger than modeled medians (see Fig. 3). Deposition velocity of  $\text{NH}_3$  was in  
the range of values reported by Schrader and Brümmer (2014) for mixed forests. In addition, Horii et al. (2006), Pryor and  
695 Klemm (2004), and Farmer and Cohen (2008) found deposition velocities for  $\text{HNO}_3$  similar to our results. However, emissions  
for  $\text{HNO}_3$  were reported in recent publications (Tarnay et al., 2002; Farmer and Cohen, 2006, 2008). The latter conducted flux  
measurements of  $\text{HNO}_3$  above a pine forest and found a significant contribution of emission fluxes during summer. Those  
emission could also be induced by the evaporation of  $\text{NH}_4\text{NO}_3$  from leaf surfaces occurring at higher temperatures (Wyers and  
Duyzer, 1997; Van Oss et al., 1998), by interactions with hydrochloric acid, or particles deposited or formed on leaf surfaces  
700 as discussed by Nemitz et al. (2004).

Deposition velocities for  $\text{NO}$  and  $\text{NO}_2$  were in agreement with values reported in several studies, e.g., mostly ranging between  
 $0.005$  and  $0.012 \text{ cm s}^{-1}$  for  $\text{NO}$  (Delaria, et al., 2018) and between  $0.015$  and  $0.51 \text{ cm s}^{-1}$  for  $\text{NO}_2$  (e.g., Rondon et al., 1993;  
Horii et al., 2004; Chaparro-Suarez et al., 2011; Delaria, et al., 2018, 2020). However, emission fluxes of  $\text{NO}$  and  $\text{NO}_2$  were  
705 reported in several publications, e.g., Farmer and Cohen (2006), Horii et al. (2004), and Min et al. (2014) leading to the  
assumption of the existence of a compensation point (Thoene et al., 1996), but a compensation point for  $\text{NO}$  and  $\text{NO}_2$  is still  
under discussion (Chaparro-Suarez et al., 2011; Breuninger, et al. 2013; Delaria, et al., 2018, 2020).

Including a soil compensation point in DEPAC, can lead to a reduction in deposition at sites with generally low  $\Sigma\text{N}_r$  deposition  
710 and at sites with sparse vegetation. For entire campaign, median deposition velocities for  $\text{tot-NH}_4^+$  and  $\text{tot-NO}_3^-$  ( $3.4$  and  $4.2$   
 $\text{cm s}^{-1}$ , respectively) are likewise comparable to values reported by Wolff et al. (2010). Their values for  $v_d$  agreed well with the  
inverse of  $R_a$ . Farmer et al. (2011) and Gordon et al. (2011) reported  $v_d$  for  $\text{NH}_4^+$  and  $\text{NO}_3^-$ , respectively. They found an average  
 $v_d$  of  $0.48 \text{ cm s}^{-1}$  for  $\text{NO}_3^-$  and  $0.19 \text{ cm s}^{-1}$  for  $\text{NH}_4^+$  around noon.

715 Besides the current implementation of the exchange pathways in DEPAC, deposition estimates could be more accurate if  
concentration measurements at a higher time resolution and measurements of the LAI would have been available. We did not  
take measurements of the LAI or other vegetation properties at the measurement site. Still, the interpretation of differences to  
flux measurements would be challenging since the vegetation inside the flux footprint was not uniform. Inside the footprint,  
we identified dead wood in southern direction and a mix of rather young and matured trees in easterly direction. Differences  
720 in tree age were related to a dieback by bark beetle in the mid-1990s and 2000s (Beudert and Breit, 2014) from which the  
forest stand is still recovering. Shifting  $z_0$  or  $d$  by  $\pm 50 \%$ , caused a change of  $+5.0 \%$ / $-3.2 \%$  and  $+5.6 \%$ / $-9.1 \%$ , respectively,  
in the nitrogen dry deposition after 2.5 years. An incorrect assessment of the modeled LAI by  $\pm 50 \%$  had a significant influence  
on the dry deposition. It led to a change of  $+18.9 \%$ / $-27.2 \%$ . It shows that in further field applications of DEPAC-1D  
measurements the LAI should be considered, but an incorrect assessment of the LAI would not solely explain the  
725 overestimation of DEPAC-1D to TRANC measurements. The main uncertainty of DEPAC-1D fluxes was most likely the  
usage of monthly integrated DELTA concentrations for the  $\text{N}_r$  compounds. Thus, instationarities in the timeseries of these  
compounds happened on timescales of a few seconds were not accounted in deposition modeling. Even with high-resolution

730 measurements of the QCL, the short-term variability in  $\text{NH}_3$  concentrations was not detectable (Wintjen et al., 2022). As stated  
in Sec. 2.2.3, we did not superimpose monthly concentrations values with synthetic diurnal patterns. Concentrations of  $\text{N}_r$   
compounds are highly variable during the day and depend on various parameters such as turbulence, temperature, relative  
humidity, precipitation, emission sources, etc. Reproducing influences of those parameters with averaged diurnal cycles about  
at least weeks or months, is not possible. We found that  $\text{NH}_3$  concentration was generally low during winter and assigned with  
a low variability as found by measurements. During those times, using monthly integrated averages is reasonable (Schrader et  
al., 2018). However, we probably overestimated modeled fluxes due to the use of monthly averaged concentrations. In order  
735 to get at least an impression which  $\text{N}_r$  compounds' fluxes are probably biased by this approach, we compared monthly averaged  
fluxes of LOTOS-EUROS (A1) with fluxes calculated by multiplying monthly averaged  $v_d$  with their monthly concentration  
averages (A2) and subsequently corrected them by applying Eq. (9) and (10) of Schrader et al. (2018). Generally, we found  
that all  $\text{N}_r$  compounds' fluxes were overestimated by A2 whereas the difference to A1 depends on the investigated  $\text{N}_r$   
compound and season. All  $\text{N}_r$  compounds had in common that the difference between both approaches was negligible during  
740 seasons with small deposition fluxes, for example in winter. Within seasons of large deposition fluxes, significant discrepancies  
were found, in particular for  $\text{NH}_3$ . Overall, mean absolute deviations to A1 were 35.0, 0.27, 0.18, 0.92, 2.5, and 2.4  $\text{ng N m}^{-2}$   
 $\text{s}^{-1}$  for  $\text{NH}_3$ ,  $\text{NO}_2$ ,  $\text{NO}$ ,  $\text{HNO}_3$ ,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$ , respectively.

745 It should be considered that we used LOTOS-EUROS data for this comparison. Especially for  $\text{NH}_3$ ,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$ , their  
modeled seasonality and concentrations exhibited significant disagreements to DELTA measurements. Thus, the flux  
overestimations should be seen as highest guess. Measured high resolution concentrations would have led to lower values.  
Still, the comparison highlights the necessity for high-resolution measurements of  $\text{N}_r$  compounds. Those measurements should  
be made for  $\text{N}_r$  compounds, which probably prevail the exchange dynamics of  $\Sigma\text{N}_r$  at a certain site and thereby at least cover  
time periods with large temporal variations in their concentrations. This procedure was performed for  $\text{NH}_3$  and  $\text{NO}_2$  at the  
750 measurement site.

Devices measuring  $\text{NH}_3$ ,  $\text{HNO}_3$ , or  $\text{NO}_x$  with a high sampling rate have high costs, high power consumption, and require  
regular maintenance, e.g. for  $\text{NH}_3$  (Whitehead et al., 2008; Ferrara et al., 2012, 2021; Zöll et al., 2016; Moravek et al., 2019).  
A setup consisting of such instruments for each  $\text{N}_r$  compound, installed at various ecosystems is in most cases not affordable.  
755 A combination of DELTA and high-resolution sampling devices installed at sites for a limited time period to investigate  
concentration and flux dynamics may become a proper solution as suggested by Schrader et al. (2018) for  $\text{NH}_3$  and could lead  
to significant improvements in the implemented parameterizations of various  $\text{N}_r$  compounds. Depending on vegetation and  
pollution climate, only high-resolution measurements of certain  $\text{N}_r$  compounds may be of interest. At agricultural sites as an  
example, only instruments measuring the  $\text{NH}_3$  exchange are needed since processes controlling the  $\Sigma\text{N}_r$  exchange are most  
760 likely driven by a high  $\text{NH}_3$  background concentration (Ammann et al., 2012; Brümmer et al., 2013).

#### 4.3 Uncertainties in LOTOS-EUROS

The larger nitrogen deposition values for the measurement site as modeled by LOTOS-EUROS are mostly related the  
overestimation of  $\text{NH}_3$  concentrations. As visualized by Fig. S1, LOTOS-EUROS clearly overestimated observed  $\text{NH}_3$   
765 concentrations in spring and autumn. Such an overestimation of  $\text{NH}_3$  and  $\text{NH}_4^+$  in precipitation at forest monitoring sites was  
identified before for stations in Baden-Württemberg and Bavaria (Schaap et al., 2017). A similar systematic overestimation in  
southern Germany has also been identified in comparison to novel  $\text{NH}_3$  satellite data (Ge et al., 2020). This leads us to believe  
that the overestimation is for a large part due to shortcomings in the emission information, potentially in combination with the  
model resolution.

770 The emission inventory used in this study spatially allocates  $\text{NH}_3$  manure derived emissions through a procedure in which the  
animal numbers per region and agricultural land within a region are the two proxies used. Emissions from fertilizer application  
are allocated solely on land use. Hence, within a region all agricultural land is assumed to emit the same amount of  $\text{NH}_3$ ,  
although the intensity of the agricultural practice and distribution of housing may vary substantially within such a region. Only  
south of the station, agricultural lands are located within  $7 \times 7 \text{ km}^2$  (the model resolution) of the site. This means that in the  
775 grid cell of the model, in which the station is located, there is an emission source present contributing an increased  $\text{NH}_3$   
concentration even when the wind directions are not transporting air from this agricultural region towards the station. The low  
measured concentrations of  $\text{N}_r$  compounds show that the site was mostly outside the transport range of nitrogen enriched air  
masses. A reduction in grid cell size could lead to a more precise localization of potential nitrogen emission sources and a  
better description of close-range transport and dilution effects. For a simulation covering 2015, we were able to calculate  
780 concentrations and fluxes at a higher grid cell resolution ( $2 \times 2 \text{ km}^2$ ) and compared the results to the standard resolution. In  
case of the high grid cell resolution, concentrations were lower but only by 2 to 10 % depending on the compound compared  
to standard resolution. For the whole grid cell, annual N budget of the high-resolution fluxes was higher than the budget of the  
standard resolution case study, but only by 4.3 % probably due to the relative increase in forest cover. The higher grid cell  
resolution probably led to improvements in modeling atmospheric turbulence resulting in higher deposition velocities. This  
785 example shows that the grid cell resolution of  $7 \times 7 \text{ km}^2$  is not mainly responsible for the overestimation of the  $\text{NH}_3$   
concentrations and  $\text{N}_r$  fluxes.

Nevertheless, the seasonal cycle also indicates that the emissions in spring, which are related to manure and fertilizer  
application, are too strong. The agricultural fields close to the Bavarian Forest are predominantly extensively managed grass  
lands. Manure application to grass lands is known to occur much more spread out across the year in comparison to the  
790 application for crop production, which mainly occurs before the growing season. Hence, in reality the emission variability  
maybe prone more to summer conditions favoring fast mixing and dilution of  $\text{NH}_3$ . Currently, the detailing of crop dependent  
emissions, the use variable emission fractions within German regions in combination with the recent timing module of Ge et  
al. (2020) is under investigation to elucidate if these factors are contributing to the observed mismatches.

795 Additional features may also contribute to the observed differences. Within LOTOS-EUROS, modeled concentrations were  
written out for a reference height of 2.5 m above ground, which was lower than the measurement height of the flux tower.  
Thus, slight differences in micrometeorological data could be expected, for example the difference in relative humidity in the  
first half of 2016. Differences for that time period were related to the usage of local meteorological data taken at 50 m, with  
their instrumentation being installed at the 50 m platform. The deviations in  $u^*$  as illustrated in Fig. S6 and Fig. 5 were related  
800 to differences in measurement heights at which wind speeds and roughness lengths were calculated. The model grid cell  
consists of various vegetation types each with a unique surface roughness length. We showed that the weighting of the land  
use classes within the grid cell was not in agreement with the vegetation of the flux foot print affecting micrometeorological  
variables, e.g.  $u^*$ ,  $L$ , and thereby the calculation of  $R_a$  and  $R_b$ . Aerosol deposition contributed significantly to overall dry  
deposition of LOTOS-EUROS as shown in Fig. 7. In particular during winter,  $v_d$  of LOTOS-EUROS was greatly enhanced  
805 for  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{HNO}_3$  compared to DEPAC-1D. Above snow-covered surfaces, unstable stratifications prevailed in the  
simulations. In addition, Figure S6 revealed large discrepancies in  $u^*$  to the measurements. Consequently,  $R_a$  and  $R_b$  were  
reduced compared to DEPAC-1D resulting in large deposition velocities.

An incorrect setting of the LAI and  $z_0$  can have a significant influence on  $\Sigma\text{N}_r$  deposition as shown in the previous chapter.  
The results of our sensitivity analysis for LAI and  $z_0$  were comparable to values presented recently by van der Graaf et al.  
810 (2020), who used satellite-derived LAI and  $z_0$  data from Moderate Resolution Imaging Spectroradiometer (MODIS) to  
calculate  $\Sigma\text{N}_r$  deposition with LOTOS-EUROS for a grid cell size of  $7 \times 7 \text{ km}^2$ . Overall, they observed changes in  $\Sigma\text{N}_r$  dry  
deposition of up to 30%. However, there was almost no change in  $\Sigma\text{N}_r$  dry deposition and in  $\text{NH}_3$  concentration observable for

the Bavarian Forest measurement site if LAI and  $z_0$  from MODIS were used. The attempts of van der Graaf et al. (2020) and Ge et al. (2020) did not provide a solution for the general overestimation of the  $\text{NH}_3$  deposition above southern Germany. It  
815 seems that larger scale and temporal discrepancies in modeled  $\text{NH}_3$  concentrations could be responsible for the disagreement to flux measurements, and overestimation was only partly related to other issues, for example, the grid cell size of  $7 \times 7 \text{ km}^2$ . Further investigations on these issues are needed.

### Summary & Conclusions

We conducted a comparison of total reactive nitrogen ( $\Sigma\text{N}_r$ ) dry deposition estimates determined by ecological and  
820 micrometeorological methods at a remote, mixed forest site for 2.5 years. We determined annual  $\Sigma\text{N}_r$  deposition from flux measurements by using the Total Reactive Atmospheric Nitrogen Converter (TRANC) coupled to a chemiluminescence detector (CLD), an in-situ inferential modeling approach using the bidirectional resistance scheme DEPAC (Deposition of Acidifying Compounds) (here called DEPAC-1D), the chemical transport model LOTOS-EUROS (Long Term Ozone Simulation – EUROpean Operational Smog) v2.0, and by applying the canopy budget technique (CBT).

825 We found that modeled  $\Sigma\text{N}_r$  concentrations were on average at  $5.0 \mu\text{g N m}^{-3}$ , compared to  $3.1 \mu\text{g N m}^{-3}$  measured with the TRANC for the entire campaign. A comparison to monthly integrated concentrations of compounds contributing to  $\Sigma\text{N}_r$ , obtained from passive sampler and DELTA (DENuder of Long-Term Atmospheric sampling) measurements revealed that ammonia ( $\text{NH}_3$ ) concentrations were overestimated by the model by a factor of two to three compared to measured values. In addition,  $\text{NH}_3$  contributed most to the  $\Sigma\text{N}_r$  concentration pattern in LOTOS-EUROS whereas  $\text{NO}_x$  was identified as  
830 predominant compound by measurements. Fluxes predicted by LOTOS-EUROS were substantially higher during spring and winter, and the diurnal flux pattern was not in agreement with TRANC fluxes. DEPAC-1D fluxes were close to the measured fluxes in winter, but deposition was clearly overestimated in summer. From May to September, TRANC and DEPAC-1D deposition velocities differed in their response to micrometeorological variables. A further investigation of stomatal vs. non-stomatal deposition pathways needs to be conducted as these are likely factors for discrepancies in modeling vs. measuring.

835 For 2016 and 2017, the following averaged annual  $\Sigma\text{N}_r$  dry deposition were found:

- For TRANC measurements,  $4.3 \pm 0.4$  and  $4.7 \pm 0.2 \text{ kg N ha}^{-1} \text{ a}^{-1}$  were estimated using the Mean-Diurnal-Variation approach in combination with DEPAC-1D and DEPAC-1D only, respectively.
- The application of DEPAC-1D resulted in  $5.8 \pm 0.1 \text{ kg N ha}^{-1} \text{ a}^{-1}$ .
- For the site-specific land-use fractions,  $6.5 \pm 0.3 \text{ kg N ha}^{-1} \text{ a}^{-1}$  was predicted by LOTOS-EUROS
- Minimum and maximum dry deposition of the CBT analysis were  $3.8 \pm 0.5$  and  $6.7 \pm 0.3 \text{ kg N ha}^{-1} \text{ a}^{-1}$ , respectively.

840 Including wet deposition estimates from nearby wet-only samplers in the budget calculation, resulted in annual total nitrogen depositions between  $11.5$  and  $14.6 \text{ kg N ha}^{-1} \text{ a}^{-1}$  and between  $11.7$  and  $14.8 \text{ kg N ha}^{-1} \text{ a}^{-1}$  for 2016 and 2017, respectively, thereby being close to the upper limit of the critical load ranges for deciduous and coniferous forests implying that the forest is just at the limit of receiving too much nitrogen from the atmosphere.

845 Differences between DEPAC-1D and TRANC measurements could be related to erroneous parametrizations in the exchange pathways of reactive gases, the usage of low-resolution input data, or the missing exchange pathway with soil. Besides possible uncertainty sources in DEPAC-1D, dry deposition estimates of both gap-filling approaches were similar showing that DEPAC-1D (and by extension, inferential modeling in general) is a valuable gap-filling tool at sites with prevailing N deposition. The difference to LOTOS-EUROS was mainly related to an overestimation of  $\text{NH}_3$  concentrations. A larger-scale aspect may be  
850 responsible for that issue since the general overestimation of  $\text{NH}_3$  concentrations has still not been solved by several attempts. We found that all estimates were in similar within reasonable margins. However, further comparisons of flux measurements and model applications are needed to investigate exchange characteristics of  $\Sigma\text{N}_r$  and its individual compounds, if possible, simultaneously and at different ecosystems. Measuring several  $\text{N}_r$  compounds and  $\Sigma\text{N}_r$  at a high time resolution is probably

not affordable due to maintenance costs, high technical requirements, and time-consuming processing of the acquired data. A  
855 solution could be continuous monitoring of  $N_r$  compounds by low-cost samplers complemented by high-frequency  
measurements of  $\Sigma N_r$  and selected compounds like  $NH_3$  for a limited time, which will result in a better understanding of  
exchange processes and thus in an improvement of deposition models (cf. Schrader et al., 2018).

860

*Code and data availability.* All data are available upon request from the first author of this study (pascal.wintjen@thuenen.de).  
Concentration, flux, and micrometeorological data from measurements and ecological information about the site are included  
in the following repository: <https://zenodo.org/record/5841074> (Brümmer et al., 2022a). Also, Python 3.7 code for flux data  
analysis can be requested from the first author.

865

*Author contributions.* PW, FS, MS, and CB conceived the study. PW wrote the manuscript, carried out the measurements at  
the forest site, and the comparison of measured and modeled flux data and interpretation. FS evaluated meteorological  
870 measurements and set up DEPAC-1D. MS and RK provided insights in interpreting LOTOS-EUROS results. BB conducted  
canopy throughfall and wet deposition measurements. CB installed the instruments at the site. The results were thoroughly  
discussed with all authors, and FS, MS, BB, RK, and CB contributed to the manuscript.

875

*Competing interests.* The authors declare that they have no conflict of interest.

880 *Acknowledgements.* We thank Undine Zöll for scientific and logistical help to the measurements, Jeremy Rüffer and Jean-  
Pierre Delorme for excellent technical support, Ute Tambor, Andrea Niemeyer, and Dr. Daniel Ziehe for conducting laboratory  
analyses of denuder and filter samples, and the Bavarian Forest Nationalpark (NPBW) Administration, namely Wilhelm Breit  
and Ludwig Höcker for technical and logistical support at the measurement site.

885

*Financial support.* This work has been funded by the German Environment Agency (UBA) (project FORESTFLUX, support  
code FKZ 3715512110) and by the German Federal Ministry of Education and Research (BMBF) within the framework of the  
Junior Research Group NITROSPHERE (support code FKZ 01LN1308A).
