Abstract. The reasons for spatial and temporal variation of methane emission from mire ecosystems are not fully understood. Stable isotope signatures of the emitted methane can offer cues to the causes of these variations. We measured the methane emission and ^{13}C -signature of emitted methane by automated chambers at a temperate mire for two growing
15 seasons. In addition, we used ambient methane mixing ratios and $\delta^{13}\text{C}\text{-CH}_4$ to calculate a mire-scale ^{13}C signature using a nocturnal boundary-layer accumulation approach. Microbial methanogenic and methanotrophic communities were determined by a captured metagenomics analysis. The chamber measurements showed large and systematic spatial variations in $\delta^{13}\text{C}\text{-CH}_4$ of up to 15 ‰ but smaller and less systematic temporal variation. The trophic status of methanogenesis was the
20 dominant factor explaining the spatial variation. Genetic analysis indicated that methanogenic communities at all sample locations were able to utilize both hydrogenotrophic and acetoclastic pathways and could thus adapt to trophic status. The temporal variation of methane emission and $\delta^{13}\text{C}\text{-CH}_4$ over the growing seasons showed hysteresis-like behavior, indicative of time-lagged responses to temperature and trophic status. The up-scaled chamber measurements and nocturnal boundary-layer accumulation measurements showed similar average $\delta^{13}\text{C}\text{-CH}_4$ values of -81.3 ‰ and -79.3 ‰, respectively, lending
25 confidence to the use of mire scale isotopic signatures to be used in e.g. atmospheric inversion modelling of methane sources. The results obtained can constrain our theories on the variability of methane emission from mire ecosystems and be useful in development of numerical models of mire biogeochemistry.

1 Introduction

30 Methane (CH_4) is the one of the three main drivers of anthropogenic climate change. Its sources include both biological and anthropogenic processes, with the most significant natural source being wetland ecosystems (Ciais et al., 2013). As changing

climate may influence global CH₄ emission from wetlands, a mechanistic understanding of the processes behind these emissions is crucial.

35 The CH₄ emission rates from wetlands are controlled by CH₄ production (methanogenesis), CH₄ oxidation (methanotrophy),
and the transport of CH₄ from peat into the atmosphere (e.g. Lai, 2009). A fundamental factor for CH₄ production by
Archaea is the trophic status (i.e. availability of substrates), as H₂ or acetate for hydrogenotrophic or acetoclastic
methanogenesis, respectively (e.g. Lai, 2009). Furthermore, temperature is a key driver of the CH₄ emission rate via its effect
on microbial activity, as seen by the incubations of peat samples conducted at different temperatures (Juottonen et al., 2008).
Water table position and the presence of alternative electron acceptors can also influence the spatial or temporal behavior of
40 CH₄ production (e.g. Serrano-Silva et al., 2014). A part of the produced CH₄ is commonly oxidized in the wetland, and thus
not emitted into the atmosphere (e.g. Larmola et al., 2010). This methanotrophy is caused by methanotrophic micro-
organisms (*bacteria*), and it may also be dependent on temperature (Serrano-Silva et al., 2014). Finally, CH₄ can be
transported from the anoxic layers to the atmosphere by three different mechanisms: diffusion through the peat matrix,
ebullition, and plant mediated transport (Lai, 2009). The later can be further divided into passive diffusive transport and
45 active convective transport (Brix et al., 1992).

The observed CH₄ emissions from wetland ecosystems exhibit both temporal and spatial variations, which reflect the
variation in the above-mentioned processes, often in tandem. Typically, CH₄ emission rates vary spatially over short
distances following surface microtopography (Riutta et al., 2007; Keane et al., 2021), and related differences in vegetation
50 characteristics. The highest emission rates are commonly observed in wetter locations, with abundant aerenchymatous
vegetation, whereas the lowest emission rates are observed at dry hummocks or inundated locations (e.g. Riutta et al., 2007,
Keane et al., 2021). This microtopography-scale spatial variation in CH₄ emission can be caused by differences in the
methanogenesis, methanotrophy, or transport pathways in these different locations (Joabsson et al., 1999; Joabsson &
Christensen 2001).

55

Temporally, we commonly see a seasonal cycle in the CH₄ emission rates, with the highest emission rates in late summer
(Rinne et al., 2018; Heiskanen et al., 2021b; Łakomiec et al., 2021). This seasonal variation has been associated with the
seasonal cycle of peat temperature, substrate availability, and transport pathways (Rinne et al., 2018; Chang et al., 2020;
2021). Diel variation of CH₄ emission rates has also been observed in wetlands with vegetation such as *Phragmites*, *Typha*,
60 and Water lilies that exhibits pressurized airflow into the root systems, (Kim et al., 1998; Kowalska et al., 2013), whereas
wetlands with vegetation that exhibits diffusive air transport show little or no diel cycle in their CH₄ emission (Rinne et al.,
2007; Jackowicz-Korczyński et al., 2010; Kowalska et al., 2013). In many cases the predominance of any one cause for
temporal variation in CH₄ emission may be difficult to verify, as the variation of these different processes may lead to similar
variations in the resulting CH₄ emission rate (Chang et al., 2021).

65

CH₄ emitted from different sources (e.g. mires with different methanogenic pathways, waste, ruminants, termites etc.) is characterized by different isotopic composition (Miller, 2005; Hornibrook 2009), and this isotopic composition can offer clues to the processes behind these emissions. The major component of CH₄, carbon, has two stable isotopes, ¹²C and ¹³C, which make up 98.9% and 1.1% of carbon in nature, respectively. While different isotopes of the same element behave chemically identically, their different masses cause differences in their diffusion rates, and thus in the rates of many biological processes. This will lead to differences in the isotopic ratios of CH₄ as it goes through methanotrophy, methanogenesis or transport from the anoxic peat layers to the atmosphere

70

The ¹³C signature, or δ¹³C value, of CH₄ emitted by mire ecosystems depends on its production pathway, and subsequent transport and oxidation (Hornibrook, 2009). Of the two dominating methanogenic pathways in wetlands, hydrogenotrophic methanogenesis typically produces isotopically lighter CH₄ (lower δ¹³C) than CH₄ produced by acetoclastic pathway (Hornibrook, 2009). Furthermore, microbial oxidation of CH₄ can shift the emitted CH₄ in the isotopically heavier direction (higher δ¹³C) as microbial methanotrophy prefers lighter ¹²C-CH₄ (Hornibrook 2009). Thus, the δ¹³C values of the emitted CH₄ can be used as an additional constraint when interpreting the observed CH₄ emission rates to disentangle the processes responsible for the spatial and temporal variation in CH₄ emission. For example, recent analysis has shown hysteresis-like behavior between surface temperatures and CH₄ emission rates in mire ecosystems, and the possible causes of this phenomenon are debated (Chang et al., 2020; 2021; Łakomiec et al., 2021). Similar hysteresis-like behavior has also been observed between photosynthesis and CH₄ emission rates (Rinne et al., 2018). Stable isotope signatures of emitted methane can constrain our hypotheses on the causes of these behavior.

85

In this study, we analyze the observed spatial and temporal variation of CH₄ emission rates from a temperate mire ecosystem and its ¹³C signature to understand the causes of these variations. We aim to resolve the relative importance of methanogenesis and methanotrophy for the spatial variation in the CH₄ emission rate, and the roles of precursor substrate availability and temperature for the seasonal variation of the CH₄ emission rate. We also use taxonomy data to characterize the methanogenic and methanotrophic microbial communities in the mire to reveal the potential of methane production via different pathways as well as microbial methane oxidation.

90

In order to interpret the variation in CH₄ emission rates and their δ¹³C values, we have formulated alternative hypotheses for the causes of the spatial and temporal variations of methane emission rates. From these we have deduced expected relations between CH₄ emission rates and their δ¹³C values.

95

2 Hypotheses

We will consider two commonly observed phenomena in the variation of CH₄ emission rates from mires. First, there is a spatial variation at the microtopographic level, with the lowest emissions from dry hummocks and inundated ponds and
100 highest emissions from wet lawns (e.g. Riutta et al., 2007; Keane et al., 2021). Second, there is a temporal variation at the seasonal scale, which lags the cycle of air and peat surface temperature and GPP, but follows the temperature of deeper peat (e.g. Rinne et al., 2018; Chang et al., 2020; 2021; Łakomiec et al., 2021).

We have two hypotheses regarding the processes leading to the small-scale spatial variability of the CH₄ emission rate. In the
105 first hypothesis on spatial variability (HS1), we assume that the production of CH₄ beneath wetter and drier surfaces is equal but that oxidation by methanotrophic organisms in the drier surfaces leads to lower emission of CH₄ from the drier surfaces compared to the wetter surfaces (Figure 1). In the second spatial hypotheses (HS2), we assume that the differences in CH₄ emission rate between wet and dry surfaces reflect differences in CH₄ production due to differences in the trophic status (substrate availability) for methanogenesis. HS1 would lead to negative correlation between CH₄ emission rate and δ¹³C
110 value of emitted CH₄ (because methanotrophy prefers ¹²C, leaving more ¹³C to the emitted CH₄). HS2, on the other hand, would lead to positive correlation between CH₄ emission rate and its δ¹³C value, because acetoclastic CH₄ production while typically associated with higher methane emission rates of more productive mires, leads to less ¹³C depleted CH₄ than the hydrogenotrophic pathway (Chanton et al., 2005). Thus, the two hypotheses lead to distinctly different predictions on the relationship between CH₄ emission rate and its δ¹³C value (Hornibrook 2009).

115 For the seasonal variation of CH₄ emission rate, we hypothesize that the variation is either due to the seasonal development of temperature, or that it is modified heavily by the availability of precursor substrates for methanogenesis (Chang et al., 2020; 2021). In the first hypothesis on the temporal variation (HT1), we assume that the temporal variation is due to the seasonal change in peat temperature. As this does not change the δ¹³C value of emitted CH₄, there will be no temporal
120 correlation between CH₄ emission rate and its δ¹³C value (Figure 2). In the second temporal hypothesis (HT2) we assume that the seasonal cycle of the CH₄ emission rate is due to the changes in trophic status, i.e. between acetoclastic-dominated (AM) and hydrogenotrophic-dominated (HM) methanogenesis. This would lead to positive correlation between CH₄ emission rate and its δ¹³C value. In the third temporal hypothesis (HT3) we assume that there are time lags between the seasonal cycles of temperature, trophic status, and CH₄ emission rate, which leads to hysteresis-like behavior in the
125 relationship between CH₄ emission rate and its δ¹³C value.

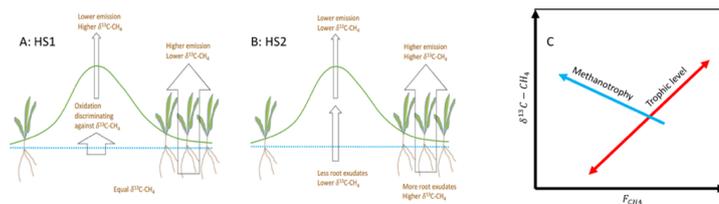

Figure 1: Spatial variation of methane emission based on two hypotheses: A: HSI, variation is due to methanotrophy; and B: HS2, variation is due to methanogenesis and substrate status. Resulting relations between $\delta^{13}\text{C}-\text{CH}_4$ and F_{CH_4} are shown in panel C.

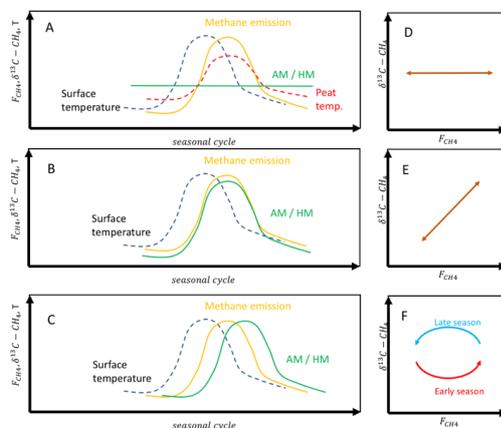

Figure 2: Seasonal variation of methane emission with hypotheses on controlling processes (A: HT1; B: HT2; C: HT3) and resulting relations between $\delta^{13}\text{C}-\text{CH}_4$ and F_{CH_4} (D-F). AM/HM indicates trophic status (AM: Acetoclastic-dominated methanogenesis, HM: Hydrogenotrophic-dominated methanogenesis).

3 Methods

3.1 Study site and ancillary measurements

140 We conducted the measurements at Mycklemossen mire (58°21'N 12°10'E, 80 m a.s.l., Figure 3) in south western Sweden
in 2019 and 2020. The site is a part of SITES¹ Skogaryd research catchment and a candidate to be a class 2 ecosystem site
within the ICOS² research infrastructure (Heiskanen et al., 2021a). Mycklemossen mire lies within the temperate /
hemiboreal forest zone. The annual 30-year average air temperature from a nearby weather stations is 6.8°C (1981-2010,
SMHI Vänersborg) and annual precipitation is 800-1000 mm (1981-2010, SHMI Vänersborg and Uddevalla). The mire is a
145 poor fen with bog characteristics in its vegetation and pH of 3.9-4.0 (Rinne et al., 2020).

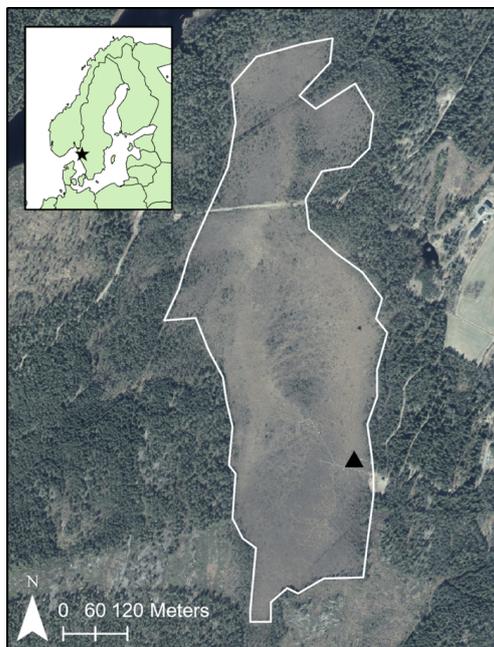

Figure 3: Map of Mycklemossen (outlined in white). Black star indicates the location of Mycklemossen within Scandinavia, black triangle indicates the location of the chamber and NBLA measurements. Data sources: © Lantmäteriet, ©

² Integrated Carbon Observation System, <https://www.icos-cp.eu/>

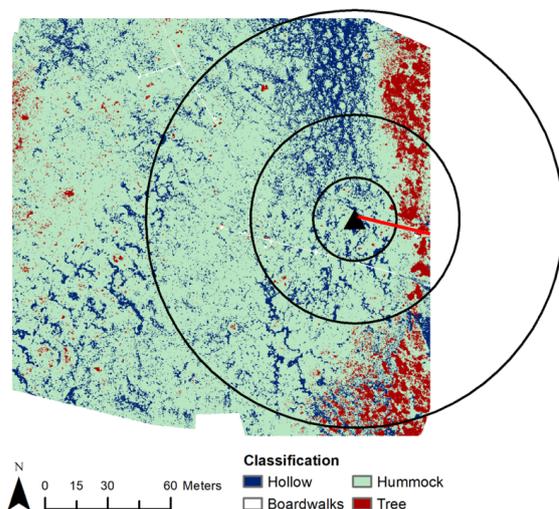

A range of meteorological and hydrological parameters are available from the Mycklemossen research site, including air temperature, peat temperature at different depths at four locations, and water table position at three locations.

3.2 CH₄ emission and δ¹³C measurements

We used two approaches to measure the δ¹³C value of the emitted CH₄, the automated static chamber approach (e.g. McCalley et al., 2014) and the nocturnal boundary-layer accumulation (NBLA) approach (e.g. Sriskantharajah et al., 2012). With the former we obtain CH₄ emission rate and its δ¹³C value resolved at the microtopographic scale, while with the latter we obtain an average δ¹³C value of the emitted CH₄ over a larger area of the mire.

For the chamber approach, we used six automated chambers with dimensions of 44.5 x 44.5 x 40.5 cm. In addition, the frame onto which the collar is placed introduces additional volume, as it is approximately 5 cm high from the peat surface. This volume is more challenging to determine accurately due to the uneven peat surface. The chambers were transparent (made out of Polymethyl methacrylate) with a lid that opened and closed automatically. Each chamber was equipped with a fan to ensure sufficient mixing of air in the chamber headspace, a soil thermometer (probe 107, Campbell Scientific, Inc., UT, USA), a PAR sensor (SQ-500, Apogee Instruments Inc., UT, USA) situated inside the chamber and a vent-tube to prevent pressure changes when opening and closing the lid. Each chamber cycle was 30 minutes and started with 5 minutes where the chamber and the tubing to and from the gas analyzer was ventilated. The chamber lid then closed for 25 minutes. The long closure time was needed to ensure a robust fit using the Keeling plot approach (Keeling, 1958). All measurements of the methane mixing ratios and δ¹³C were performed using a Picarro G2201-i cavity ring-down spectroscopic (CRDS) analyzer (Picarro Inc., CA, USA). The chamber measurements were conducted between 07:00 – 19:00, resulting in four measurements from each chamber every day. The time between 19:00 and 07:00 was used for measurements with the NBLA approach.

The chambers were placed along a boardwalk (Figure 4). The topography of the mire is not very pronounced with the maximum difference in surface height between chamber locations being 17 cm. Furthermore, the relative elevations were not indicative for the dominant vegetation in the chambers (Table 1, Figure 5). The vegetation in the chamber plots falls into three categories. In plots 1 and 2 there is a major presence of aerenchymatous sedges, typical for moist conditions in the mire. Plot 3 is dominated by *Sphagnum* mosses, also common in moist conditions. In 4 and 5 there is considerable presence of woody shrubs, typical for drier conditions. Plot 6 is an intermediate between sedge-dominated and shrub-dominated.

180

Figure 4: Distribution of dry and wet areas in Mycklemossen according to microtopography. The black triangle indicated the sampling location of measurements used for nocturnal boundary-layer accumulation (NBLA) approach. The chambers were situated along the boardwalk (red line). Black circles indicate the distances (20 m, 50 m, 100 m) from NBLA sampling point.

185

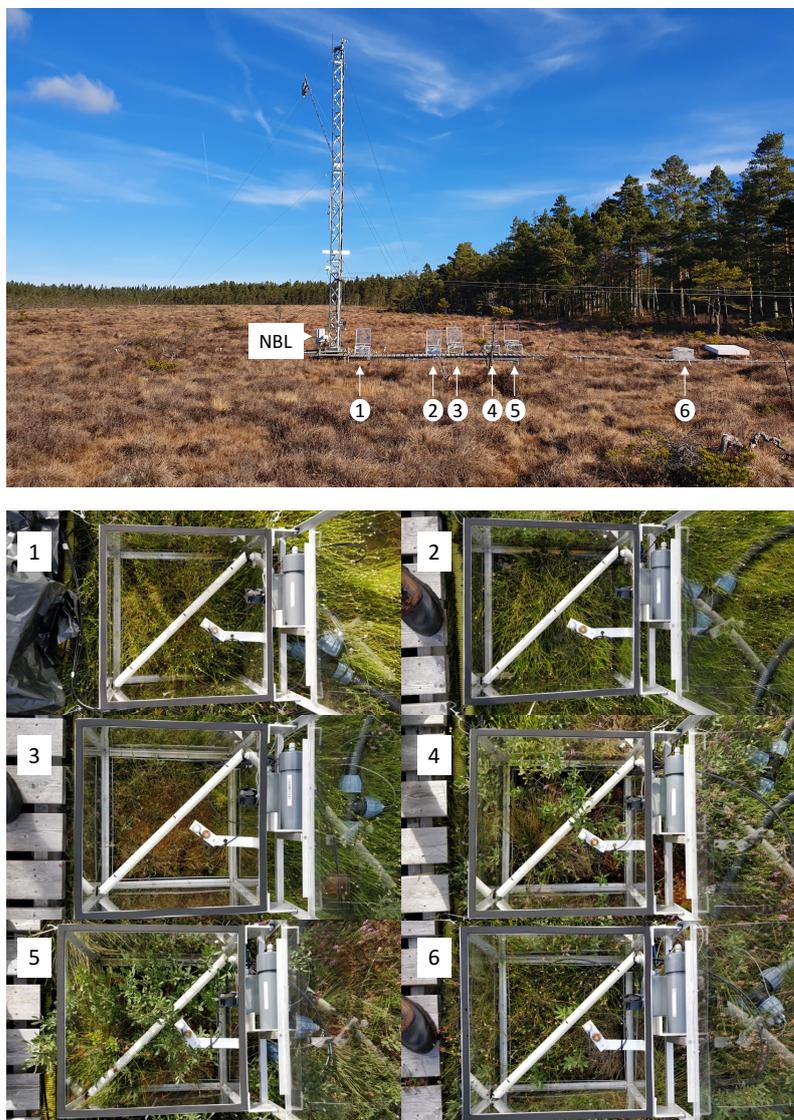

The emission rate of CH₄ was calculated as linear fit of CH₄ mixing ratio to time during the first 4 minutes of the closure. The first 60 seconds were discarded to avoid the disturbances at lid closure, leaving three minutes of data for the linear fitting. For data quality assurance r² and RMSE were calculated for each chamber closure.

190 The $\delta^{13}\text{C}$ of the emitted CH₄ was obtained by the Keeling plot approach (Keeling, 1958). In this approach, we plotted the measured $\delta^{13}\text{C}$ against the inverse of the CH₄ mixing ratio (χ). The $\delta^{13}\text{C}$ of the emitted methane was then obtained as the intercept of the $\delta^{13}\text{C}$ value at $1/\chi = 0$, by fitting a line

$$\delta^{13}\text{C}(\chi) = a + b\chi^{-1}, \quad (1)$$

to the data. Here $\delta^{13}\text{C}(\chi)$ is the observed $\delta^{13}\text{C}$ value of CH₄ in the chamber air at the methane mixing ratio of χ , and a and b are coefficients obtained by line fitting. Coefficient a is the intercept, which will give us the isotopic signature of the emitted methane. The confidence interval of the $\delta^{13}\text{C}$ at intercept was obtained by the function `linfitxy` in MATLAB (Browaeys 2021). We removed the data from closures where the uncertainty of $\delta^{13}\text{C}$ of emitted CH₄ was larger than 20 %.

195

200 *Figure 5: Top panel: Photo showing the relative location of chambers along the boardwalk. Lower panel: Photos of vegetation inside each chamber, numbered 1-6.*

For the NBLA approach we measured the CH₄ mixing ratio and δ¹³C at 0.4 m above the mire surface during night-time. As the emitted CH₄ is accumulated in the shallow stable nocturnal surface layer, we can employ a similar two-end-member
205 mixing model as for the chamber measurements. Thus, we obtain the δ¹³C of the emitted CH₄ by the Keeling plot approach.

In addition to the automated measurements, we occasionally took manual air samples from chambers during closures and analyzed these with isotope ratio mass spectrometric, for comparison with the automated measurements. From each chamber closure, eight samples were taken into two liter SupelTM Inert Foil Gas Sampling bags (Sigma Aldrich, Co, LLC, USA). The
210 eight samples from each chamber were divided into two sets, one transported to Utrecht University and the other one to Royal Holloway, University of London for analysis. The analysis methods are described by Röckmann et al. (2016) and Fisher et al. (2006). These results were compared with CRDS results and the difference in the resulting δ¹³C-CH₄ values of 3.4 per mille was added to the δ¹³C-CH₄ values calculated using the CRDS data.

215 In order to reduce measurement noise, especially in the δ¹³C values, we aggregated the calculated CH₄ emissions and their δ¹³C values to ten-day averages. To analyze the spatial variability, we plotted the δ¹³C values against CH₄ emission rates during each ten-day interval. For the analysis of temporal variation, we plotted the δ¹³C values against the CH₄ emission rates from each chamber.

3.3 Upscaling the δ¹³C estimates

220 To scale up the δ¹³C values obtained from the different surface types to the isotopic signature of the whole mire, δ¹³C_{mire}, we weighted the δ¹³C values of different surface types by the areal contribution of these surface types, and by their CH₄ emission rates,

$$\delta^{13}C_{mire} = (\sum \delta^{13} C_i f_i F_i) (\sum f_i F_i)^{-1}, \quad (2)$$

where δ¹³C_{*i*} is the isotopic signature of the CH₄ emission from the surface type *i*, *f_i* is fraction of the mire covered by surface
225 type *i*, and *F_i* is CH₄ emission rate of the surface type *i*. Both the δ¹³C_{*i*} and *F_i* are based on the chamber measurements.

The map of mire surface types used to determine *f_i* in Equation 2 was based on RGB and multispectral images collected with an Unmanned Aerial Vehicle in 2017. A random forest classifier (Breiman 2001) was used to divide the mire into three vegetation classes: hummocks (vascular shrub-dominated), hollows (*Sphagnum*-dominated) and trees; producing a total
230 accuracy of 81% (see Figure 4 and Kelly et al. 2021 for more details). Table 2 shows the proportion of each surface type for different radii around the NBLA tower. In the upscaling, average δ¹³C and CH₄ emission rate from chambers 1 and 2 represented the values of wet hollows while average values from chambers 4-6 represented those from dryer hummocks. The hollows were given areal coverage of 20% and hummocks 80%.

235 **3.4 Genomic analysis**

Peat material for genomic analysis was collected in 2018 from three different surface types specified through the wetness classification ($n = 17$). Using a 1.5m long box corer, peat material was cut from the oxic-anoxic interface (~5cm) and the anoxic zone (~30cm). The peat material was immediately frozen using liquid nitrogen and stored in a -80°C freezer prior to beginning gDNA extraction. The gDNA was extracted from 0.25 mg of peat following the DNeasy® PowerSoil® Kit manufacturer's protocol (Qiagen, Hilden, Germany).

The extracted gDNA was hybridized to a set of custom designed oligonucleotide probes which enrich the gene sequences related to CH_4 metabolism. This was achieved using the "captured metagenomics" method. Briefly, genes encoding enzymes related to the CH_4 production and consumption were identified in the Kyoto Encyclopedia of Genes and Genomes database (KEGG) (Kanehisa et al., 2015) and were downloaded via a custom R script (<https://github.com/dagahren/metagenomic-project>). The target sequences downloaded from KEGG were used to design custom hybridisation-based probes for sequence capture based on the MetCap pipeline (Kushwaha et al., 2015). For further details on probe design, library construction and sequencing refer to White et al. (2022).

250 Libraries were multiplexed in pools of 15 in equimolar amounts based on the concentrations and sizes of samples. 1 μg of each pool was transferred to a capture tube where target gDNA was hybridised to the custom probes according to the NimbleGen SeqCap EZ SR User's Guide (Version 4.3, October 2014). The captured libraries were sequenced on an Illumina HiSeq4000 platform using sequencing by synthesis technology to generate 2 x 150 base pair paired-end reads.

255 Following sequencing, raw fastq files were trimmed for the presence of Illumina adapter sequences using Cutadapt version 1.2.1 (Martin, 2011). The reads were further trimmed using Sickle version 1.200 with a minimum window quality score of 20 (Joshi, 2011). The sequence reads from each of the captured data set were submitted to MG-RAST, an online metagenomic annotation program using default parameters (Meyer et al., 2008). The taxonomic abundances were annotated using the RefSeq database (O'Leary et al., 2016) Following annotation, taxa were filtered for off-target sequences leaving only abundances of methanogenic and methanotroph microbial communities using the built in taxonomic filter within MG-RAST analysis page.

The relative abundance of methanogens and methanotrophs was calculated via the phyloseq package v1.3.0 (McMurdie and Holmes, 2013). To allow for the small samples size and uneven distribution of replicates, a PERMANOVA was used with 999 permutations (Anderson, 2001) to identify significant differences between categories. Following double root transformation, we calculated ordination using Bray-Curtis distances and finally, a Wilkson pairwise post-hoc test was used to identify significant differences between the different wetness categories via the vegan package v2.5 (Oksanen et al.,

2019). All analysis was completed in R statistics package v 3.6.1 (R Core Team, 2018) and visualized using the ggplot2 package v 3.3.2 (Villanueva and Chen, 2019).

270 4 Results

4.1 Climate

The average daily air temperatures at the mire range from slightly below zero to above 20°C (Figure 6). Water table is typically drawn down during early summer, before being replenished by late summer and autumn rains (Figure 6). In 2018, the mire was affected by a severe heatwave and drought, as shown by the long duration of the water table drawdown, as well as from the high air temperatures that summer. However, even with the high air temperatures in the summer of 2018, the peat temperature at the depth of 30 cm seems to be quite similar to that of the next two summers. 275 as from the high air temperatures that summer. However, even with the high air temperatures in the summer of 2018, the peat temperature at the depth of 30 cm seems to be quite similar to that of the next two summers.

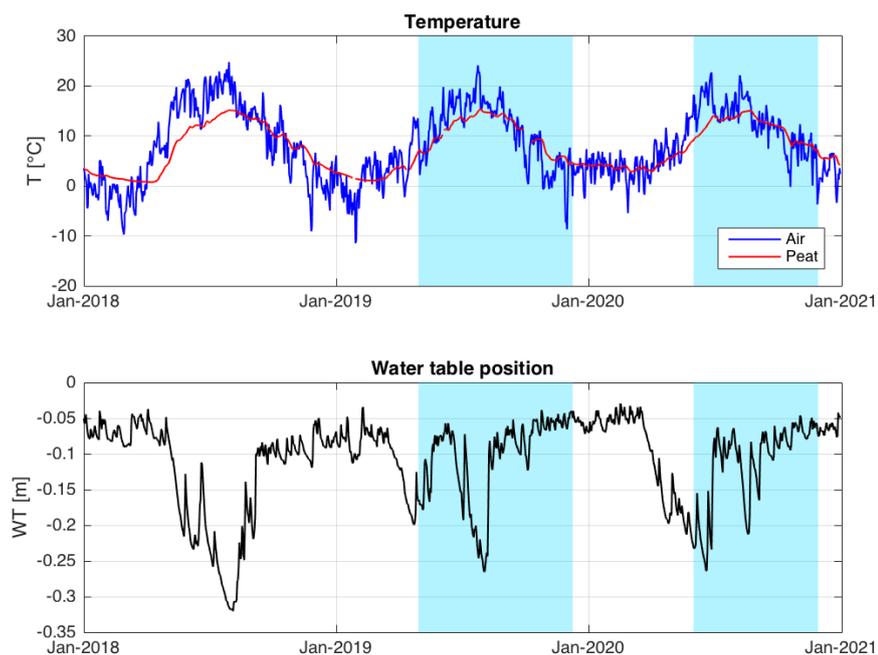

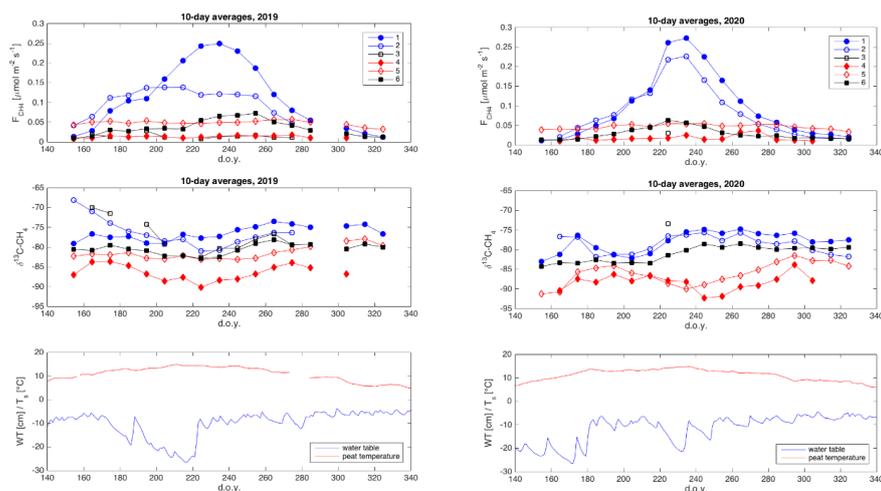

Figure 6: Meteorological conditions during 2018-2020. Periods of $\delta^{13}\text{C}-\text{CH}_4$ and F_{CH_4} measurements are indicated by blue shading. 280

285

Figure 7: Time series of ten-day averages of methane emission and $\delta^{13}\text{C-CH}_4$ measured from the six chambers, and peat temperature at 30 cm depth and water table position in 2019 and 2020.

4.2 CH₄ emission rates and $\delta^{13}\text{C}$ values

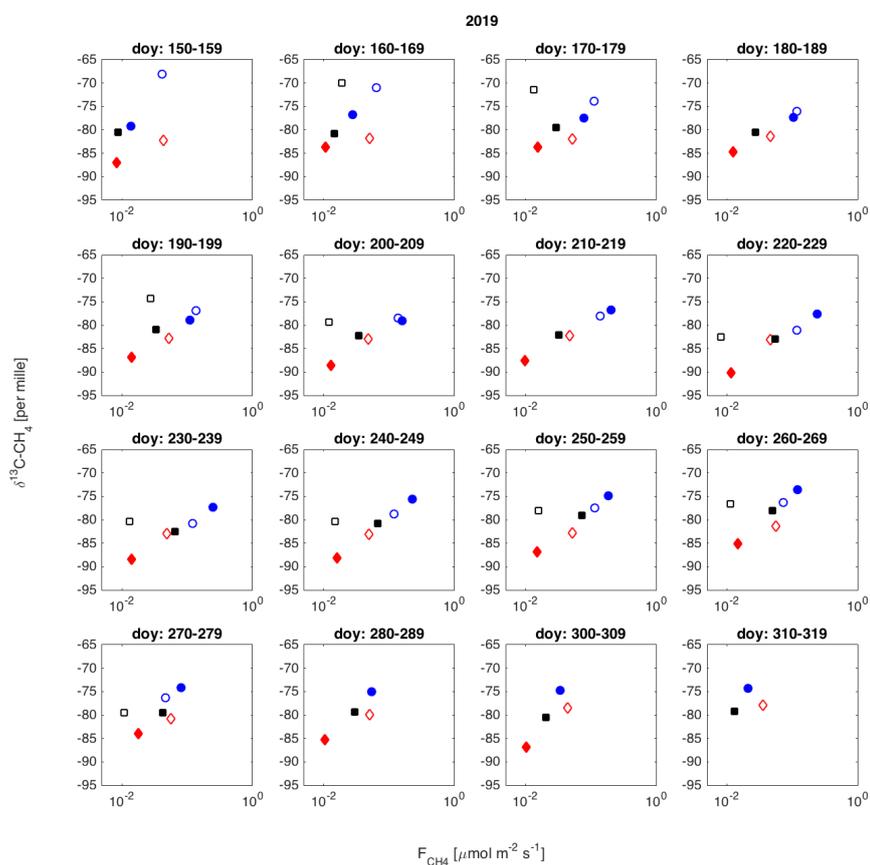

The time series of CH₄ emission rates from most chamber locations shows a typical seasonal cycle of CH₄ emission, with the highest emission rates in late summer (Figure 7; Supplementary material Figures S1 and S2). We see also distinct differences between the emission rates from different chambers indicating strong small-scale spatial variation in CH₄ emission rate. The highest emission rates are observed from chambers 1 and 2, with abundant aerenchymatous sedges. Chambers 3 and 4 have very low CH₄ emission rates, despite differences in vegetation, while 5 and 6 have intermediate emission rates. Emission rate from chamber 5 has a less pronounced annual cycle than from the other chambers.

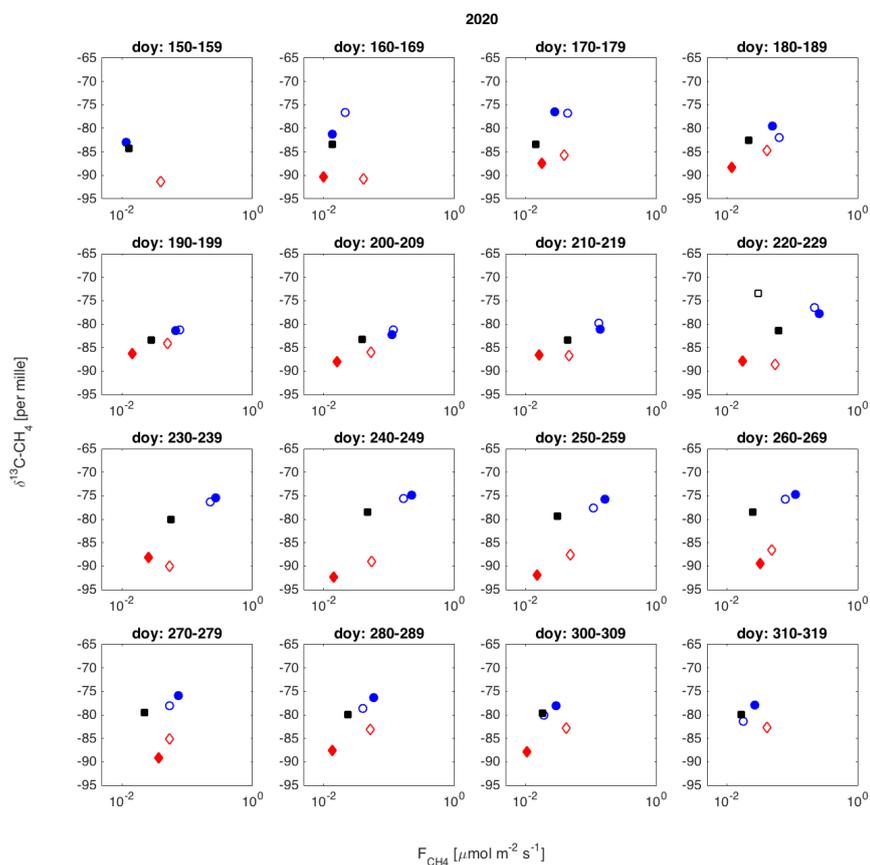

295

The $\delta^{13}\text{C}$ values of emitted CH₄ also show relatively large differences depending on chamber location (Figure 7). In general, chamber locations with high emission rates have less depleted (less negative) $\delta^{13}\text{C}$ values of emitted CH₄. The seasonal cycle of the $\delta^{13}\text{C}$ values is much less obvious or systematic than that of the CH₄ emission rate.

300 The $\delta^{13}\text{C}$ values and CH_4 emission rates generally show a positive relationship during many of the 10-day periods (Figure 8).
The positive relationship was more pronounced during the period of high emission rates (doy 200-260), and more evident in
2019 than in 2020. However, chamber 3 deviated consistently during 2019 from the general behavior of the other chambers.
Unfortunately, there was hardly any data that passed the quality assurance and control criteria from that chamber during
2020 due to low CH_4 emission rates. Omitting data from chamber 3 led to statistically significant correlations between CH_4
305 emission rate and its $\delta^{13}\text{C}$ value during many of the 10-day periods.

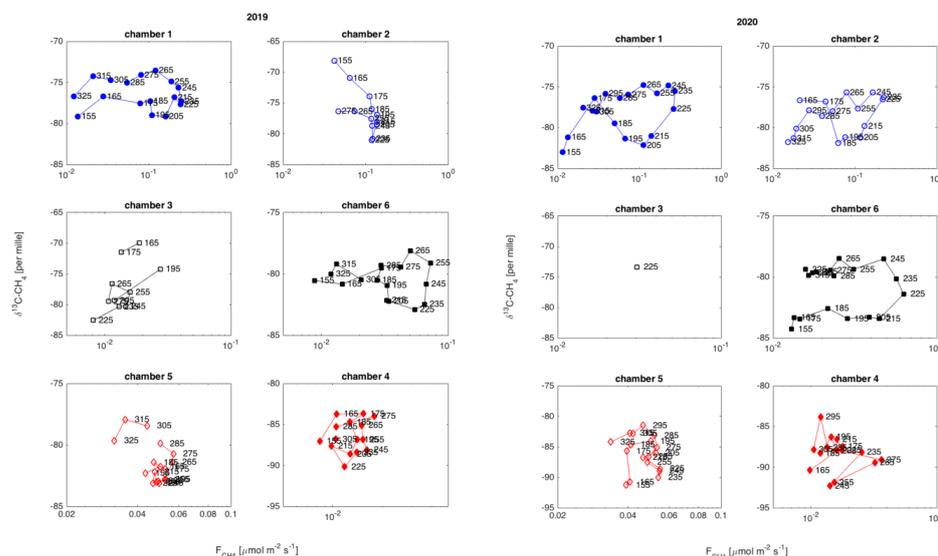

310

Figure 8: Spatial variation of $\delta^{13}\text{C}-\text{CH}_4$ against F_{CH_4} , during ten-day time windows for 2019 and 2020.

315 The temporal relation of $\delta^{13}\text{C}$ values and CH_4 emission rates shows a hysteresis-like behavior at three of the measurement locations (chambers 1, 2 and 6) during 2020 and at two locations (chambers 1 and 6) in 2019 (Figure 9). These locations are either wet or intermediate sites with relatively high emission rates. In these locations, the $\delta^{13}\text{C}$ values of emitted CH_4 are lower in the early part of the growing season than during a period with similar emission rates later in the season. The dry sites do not show observable systematic behavior in their $\delta^{13}\text{C} - \text{CH}_4$ emission rate relation.

The $\delta^{13}\text{C}$ values of emitted CH_4 derived by the nocturnal boundary layer method are in the same range as the $\delta^{13}\text{C}$ values
 320 observed at the wet and intermediate chambers, with some similarities in their seasonal cycle (Figure 10). The upscaling of
 the chamber data using the microtopographic map resulted in an average $\delta^{13}\text{C}$ value of emitted CH_4 of -81.3% . The average
 $\delta^{13}\text{C}$ value of emitted CH_4 according to NBLA measurements was -79.3% .

325 Figure 9: Temporal variation of $\delta^{13}\text{C}\text{-CH}_4$ against F_{CH_4} in each chamber location in 2019 and 2020. The marker labels
 indicate the day of year. Only very few data points in from chamber 3 passed the quality criteria in 2020, resulting in only
 one ten-day average.

4.3 Genomic analysis

In total, 20 methanogens and five methanotrophs were identified at *genus* level. *Genera* were spread across four classes of
 330 methanogens including *Methanobacteria*, *Methanococci*, *Methanomicrobia* and *Methanopyri*. In addition, three *classes* of
 methanotrophs including type I *Gammaproteobacteria*, type II *Alphaproteobacteria* and *Verrucomicrobia* were also
 detected. These *genera* included methanogens with the ability to perform methanogenesis via all metabolic pathways
 including hydrogenotrophic, acetoclastic, methylotrophic and the specialist methanogen, *Methanosarcina*
 (Hydr/Methyl/Aceto methanogen), which holds the ability to metabolize via multiple alternative pathways.

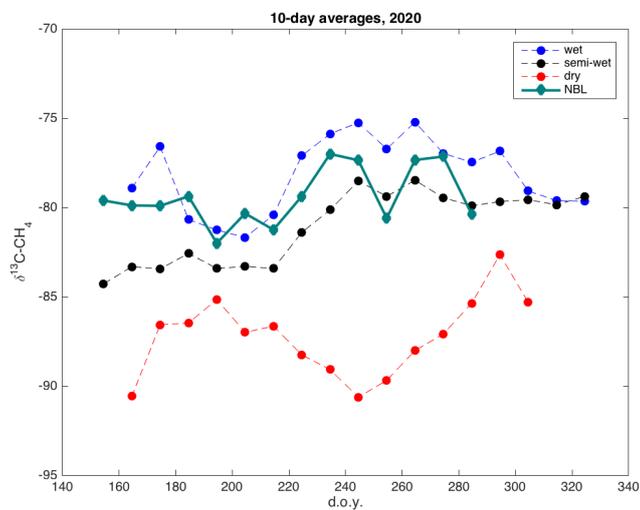

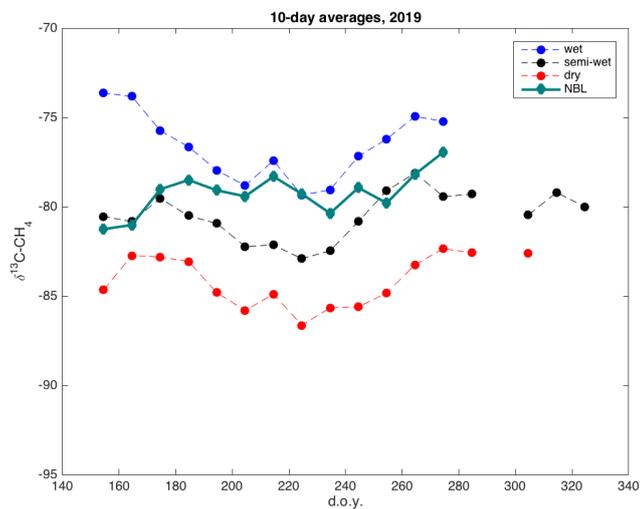

335

The proportion of methanogens to methanotrophs is a 58% to 42% split when combining all the samples. The dominant methanogens were hydrogenotrophic methanogens (46%), followed by the multiple metabolic pathway genus *Methanosarcina* (10%), with the methylotrophic and acetoclastic methanogens contributing 2% and $\leq 1\%$ respectively. The dominant methanotrophs were the type II *Alphaproteobacteria* (30%), followed by type I *Gammaproteobacteria* (8%) and
340 *Verrucomicrobia* (4%).

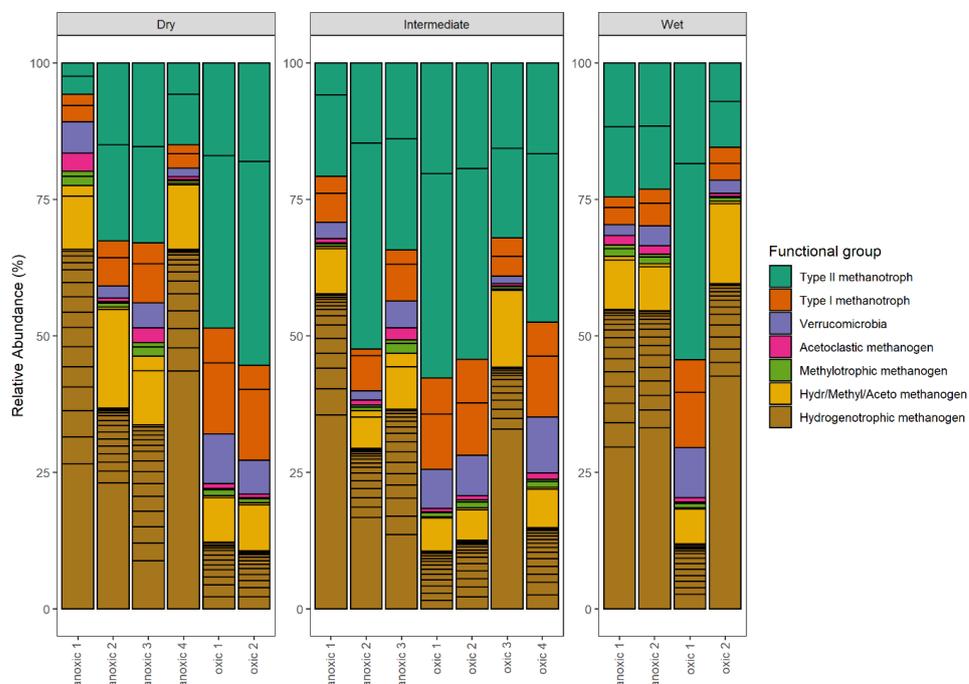

Significant variation in the relative abundance of taxa was observed between the wet, intermediate and dry categories ($p \leq 0.02$) (figure 11). The PERMANOVA indicated that 37% of the variation in taxa was explained by the wetness category (R^2 0.37, $p \leq 0.02$). When testing pairwise between categories, significant differences occurred between wet - dry ($p \leq 0.04$) and
345 wet - intermediate categories ($p \leq 0.04$), but not between the dry - intermediate categories ($p \geq 0.05$).

The functional group contributing the most to dissimilarity in all comparisons was the hydrogenotrophic methanogens, with an average dissimilarity of 0.29 ± 0.19 SD between intermediate - wet, 0.20 ± 0.16 SD between intermediate - dry and finally, 0.30 ± 0.17 SD between wet - dry categories (Tables 3, 4, 5). Although contributing the highest to dissimilarity the
350 difference was identified as non-significant when comparing between categories. Type II methanotrophs, multiple metabolic pathway *Methanosarcina*, Type I methanotrophs and hydrogenotrophic methanogens contributed second, third, fourth and fifth to dissimilarity, respectively. Interestingly, methylotrophic methanogens contributed little to dissimilarity but were the only methanogenic functional group to be significantly higher in abundance in wet locations when compared to intermediate ($p \leq 0.027$) and dry plots ($p \leq 0.046$). Type I methanotrophs and *Verrucomicrobia* methanotrophs had significantly higher
355 average abundance in wet locations when compared to intermediate ($p \leq 0.01$) and dry plots ($p \leq 0.004$). However, type II methanotrophs were only significantly higher in abundance in wet plots when compared to dry ($p \leq 0.036$).

360

Figure 10: Time series of ten-day average $\delta^{13}\text{C-CH}_4$ derived by nocturnal boundary-layer Keeling plot approach (green), and averages of wet (blue), intermediate (black) and dry (red) locations, for 2019 and 2020.

5 Discussion

The CH₄ emitted from surfaces covered by different vegetation types show large differences in its $\delta^{13}\text{C}$ values. In the late summer of 2020, the differences between the 10-day average $\delta^{13}\text{C}$ values from different chambers were up to 10-15 %.

370 Considering the modest microtopography of Mycklemossen mire, and the closeness of the measurement locations (Table 1, Figure 10), this indicates a considerable small-scale spatial variation in the processes leading to CH₄ emission. Our findings are in line with the large observed differences in CH₄ emission rates due to small-scale spatial variability from other mire ecosystems (e.g. Riutta et al., 2007; Keane et al., 2021). The spatial variation of $\delta^{13}\text{C}$ values observed at Mycklemossen are in the same range with that observed at Abisko-Stordalen mire by McCalley et al. (2014). Furthermore, McCalley et al.

375 (2014) and Mondav et al. (2017) identified the same domain genus of Hydrogenotrophic methanogens *Methanoregula* in

Abisko-Stordalen mire, which we found at Mycklemossen. The similar range of the $\delta^{13}\text{C}$ values at Mycklemossen and Abisko-Stordalen is interesting as these mires differ in their microtopography and climate. The microtopographic height differences at Abisko-Stordalen are about a meter, as compared to about 20 cm at Mycklemossen. Furthermore, due to the cold climate and thin wintertime snow cover Abisko-Stordalen has permafrost palsas, whereas Mycklemossen in a temperate
380 non-permafrost mire.

The spatial variation in the $\delta^{13}\text{C}$ values of emitted CH_4 is systematic over the growing season and two years of measurements. Generally, the wet sedge-dominated plots with higher emission rates are associated with higher $\delta^{13}\text{C}$ values, and the dry shrub-dominated plots with lower emission rates with lower $\delta^{13}\text{C}$ values, indicating the importance of
385 methanogenesis in determining the spatial variation in the CH_4 emission rate. Similar spatial relations between $\delta^{13}\text{C}$ and CH_4 emission rate have been observed by e.g. Hornibrook and Bowes (2007) in Welsh mires, and by McCalley et al. (2014) in a Swedish subarctic mire Abisko-Stordalen. However, the position of the chamber 3 in the $\delta^{13}\text{C}$ - CH_4 emission rate diagram (Fig 8), suggests an effect of methanotrophy on CH_4 emission and its $\delta^{13}\text{C}$ value from this location. This may be due to the dominance of Sphagnum mosses, which have been shown to support significant methanotrophy (Larmola et al., 2010). The
390 significantly higher abundance of type II methanotrophs in wetter locations as compared to dry and intermediate supports this suggestion.

Of our two hypotheses on the origins of the spatial variation of CH_4 emission rates, one (HS1) assumes methanotrophy to be the key explanatory process while the other (HS2) assumes substrate availability to drive the spatial variation. The relation
395 between the CH_4 emission rate and $\delta^{13}\text{C}$ values of emitted CH_4 we observed mostly corroborates the latter hypothesis (HS2). Corroboration of the HS1 hypothesis would have required a negative relation between the $\delta^{13}\text{C}$ and CH_4 emission rate. Furthermore, the presence of Hydrogenotrophic, acetoclastic and methylotrophic methanogens enables the community to utilize all substrates available. Thus, methanotrophy does not play a major role in explaining most of the spatial variation of CH_4 emission from this mire system.

400
As it is possible that there are seasonal differences in the factors affecting the spatial variability of the methane emission (temperature, trophic status, methanotrophy), we analyzed the spatial variation throughout the growing seasons as ten day averages. According to the observed spatial relations between $\delta^{13}\text{C}$ and CH_4 emission rates during these two growing seasons there were no major temporal shifts in the behavior of the $\delta^{13}\text{C}$ - CH_4 emission rate relationship. Thus, it seems that
405 the processes leading to the spatial variations in CH_4 emission are similar throughout the growing season.

The temporal variation in $\delta^{13}\text{C}$ was smaller and less systematic than its spatial variation. Interestingly, the temporal behavior of $\delta^{13}\text{C}$ in relation to CH_4 emission rate shows a hysteresis-like behavior at some of the chamber plots. The hysteresis

behavior is clear in wet or intermediate plots with high emission rates. The lack of observable hysteresis-like behavior in the
410 other plots could be due to the small range of emission rates. The hysteresis behavior indicates that the temporal variation of
CH₄ emission rates from this mire could be a result of two compounding effects, following the HT3 hypothesis. Specifically,
the increasing CH₄ emissions during the first half of the growing season could be caused by increasing peat temperature
enhancing the activity of methanogenic *Archaea* (Juottonen et al., 2008). Later in the growing season, the increased input of
root exudates from vascular plants would increase the substrate availability, resulting in higher $\delta^{13}\text{C}$ values than in the early
415 season yet similar CH₄ emission rates. However, we cannot assign the whole seasonal cycle of CH₄ emission rates to
changes in trophic status, as this would result in a pronounced positive relationship between $\delta^{13}\text{C}$ and CH₄ emission rates,
which we did not observe. According to the genetic analysis, the microbial community holds the functional potential to
produce CH₄ via the hydrogenotrophic and acetoclastic pathways, thus enabling shifts in $\delta^{13}\text{C}$ following the seasonal
changes in trophic status. Thus, the hysteresis between temperature and CH₄ emission, similar to that observed by Chang et
420 al., (2020; 2021) and Łakomiec et al. (2021), could be partly due to the seasonal development of peat temperature and partly
due to the changes in trophic status for methane production.

The $\delta^{13}\text{C}$ values of emitted CH₄ derived by the nocturnal boundary-layer approach (NBLA) corresponded in magnitude to the
values of the wet and intermediate surfaces. As these surfaces dominate the emission, it is natural that the NBLA approach
425 will correspond to these more closely than to the dry surfaces with low CH₄ emission. The up-scaled $\delta^{13}\text{C}$ from the chamber
measurements was in a similar range to the mire-scale $\delta^{13}\text{C}$ measured by the NBLA method, indicating the dominance of
hydrogenotrophic methanogenic pathways. Obtaining reliable mire scale isotopic signatures is crucial, for example for the
use of isotopic data for source apportioning of CH₄ by atmospheric inversions. Here we show that the chamber $\delta^{13}\text{C}$
measurements can be successfully upscaled using a mire surface characterization based on UAV data. Such an approach
430 enables the calculation of mire-scale $\delta^{13}\text{C}$ estimates at sites where NBLA measurements are not available. In combination
with UAV-upscaled CO₂ fluxes (e.g. Kelly et al 2021), there are further opportunities to examine the impacts of spatial
variations in vegetation productivity and respiration on CH₄ emission rates and $\delta^{13}\text{C}$ values.

6 Conclusions

We conducted automatic chamber and nocturnal boundary layer (NBLA) measurements, as well as genomic analyses of the
435 CH₄-relevant microbial communities, to investigate the drivers of the spatial and temporal variability of CH₄ emission and
 $\delta^{13}\text{C}$ in a temperate Swedish mire. Despite the small elevation differences (<20 cm) between the microtopographic zones in
the mire, we observed stark contrasts in the CH₄ emission rates and $\delta^{13}\text{C}$ between the zones, similar in magnitude to mires
which have much more pronounced microtopography. According to the relationships between $\delta^{13}\text{C}$ and CH₄ emission rates
we observed, the spatial variability of CH₄ emission from Mycklemossen mire is mostly controlled by variations in

440 methanogenesis due to the differences in trophic status, rather than differences in methanotrophy between mire
microtopographic zones, following our hypothesis 2 on spatial variability (HS2). The seasonal variation of CH₄ emission is
controlled by both temperature and trophic status, leading to hysteresis-like behavior in the $\delta^{13}\text{C}$ - CH₄ emission rate
relationship, following our hypothesis 3 on temporal variability (HT3). The taxonomic data shows the functional potential to
produce CH₄ via multiple metabolic pathways, enabling shifts following changes the trophic status and supporting the results
445 from the chamber and NBLA measurements. Interestingly, the measurement plot with Sphagnum-dominated vegetation
diverged from the general spatial $\delta^{13}\text{C}$ -F_{CH₄} relation, warranting future studies on this vegetation type. In addition, we
confirmed that drone-based upscaling of $\delta^{13}\text{C}$ chamber measurements provides reliable mire-scale estimates when compared
to NBLA $\delta^{13}\text{C}$ estimates. The results obtained can help to constrain our theories on the causes of the variability of methane
emission from mire ecosystems and can thus be useful in development of numerical models of mire biogeochemistry, needed
450 to predict the fate of northern mire ecosystems in the changing climate.

Acknowledgements

We thank Malika Menoud and Thomas Röckmann at IMAU, and David Lowry at RHUL for help in isotopic analysis of bag
samples. The access to the Mycklemossen site was made possible by Swedish Infrastructure for Ecosystem Sciences (SITES,
co-financed by the Swedish Research Council) and ICOS Sweden network (co-financed by the Swedish Research Council
455 (grant no. 2015-06020, 2019-00205). Probe hybridization and sequencing was performed at the Center for Genomic
Research, University of Liverpool. Data handling was enabled by resources in project (SNIC 2019/8-365) provided by the
Swedish National Infrastructure for Computing (SNIC) at UPPMAX, partially funded by the Swedish Research Council
through grant agreement no. 2018-05973.

Financial Support

460 This research has been supported by the MEthane goes Mobile: MEasurement and MOdeling (MEMO2) project from the
European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant no. 722479. We
acknowledge Crafoord foundation for financial support for financing the Picarro isotope analyzer. We acknowledge funding
from Strategic Research Area BECC (2018).

Data availability

465 The annotated metagenomes are available at the MG-RAST server under the project ID: 91145. The isotopic and methane
emission data will be available at zenodo.

Code availability

Code used in the taxonomic analysis can be found at https://github.com/joel332/Analysis-of-captured-metagenomic-data/blob/main/Mycklemossen_isotopes_taxonomic_analysis. The code for methane flux and isotopic analysis will be available at zenodo.

White, J.D., Ström, L., Lehsten, V., Rinne, J. & Ahrén, D. 2022. Genetic functional potential displays minor importance in explaining spatial variability of methane fluxes within a Eriophorum vaginatum dominated Swedish peatland. Biogeosciences Discuss., 2022, 1-38.

640 **Tables**

Table 1 : Dominant vegetation in flux chambers. D : dominant ; P : present. Niche indicates the niche of the species. The relative elevation (above 80 m a.s.l.) of moss surface at each chamber is indicated.

645

SPECIES	CH_1 13 CM	CH_2 6 CM	CH_3 6 CM	CH_4 14 CM	CH_5 20 CM	CH_6 3 CM	NICHE
<i>Rhynchospora alba</i>	D	D	-	-	-	D	Wet
<i>Eriophorum vaginatum</i>	-	-	P	D ^{50%}	P	P	Wet - Moist
<i>Andromeda polifolia</i>	-	-	P	-	-	-	Moist
<i>Myrica gale</i>	-	-	-	D ^{50%}	D	P	Moist
<i>Erica tetralix</i>	-	-	P	P	P	P	Moist
<i>Calluna vulgaris</i>	-	-	P	P	-	-	Moist – Dry
<i>Sphagnum papillosum</i>	-	-	D	P	-	-	Moist

Table 2 : Proportions of different vegetation types in different radii around the NBLA tower.

Radius [m]	Wet [%]	Dry [%]	Trees [%]
20	20	78	1.0
50	16	76	7.2
100	17	75	8.6

650 Table 3 : Results of SIMPER analysis between intermediate (n = 7) and wet (n = 4) plots. Functional group are ranked according to their average contribution to dissimilarity between plots. Standard deviation (SD), average abundances, percentage of cumulative contribution and permutation *p*-value (Probability of getting a larger or equal average contribution in random permutation of the group factor) are also included.

Functional group	Average dissimilarity	SD	Average abundance intermediate	Average abundance Wet	Cumulative Percentage	p
Hydrogenotrophic methanogens	0.30	0.19	3155	20214	48%	0.10
Type II methanotrophs	0.18	0.13	3583	11503	76%	0.08
Hydr/Methyl/Aceto methanogens	0.06	0.03	839	3844	85%	0.13
Type I methanotrophs	0.05	0.04	821	3006	93%	0.01
Verrucomicrobia	0.03	0.02	281	1482	97%	0.00
Methylotrophic methanogens	0.01	0.01	94	715	99%	0.03
Acetoclastic methanogen	0.01	0.01	80	605	100%	0.13
