**Abstract.** Satellite microwave remote sensing techniques can be used to monitor vegetation optical depth  
10 (VOD), a metric which is directly linked to vegetation biomass and water content. However, these large-  
scale measurements are still difficult to reference against either rare or not directly comparable field  
observations. So far, in-situ estimates of canopy biomass or water status often rely on infrequent and time-  
consuming destructive samples, which are not necessarily representative of the canopy scale. Here, we  
present a simple technique based on Global Navigation Satellite Systems (GNSS) with the potential to  
15 bridge this persisting scale gap. Because GNSS microwave signals are attenuated and scattered by  
vegetation and liquid water, placing a GNSS sensor under a vegetated canopy and measuring changes in  
signal strength over time can provide continuous information on VOD, and thus on vegetation biomass  
and water content. We test this technique at a forested site in Southern California for a period of 8 months.  
We show that variations in GNSS signal to noise ratios reflect the overall distribution of biomass density  
20 in the canopy and can be monitored continuously. For the first time, we show that this technique can  
resolve diurnal variations in VOD and canopy water content at hourly to sub-hourly time steps. Using a  
model of canopy transmissivity to assess these diurnal signals, we find that temperature effects on the  
vegetation dielectric constant, and thus on VOD, may be non-negligible at the diurnal scale or during  
extreme events like heatwaves. Sensitivity to rainfall and dew deposition events also suggests that canopy  
25 water interception can be monitored with this approach. The technique presented here has the potential to  
resolve two important knowledge gaps, namely the lack of ground truth observations for satellite-based  
VOD, as well as the need of a reliable proxy to extrapolate isolated and labour-intensive in-situ

measurements of biomass, canopy water content, or leaf water potential. We provide recommendations  
30 for deploying such off-the-shelf and easy-to-use systems at existing ecohydrological monitoring networks  
such as FluxNet or SapfluxNet.

## 1. Introduction

Complementary to observations in the visible and near-infrared spectrum, microwave-based remote  
sensing of the vegetation can be used to obtain information on aboveground biomass and vegetation water  
35 content (Konings et al., 2019;Frappart et al., 2020). Such information is essential to improve our  
understanding of how ecosystems respond and adapt to both natural and anthropogenic changes, including  
for instance droughts, deforestation, or global warming. However, while satellite products can provide a  
global picture, their algorithms also need to be calibrated and evaluated against other reference  
measurements, thus raising the need for ground truth observations. In the case of vegetation optical depth  
40 (VOD), which is one of the main microwave observables for vegetation, a network of continuously  
gathered ground truth data does not exist yet (Li et al., 2021). In this introduction, we provide a quick  
introduction to microwave observations, highlight current applications of VOD, and review recent  
attempts to compare satellite VOD against other data. We then present a ground-based technique relying  
on Global Navigation Satellite Systems (GNSS) with the objective to address the lack of ground-based  
45 VOD observations.

Microwave remote sensing methods are broadly categorized as either passive or active. Passive  
instruments (like radiometers) measure the amount of microwave radiation that is naturally emitted by  
the Earth, whereas active instruments (like radars) transmit a specific radio signal and measure the  
50 properties of the backscattered (reflected) signal. In both cases, the measured signals (brightness  
temperature or backscatter) depend on various factors, but in particular on the emissivity/reflectivity of  
the surface, and the transmissivity ( $\gamma$ ) of the vegetation, which acts as a layer of temporally changing  
opacity between the ground and the atmosphere. The transmissivity of vegetation is typically controlled  
by factors influencing both its dielectric constant (e.g. vegetation water content and temperature) and its  
55 structure (density, shape, size, and distribution of the vegetation elements in the canopy). The vegetation

optical depth (VOD) is a single parameter condensing all these different contributions and, in combination with the incidence angle ( $\theta$ ), is used to express the canopy transmissivity as a function of the incidence angle:

$$\gamma = e^{\frac{-VOD}{\cos \theta}} \quad (1)$$

This formulation of the transmissivity is the expression of a Beer-Lambert's law, where VOD represents an attenuation coefficient (specific to the observation wavelength and polarization) and the term  $1/\cos \theta$  accounts for the path length through the canopy, such that VOD (as defined here) only relates to the vertical path. Higher VOD values indicate that the canopy is less transparent to electromagnetic waves.

a supprimé: as

It is worth noting that this definition of VOD is mainly inherited from the perspective of microwave remote sensing algorithms, where VOD has to be estimated in order to obtain other variables of interest such as soil moisture (Jackson et al., 1982; Jackson and Schmugge, 1991; Owe et al., 2008). Because both field campaigns and theoretical considerations showed that in-situ estimates of VOD can be related to vegetation water content and biomass (Ulaby and Jedlicka, 1984; Schmugge and Jackson, 1992; Paloscia and Pampaloni, 1992), this sparked interest in the development of more robust and long-term estimates of satellite-based VOD. Global maps of VOD have since become available from numerous satellite microwave sensors (Moesinger et al., 2020; Chaubell et al., 2020) but can hardly be validated, as systematic ground-based VOD observations do not exist at the moment. Only a few studies have managed to compare satellite-based VOD against in situ observations. Most notably, Tian et al. (2016) have found a good agreement between satellite-based VOD and in situ measurements of green biomass in African Sahel. Instead, the majority of studies assessing or using satellite-based VOD have relied on comparisons with other remotely sensed variables (e.g. Grant et al., 2016) or model-data fusion products. For instance, Rodríguez-Fernández et al. (2018) have compared VOD from the SMOS satellite against optical vegetation indices, lidar tree height and different aboveground biomass benchmark maps. Consistent with other studies, their results show that VOD is often a better proxy for tree height and biomass, compared to optical greenness indices (such as NDVI or EVI). Thus, VOD has been increasingly used to monitor

85 changes in aboveground biomass and terrestrial carbon sequestration at the inter-annual and seasonal time  
scales (Brandt et al., 2018;Wigneron et al., 2020;Fan et al., 2019).

In addition to providing information on long-term biomass changes, VOD has also been shown to exhibit  
significant short-term variability, which is thought to be related to changes in relative vegetation water  
90 content (Feldman et al., 2021). Using observations from the AMSR-E satellite, Konings and Gentine  
(2016) found significant variations between midnight and midday VOD which may put an invaluable  
constrain on plant response to water stress at the ecosystem-scale (Lee et al., 2013;Konings et al., 2021).  
Further studies also highlighted intercepted water (due to either rainfall or dew) as a potential factor  
explaining diurnal variations in VOD (Xu et al., 2021). Using a ground-based radiometer, Holtzman et  
95 al. (2021) showed that VOD variations over the course of a day could be linearly related to in-situ  
measurements of leaf water potential. This is consistent with a previous study by Momen et al. (2017)  
which found good agreement between satellite-based VOD and leaf water potential measurements across  
three different U.S. sites. Measurements with active microwave sensors have also shown that radar  
backscatter exhibits diurnal variations which can be related to both dew and relative water content  
100 (Vermunt et al., 2021;Konings et al., 2017b).

Considering some advantages of microwave-range compared to visible-range observations<sup>1</sup>, such studies  
have demonstrated the interest of VOD for monitoring vegetation dynamics from space (Konings et al.,  
2021). However, they have also revealed our limited ability to (1) validate space-borne VOD observations  
105 and (2) disentangle the multitude of factors which may affect them across a wide range of ecosystems  
and climatic conditions. Established eco-hydrological measurement networks (e.g. FluxNet or  
SapFluxNet) can provide most of the necessary collocated observations in terms of meteorological  
parameters, water fluxes, canopy structure, and biomass (e.g. Momen et al., 2017), but only few of these

---

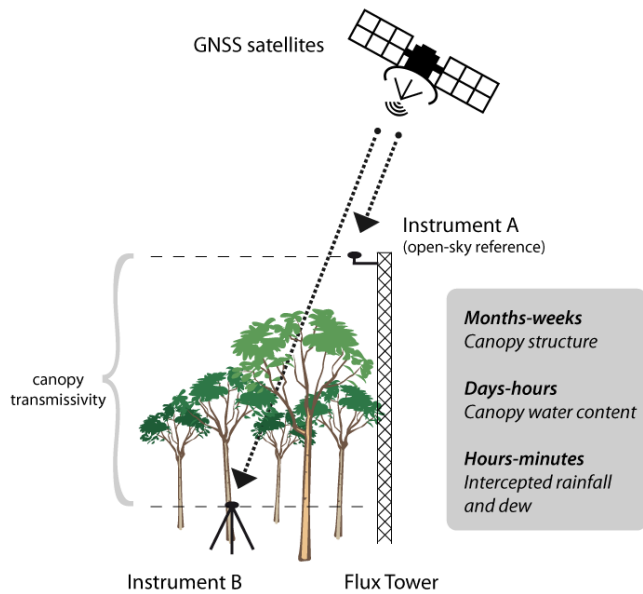

<sup>1</sup> Microwave remote sensing has two key interesting properties, first it is relatively independent of cloud cover and solar  
illumination conditions, second it is not only sensitive to the surface of the observed material but also to its content, up to a  
certain penetration depth. Drawbacks include a lower energy and longer wavelength, which usually translates into coarser  
spatial and/or radiometric resolutions, and some difficulty in disentangling the many different factors contributing to the  
measured signal (i.e. the ground versus the vegetation contributions, the surface roughness, the material's temperature, and its  
moisture content).

sites have ever been equipped with microwave radiometers or active radars, and if so, usually for limited  
110 periods of time. Yet, continuous in-situ VOD observations at these sites could **also** serve as a particularly  
useful indirect proxy to interpolate and gap-fill the sparse and labour-intensive measurements of biomass  
and leaf water status. There is thus a need for a cheap and robust method to obtain ground-based VOD  
measurements over a wide variety of already monitored sites.

115 Here, we propose to use microwave signals from existing Global Navigation Satellite Systems (GNSS)  
to monitor the transmissivity and VOD of a vegetation canopy. The experimental setup consists in a pair  
of GNSS receivers, one placed on a tripod below a forest canopy, and one located above the canopy with  
an unobstructed view of the sky (Fig. 1). Here, canopy is understood as the portion of vegetation lying  
above the sensor (in our case, this excludes the forest floor and ground vegetation). The main idea is that  
120 the difference in measured signal strength between the two instruments will yield information on the  
opacity of the canopy. Fortunately, many survey-grade GNSS receivers available on the market can be  
configured to log signal strengths, making it relatively easy to implement such a system. The GNSS  
microwave signals fall in the L-band (1-2 GHz), similar to frequencies used by the SMOS and SMAP  
satellites for calculating VOD. Nowadays, four major GNSS constellations (GPS, GLONASS, Galileo,  
125 and BeiDou) represent about a hundred of orbiting satellites, such that about 20 to 40 satellites may be  
visible and individually tracked from the ground at any given time and from any location in the world.  
Set-ups similar to the one shown in Fig. 1 have been tested before, for instance Rodriguez-Alvarez et al.  
(2012) used it to estimate the canopy water content of a walnut tree stand and Camps et al. (2020) used it  
to estimate VOD in a beech forest and make comparisons with optical indices. Kurum and Farhad (2021)  
130 also tested it with mobile GNSS antennas and Zribi et al. (2017) used it to monitor sunflower canopies.  
Over the last decades, GNSS-based monitoring of the Earth's surface has been demonstrated in a wide  
variety of domains ranging from oceanography to hydrology. While we rely here on the attenuation of  
the direct GNSS signal through the canopy, it is worth noting that other GNSS-based techniques, such as  
GNSS reflectometry, have been used to monitor soil moisture, snow height, vegetation water content, and  
135 biomass (Larson et al., 2009; Small et al., 2010; Chew et al., 2014; Egido et al., 2014; Larson, 2016; Chew  
and Small, 2018; Ruf et al., 2018; Santi et al., 2019; Carreno-Luengo et al., 2020; Guerriero et al., 2020; Pan

et al., 2020; Munoz-Martin et al., 2022). GNSS reflectometry relies on GNSS signals that are reflected from the Earth's surface and which are weaker than the open-sky GNSS signals used as reference here.

140 Figure 1. Instrument setup for measuring GNSS-based VOD. Each instrument consists of an antenna and a GNSS receiver.

The goal of this study is to demonstrate the potential of ground-based GNSS receivers for monitoring VOD, dry aboveground biomass, and water content continuously. In Section 2, we describe the measurements conducted at the study site and outline a simple canopy transmissivity model which is later  
145 used to estimate canopy density and water content from VOD measurements. Section 3 presents the raw GNSS measurements and the processing approach used to transform these into a canopy-averaged VOD time series. Section 4 compares the obtained seasonal and diurnal VOD time series against other in-situ and satellite measurements. Section 5 provides an example of retrieval algorithm for aboveground

biomass and canopy water content. Finally, section 6 summarizes the main conclusions and provides some recommendations with respect to future deployments at existing ecohydrological sites.

## 2. Data and methods

### 2.1 Site set up

155 The experiment consists of a reference site which has an unobstructed view of the sky, and a forested site which is located under a semi-closed forest canopy (Fig. 1). The open-sky reference site is located on the roof of a building of the California Institute of Technology in Pasadena, California (34.13624°, -118.12693°), and the forested site is located in the Huntington Library botanical garden, some 1.7 km away (34.12404° -118.11582°). The forested site is non-irrigated, with trees of about 5 to 15m height.

160 Tree species surrounding the antenna are mainly Coast Live Oaks (*quercus agrifolia* Née) and the understory is herbaceous. The overall climate is Mediterranean with weather conditions usually clear, daily maximum temperatures between 25°C and 35°C, and low relative humidity. At each site a Septentrio

165 | PolARx5e GNSS receiver, connected to a PolARnt-x MF right-hand circular polarized (RHCP) GNSS antenna, measured multi-constellation (GPS, GLONASS, Galileo, BeiDou) GNSS signals over the period of May 13 to December 10, 2020, with a logging rate of 15 seconds. Power loss at the site from June 15<sup>th</sup> to July 1<sup>st</sup> caused a data gap of 17 days. The raw GNSS data was quality-checked using the 'teqc' pre-processing software, publicly available at the UNAVCO website ([www.unavco.org/software](http://www.unavco.org/software)). The satellites' azimuth and elevation angles are also computed with teqc. Weather data is measured at the reference site by a station of the Total Carbon Column Observing Network ([http://tcon-](http://tcon-weather.caltech.edu/)

170 [weather.caltech.edu/](http://tcon-weather.caltech.edu/)). Weather data acquisition was interrupted from July 15<sup>th</sup> to 26<sup>th</sup>. Rainfall was measured with a tipping-bucket at the DPW HQ station (5km from the forested site) by the Department of Public Works of the City of Los Angeles (<https://dpw.lacounty.gov/wrd/rainfall/>).

### 2.2 Leaf water content

Forty-eight leaf samples were collected from two live oaks closest to the GNSS antenna on October 18, 2020, at 7am, 12pm and 5pm using a 2m long pruner. For each tree we equally sampled the same three different parts of the crown. Unless otherwise stated below, we followed the protocol advised in Mullan

and Pietragalla (2012). Leaves were weighed on-site immediately after being sampled (fresh weight; FW) and stored individually in cooled glass vials. They were then transported to the lab where about 1 cm of water was added to each vial to cover the leaves' petioles. Turgid weight (TW) was measured after 12  
180 hours in a refrigerator (and in darkness). Then, the leaves were dried at 80°C for a period of 24 hours, after which dry weight (DW) was measured. Relative leaf water content (RLWC, in percent) is calculated as.

$$RLWC = \frac{FW-DW}{TW-DW} \cdot 100 \quad (2)$$

185

We also calculate the gravimetric moisture content of the leaf ( $m_g$ , in  $\text{g g}^{-1}$ ), a variable that is later used to model the leaf dielectric constant.

$$m_g = \frac{FW-DW}{FW} \quad (3)$$

### 2.3 Canopy transmissivity model

190 We use a dielectric mixing model of the canopy transmissivity to investigate the potential roles of canopy volumetric density, water content, and temperature on the GNSS-based VOD measurements. We use a relatively simple formulation which only considers the attenuating effect of the canopy on the direct signal power and represents the canopy as a homogeneous layer, assumed to consist of randomly distributed elements (Ulaby and Jedlicka, 1984; Ulaby and Long, 2014; Guglielmetti et al., 2007). The transmissivity  
195 of the canopy is expressed as a function of a bulk canopy extinction coefficient ( $\kappa_e$ ), canopy height ( $h$ , in meters), and the incidence angle.

$$\gamma = e^{\frac{-2 \kappa_e h}{\cos \theta}} \quad (4)$$

We define a fixed average canopy height of 7 meters based on field observations. Neglecting scattering, the extinction coefficient is related to the complex index of refraction of the canopy layer ( $n_c''$ ) (Ulaby  
200 and Long, 2014).

$$\kappa_e = \frac{2\pi}{\lambda_0} n_c'' \quad (5)$$

where  $\lambda_0$  is the free-space wavelength (in meters). Note that this formulation and the overall concept of bulk coefficients is applicable only when the inclusions in the canopy (i.e. the pockets of water within the vegetation tissues) are smaller in size compared to the observation wavelength (here  $\lambda_0 \approx 19$  cm for the GPS L1 frequency), so that scattering effects are small enough to be neglected (also see Jackson and Schmugge, 1991; Ulaby and Long, 2014). While this may be true for leaves, this assumption may not hold for larger elements such as branches and trunks. However, using a more complex theoretical scattering model, Guerriero et al. (2020) showed (for the case of a poplar forest) that the RHCP GNSS signals measured below a forest canopy are dominated by coherent attenuation whereas only the left-hand circular polarized (LHCP) signals (which most geodetic ground-based GNSS antennas are designed to reject) are dominated by volume scattering. The complex index of refraction is calculated from the dielectric constant of the canopy layer ( $\epsilon_c$ ) (Ulaby and Long, 2014).

$$n_c'' = -\Im\{\sqrt{\epsilon_c}\} \quad (6)$$

The canopy is constituted of two main phases; the surrounding air, which makes up most of the canopy volume, and the vegetation material. The dielectric of the canopy  $\epsilon_c$  is calculated using a two-phase refractive mixing approach (Ulaby and Long, 2014, Eq. 4.45).

$$\sqrt{\epsilon_c} = v_{veg} \sqrt{\epsilon_{veg}} + (1 - v_{veg}) \sqrt{\epsilon_{air}} \quad (7)$$

where  $v_{veg}$  represents the vegetation volumetric density, a parameter that may vary as a function of the growth cycle and is defined as the volume fraction of the vegetation material within the canopy (on the order of 0.0001-0.01 m<sup>3</sup>/m<sup>3</sup>). This parameter is not to be confused with other measures of vegetation density like crown volume (i.e. including empty space) per m<sup>2</sup> for instance. The term  $(1 - v_{veg}) \sqrt{\epsilon_{air}}$  is practically equal to 1 with no imaginary part such that Eq. 7 can be rewritten as (Ulaby and Long, 2014, Eq. 11.89).

$$n_c'' \approx -\Im\{\sqrt{\epsilon_{veg}}\} v_{veg} \quad (8)$$

The dielectric of the vegetation ( $\epsilon_{veg}$ ) incorporates a real and an imaginary part, namely the dielectric permittivity and the dielectric loss ( $\epsilon_{veg} = \epsilon'_{veg} - i\epsilon''_{veg}$ ). Both depend on various factors, but most importantly on the considered wavelength, the vegetation water content, as well as the plant water's temperature and ionic conductivity. Here we model  $\epsilon_{veg}$  using the semi-empirical model for vegetation

a supprimé: right-hand circular polarized (RHCP)

230 introduced by Ulaby and El-rayes (1987) and valid over the range 0.2-20 GHz. This model is derived from an observational dataset of corn leaves, and has been successfully used for a wide range of species, including trees (e.g. Chuah et al., 1995). The model expresses the dielectric of the vegetation  $\epsilon_{veg}$  as a function of its gravimetric moisture ( $m_g$ ), its temperature, and its salinity. The numerous equations are not reported here but can be found for instance in Ulaby and El-rayes (1987) and Ulaby and Long (2014).

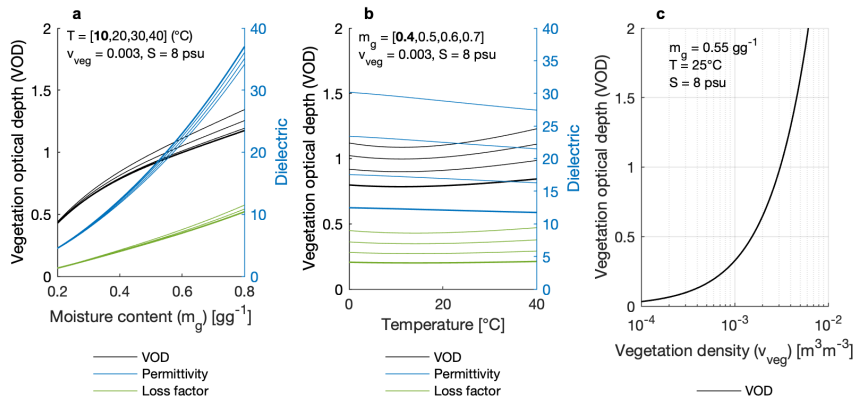

235 The purpose of the transmissivity and dielectric models described above is to provide a simple estimate of the potential effects of canopy density, temperature and water content changes on canopy transmissivity. It is important to note that this simple formulation neglects several aspects, including volume scattering, which may be important in configurations with denser biomass (and also when interpreting LHCP backscatter or LHCP signals). In Fig. 2, we illustrate the modelled VOD response (at

240 the GPS L1 1.575 GHz frequency) to potential changes in vegetation water content, temperature, and vegetation volumetric density. As expected, an increase in vegetation moisture content (Fig. 2a) leads to a substantial increase of the vegetation's dielectric permittivity and dielectric loss, which results in a lower canopy transmissivity. Temperature influences the vegetation's dielectric properties as well, although less markedly (Fig. 2b). The ionic conductivity of the plant water is the main factor explaining the slight

245 dependency of the loss factor (and of VOD) to the temperature. Finally, vegetation volumetric density within the canopy is also a parameter that strongly controls the transmissivity (Fig. 2c). Note that the shape of these response curves (the response to temperature in particular) may change depending on the considered frequency.

The bold lines in (a) are obtained assuming a temperature of 10°C, with thin lines indicating 10°C increments. The bold lines in (b) are obtained assuming a gravimetric moisture content of 0.4 gg<sup>-1</sup>, with thin lines indicating 0.1 gg<sup>-1</sup> increments. c) modelled response of canopy VOD to vegetation volumetric density. Canopy height is fixed at 7 meters and salinity to 8%.

### 3. GNSS data processing

#### 3.1 Raw SNR observations

260 Most survey-grade GNSS receivers commonly register signal-to-noise ratios (SNR, in decibel) which express the magnitude of the received signal power from each satellite compared to the background noise (Bilich et al., 2007). The quantity logged by the Septentrio receiver is the carrier-to-noise density ratio (C/N<sub>0</sub>), which we report as SNR for simplicity, assuming a 1-Hz bandwidth (Larson and Nievinski, 2012). The hemispherical plot in Fig. 3a illustrates the SNR values measured over the course of one single day at the reference (open-sky) station for just one satellite of the GPS constellation (PRN2). GNSS satellites 265 are commonly identified by their pseudorandom code (PRN) which allows the receiver to determine which satellite is being tracked, such that its azimuth and elevation can be calculated. Individual satellite tracks repeat after a period that depends on the GNSS constellation (e.g. twice per sidereal day (23h56) for GPS and every 10 sidereal days for Galileo). As is very commonly observed, the SNR increases as the satellite rises up above the horizon (12PM mark), reaches its peak value at maximum elevation (2PM

270 mark), where the antenna gain is the strongest, and decreases again until the satellite disappears from  
view (5PM mark). As can be seen from Fig. 3b, the same satellite track observed from the forested site  
shows numerous drops in SNR. Assuming a comparable level of background noise at the two sites, the  
SNR difference between the two sites ( $\Delta SNR$ , Eq. 9) reflects, for the most part, the transmissivity of the  
canopy, expressed in decibels. As expected, it is mostly negative (Fig 1c-d), indicating attenuation by the  
275 forest canopy.

$$\Delta SNR = SNR_{Forested} - SNR_{OpenSky} \quad (9)$$

Combining all available data (May to December 2021) from 102 individual GNSS satellites, we produce  
280 a hemispherical map of the average  $\Delta SNR$  (Fig. 4a), which matches the overall distribution of canopy  
density as seen from the antenna location (Fig. 4b). Note that absolute SNR values vary from spacecraft  
to spacecraft, as those have different (and occasionally time-varying) transmit powers. It is thus very  
important to first pair the individual SNR measurements taken by the two receivers and only then, average  
any  $\Delta SNR$  values.

285

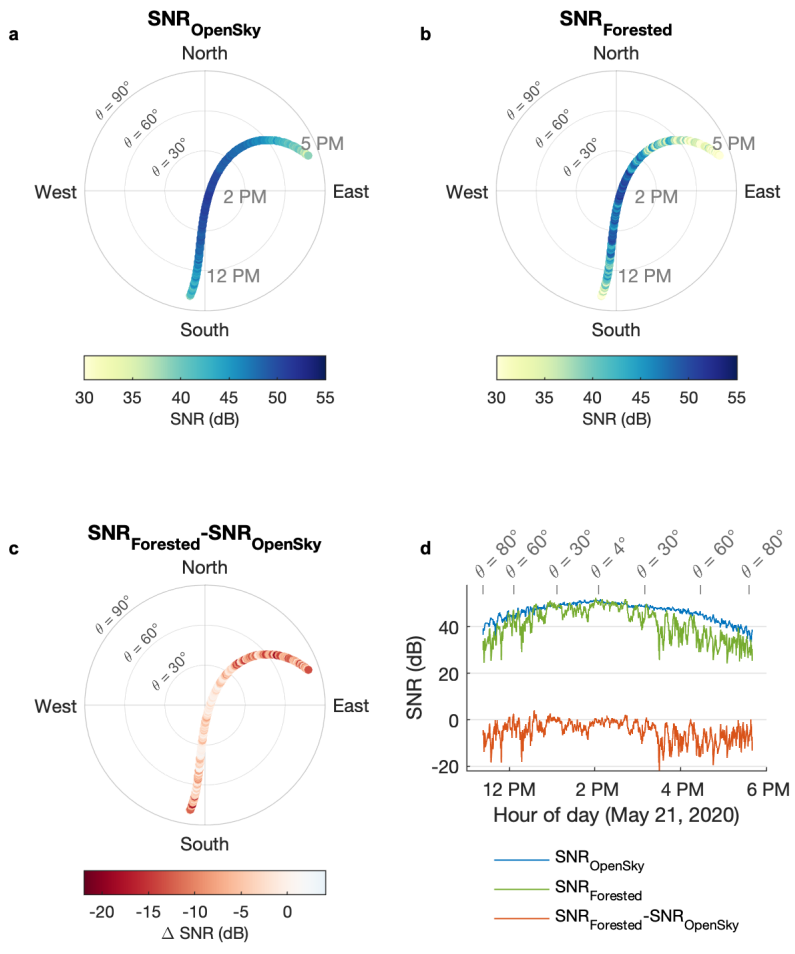

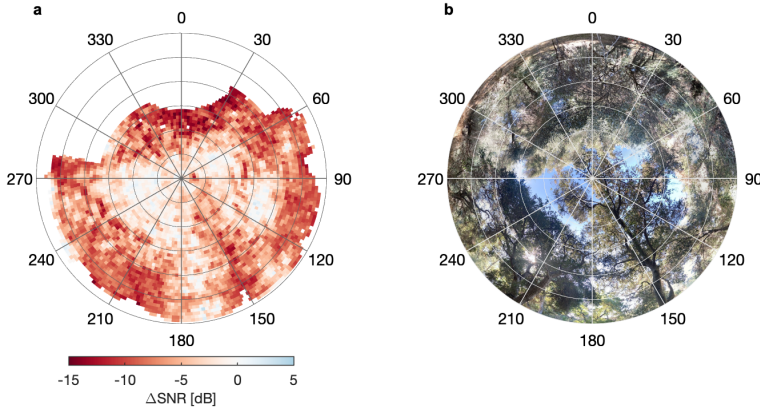

Figure 3. Sky plots illustrating the SNR observations on May 21, 2020 for one specific GPS satellite (PRN2) at the open sky site (a) and the forested site (b). (c) Difference in SNR between the two sites. (d) Same as a-c but showing the temporal evolution of the SNR. The centre of the polar plots corresponds to the local zenith.

290 It should be noted that while the SNR measurement is dominated by the contribution of the direct (line of  
sight) signal, it also includes a comparatively weaker contribution from volume scattering and indirect  
ground multipath reflections (Bilich et al., 2007; Smyrnaiois et al., 2013), the latter of which may contain  
information on soil water status for instance (Larson, 2016). Ground multipath often manifests itself as a  
periodic oscillation of the SNR which is caused by the successively constructive and destructive  
295 interference from ground reflections, as a function the satellite's elevation angle. Such periodic  
oscillations, of a few dB, are barely visible for instance in Fig. 3d at the beginning and the end of the  
SNR<sub>OpenSky</sub> time series (blue curve), where the roof's floor acts as the reflector. However, while present  
in our data, ground multipath represents a signal that is about one order of magnitude smaller than the  
attenuations caused by the presence of trees in the line of sight. It is only in some favourable situations  
300 (i.e. flat grasslands, open water bodies, ...), where large flat surfaces surrounding the antenna produce a  
coherent structure in ground reflections, that multipath is strong enough to be reliably detected in SNR,  
even though our GNSS systems are explicitly designed to reject such signals. Indeed, most geodetic-grade  
antennas have metal ground planes and are much less sensitive to the predominantly left hand circular  
polarized (LHCP) ground reflections of the transmitted right hand circular polarized (RHCP) signal (note  
305 that in contrast, spaceborne GNSS reflectometry also relies on the LHCP signal). Thus, in our case, the  
difference in SNR between the two sites is predominantly due to the attenuation of the direct RHCP signal  
by the forest canopy and it is reasonable to assume that ground multipath effects are of second order. This  
is also confirmed by a  $\Delta SNR$  close to zero in the sky sectors where the canopy is either absent or very  
sparse (Fig. 4). It is only when the incidence angle is larger than  $80^\circ$  that the majority of the reflected  
310 GNSS signal is co-polarized (RHCP) (Smyrnaiois et al., 2013). As a precaution, we discard all  
observations with an incidence angle higher than  $80^\circ$  for the remainder of the analysis.

a supprimé: M

315 Figure 4. (a) Sky plot illustrating the mean SNR difference between the open sky and the forested site for L1/L1C signals ( $n = 2.17 \cdot 10^7$  observations, taken over an 8-month period). The mean value within each 2-degree equal area sky sector is shown. Some sky sectors in (a) are obstructed by buildings at the reference site and are thus excluded from the analysis (towards the north-west and north-east). (b) Hemispherical photograph taken from the perspective of the forested site antenna.

### 3.2 Transmissivity and vegetation optical depth

320 After conversion from decibel to linear scale (Eq. 10), the  $\Delta SNR$  measurements are used as the transmissivity estimate, and VOD is calculated from Eq. 11 (Eq. 1). Note that in our case, this represents L-band VOD at RHCP polarization.

$$\gamma = 10^{\frac{\Delta SNR}{10}} \quad (10)$$

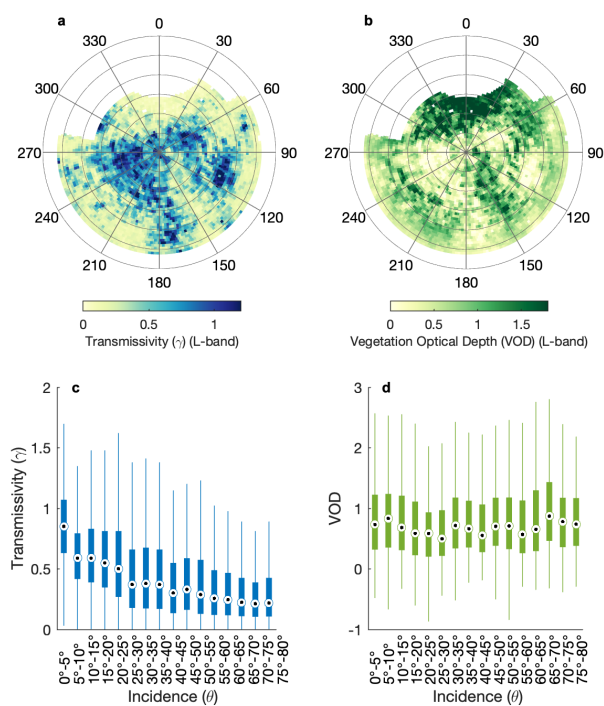

$$VOD = -\ln(\gamma) \cos \theta \quad (11)$$

325 The resulting hemispherical distribution of long-term mean transmissivity and VOD is reported in Fig. 5a-b. In some cases, the instantaneous transmissivity values computed from the raw GNSS measurements were higher than 1, leading to a VOD lower than zero (about 8% of all measurements). This occurs because individual SNR measurements unavoidably include some random noise as well as non-random multipath interferences that can cause the measured signal power at the reference site to be transiently lower than at the forested site. This especially occurs where there are gaps in the canopy and both antennas have a clear line of sight to the satellite. To preserve the error structure of the measurements, we propose 330 to still use these values when computing temporal (i.e. daily or hourly) averages later in the paper, so that

a supprimé: .  
a supprimé: which is unphysical

a supprimé: unphysical

335 positive and negative errors can cancel out, avoiding a potential bias in our estimate of the average VOD (Fig. 5b). While transmissivity has an obvious dependence on the incidence angle (Fig. 5c), this is not the case for VOD (Fig. 5d), as would be expected from Eq. 1. The strong anisotropy of the long-term VOD pattern (Fig. 5b) reflects the heterogeneous structure of the canopy (Fig. 4b), with local mean VOD values ranging from 0.16 to 2.46 (1<sup>st</sup> and 99<sup>th</sup> percentiles) depending on the azimuth and incidence angle. The whole canopy average VOD is 0.79, which is similar to what is reported for evergreen broadleaf forests at L-band (Konings et al., 2017a).

345 Figure 5. Sky plot illustrating the mean canopy transmissivity (a) and mean VOD (b). The mean value within each 2-degree equal area sky sector is shown. (c-d) The box plots show the distribution (5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 99<sup>th</sup> percentiles) of all individual transmissivity and VOD measurements ( $n = 2.17 \cdot 10^7$ ) as a function of the incidence angle (relative to zenith).

### 3.3 Computation of VOD time series

Because changes in VOD over time may provide valuable information on the vegetation's growth cycle and water content, it is of great interest to investigate its temporal evolution. However, this is complicated  
350 by the patterns of GNSS orbits, which change continuously. In Fig. 6a, we provide an overview of the most frequent orbit patterns over our site and their mean revisit time, showing which sky sectors are most often observed. While it takes about a day on average to cover most of the observable sky sectors (Fig. 6b, red curve), monitoring one specific section of the canopy every 1 or 2 hours would only be possible over a narrow band where many satellite tracks coincide (Fig. 6a). Note that the location of the highly  
355 sampled band (and the blind spot above it) depends on the site's latitude (it is closer to zenith at higher latitudes) and would be located on the opposite side in the Southern hemisphere. In practice, this means that a continuous (gap-free) and robust VOD time series can only be obtained by aggregating data collected at different azimuth and elevation angles (i.e. trading angular resolution for temporal coverage). However, as different cross-sections within Fig. 5b are observed each day, the changing and irregular  
360 sampling of the canopy introduces spurious variability in daily site-averaged VOD. When calculating sub-daily (e.g. hourly) time series, this problem is even more important and will obfuscate most of the potential real variability. For example, binning the raw GNSS-based VOD observations into hourly averages produces a rather noisy time series with just seasonal trends visible (Fig. 7a-b, 'VOD raw'). This is because a lot of the variability in 'VOD raw' is caused by the fact that different areas of a heterogenous  
365 canopy are observed every hour. This issue can also be diagnosed quantitatively. For instance, computing the serial autocorrelation<sup>2</sup> of the raw VOD time series (Fig. 7c) reveals periodicities likely not related to ecohydrological processes but instead caused by the combined repeat times of the different GNSS constellations.

---

<sup>2</sup> The serial autocorrelation is calculated using the time series shown in Fig. 7a-b and is defined here as the Pearson correlation coefficient between the time series at time  $t$  and  $t-l$ , where  $l$  is the lag.

370 Figure 6. (a) Sky plot illustrating the mean revisit time (average number of hours until the next overpass within a given sky sector). This includes the GPS, GLONASS, Galileo, and BeiDou constellations. (b) Average sampling statistics as a function of data integration time. For instance, 84% of all observable sky sectors are observed at least once after 24 hours of continuous measurements (red curve). After 30 days of continuous measurement, 62% of all observable sky sectors and hours of the day have been observed at least once (yellow curve).

375 Here, we propose to address this sampling problem by subtracting from each individual VOD observation the long-term average (similar to what is shown in Fig. 5b) taken at the same azimuth and incidence angle. The goal is to subtract the angular heterogeneity in VOD, representing the uneven canopy distribution, and only retain residuals from the locally averaged attenuation (Eq. 12). The long-term average at a given incidence angle and azimuth (Eq. 13) is calculated inside a neighbourhood  $N$  that includes all

380 measurements within some chosen angular distance  $\delta$  from that point of interest (Eq. 14).

$$VOD_{\varphi_i, \theta_i, t_i}^{residual} = VOD_{\varphi_i, \theta_i, t_i} - VOD_{\varphi_i, \theta_i}^{mean} \quad (12)$$

$$VOD_{\varphi_i, \theta_i}^{mean} = \frac{1}{n} \sum_{j=1}^n (VOD_{\varphi_j \in N_i, \theta_j \in N_i}) \quad (13)$$

$$N_i: \quad \text{hav}(\lambda_i - \lambda_j) + \cos(\lambda_i) \cos(\lambda_j) \text{hav}(\varphi_i - \varphi_j) < \text{hav}(\delta) \quad (14)$$

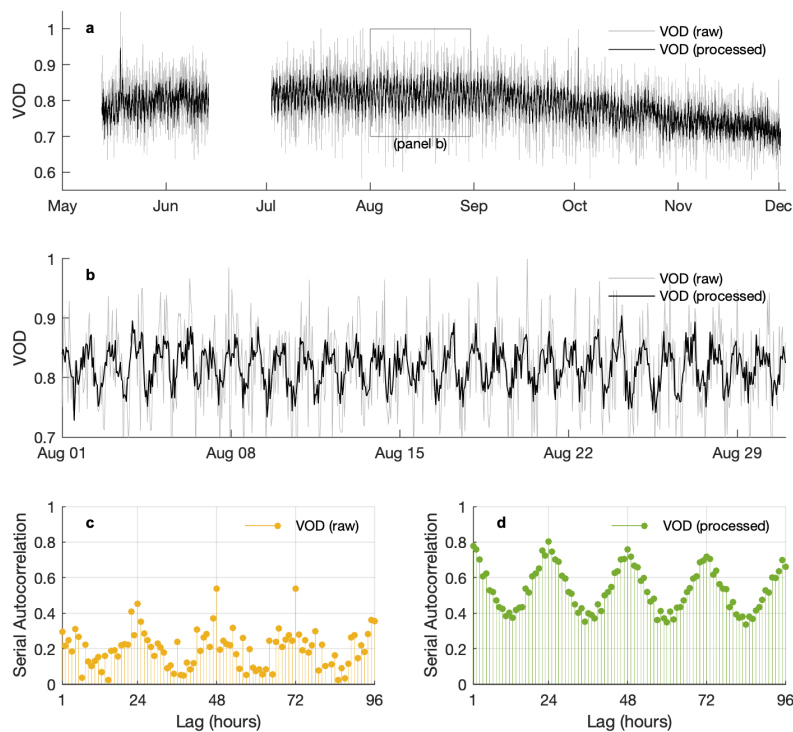

385 where the terms  $\varphi_i$ ,  $\lambda_i$ , and  $t_i$  represent the azimuth, elevation, and time step of the point of interest (for angles expressed in degrees,  $\lambda = 90 - \theta$ ). Equation 14 is the condition that determines if measurements belong to the neighbourhood around the point of interest 'i'. The left term in Eq. 14 is the formula for the

haversine of the angle between any two points on a sphere. The right term is the haversine of a chosen  
390 angle  $\delta$  which defines the extent of the neighbourhood.

An adequate value for  $\delta$  may be selected based on the autocorrelation of the VOD observations with  
respect to the angular distance (Supplementary Fig. 1). The **results** suggest that there is a high consistency  
of the VOD estimates up to an angular distance of about  $0.5^\circ$  to  $1^\circ$ . Supplementary Fig. 1 also provides  
395 some indication of the repeatability of the measurements when taken at an interval of several days. As  
can be expected, observations separated by a longer temporal interval are in lower agreement. The  
selection of  $\delta$  is ultimately a compromise between obtaining an accurate long-term VOD average while  
still retaining enough observations within the neighbourhood. In our case, we found that  $\delta = 0.5^\circ$  seems  
to be an adequate value. To avoid excessive computations, we calculate  $VOD_{\varphi_i, \theta_i}^{mean}$  at each node of a fine  
400 hemispherical grid with a spacing of  $0.1^\circ$ . The  $VOD_{\varphi_i, \theta_i}^{mean}$  value closest to each individual  $VOD_{\varphi_i, \theta_i, t_i}$  is  
then used in Eq. 12. Binning the calculated VOD **residuals** into hourly averages, we produce a processed  
time series of the average VOD (Fig. 7, ‘VOD processed’). To preserve the original absolute level of  
VOD, the average  $VOD_{\varphi_i, \theta_i}^{mean}$  (across all  $\varphi$  and  $\theta$ ) is added back to the residual time series (otherwise the  
‘VOD processed’ time series would be centred around zero). The serial autocorrelation of that processed  
405 time series (Fig. 7d) is now dominated by a more credible 24-hour cycle.

a supprimé: anomalies

410 **Figure 7.** (a) Hourly time series of VOD before and after reducing the impact of irregular sampling caused by the GNSS orbit patterns. (b) Zoom on August, showing sub-daily variability in VOD. (c-d) Serial autocorrelation of the raw and processed VOD time series.

#### 4. GNSS-based vegetation optical depth

##### 4.1 Seasonal changes

In Fig. 8, we compare processed daily VOD averages against other observations. Using quality-checked  
 415 30-meter satellite images from Sentinel 2 (Claverie et al., 2018), we calculate the enhanced vegetation index (EVI) (Liu and Huete, 1995) at our site (Fig. 8a). EVI is a commonly used vegetation index and an

overall proxy for vegetation greenness, health, and photosynthetic activity. Generally, we find that the temporal evolution of VOD appears to lag behind that of EVI by about 2 months. This is consistent with previous findings over drylands by Tian et al. (2016) who found a temporal shift (increasing as a function of forest density) between satellite-based VOD and vegetation greenness. They suggest that this may be explained by the longer growing season and later peak time of woody plants compared to the herbaceous understory. Similar lags between peak NDVI and peak VOD have been observed in other regions of the world from satellite data (Wang et al., 2020; Tian et al., 2018). The peak EVI in June coincides with the maximum in available solar energy (Fig. 8b), and with an increase in VOD which could suggest a build-up of biomass in the canopy. This is followed by a slow decline in EVI which does not occur in VOD until the end of August. The gradual decline in vegetation activity and health over the summer is typical of the region, and mainly a response to the overall increase in water stress resulting from warmer temperatures, drier atmosphere, and low soil moisture after months with no rainfall. The 2020 summer culminated with a record-breaking heatwave on September 6 (Fig. 8c), followed by a steady decline in VOD during fall season where some minor shedding of leaves could be observed at the site.

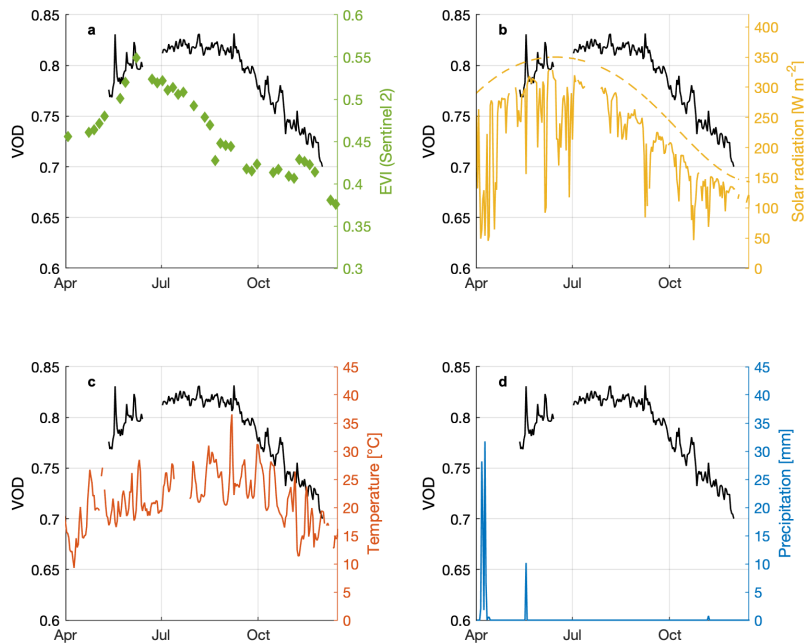

Figure 8. Daily time series of GNSS-based VOD compared against (a) Enhanced Vegetation Index calculated from harmonized Sentinel 2 images (HLS v1.4, 30 meter resolution, <https://hls.gsfc.nasa.gov/>), (b) Solar and potential solar radiation observed at the reference site, (c) Air temperature observed at the reference site, and (d) precipitation totals measured at the closest rain gauge station.

435

#### 4.2 Diurnal cycle

Even though processed hourly VOD time series contain a certain amount of noise (e.g. Fig. 7b), they also show a relatively strong 24-hour cycle (Fig. 7d). One way of obtaining a more robust and precise estimate of that diurnal cycle is to calculate the average diurnal cycle from data aggregated over a long period of time, for instance several days or even a whole month. This is what is done in Fig. 9a. The average diurnal cycle of VOD is consistent with what would be expected from the perspective of plant physiology and its response to water stress over the course of a typical day. VOD culminates in the early hours of the morning, at around 5 to 6 AM, indicating a relatively “water-rich” canopy, because leaves and stems have

440

been replenished with water overnight, and likely also due to the occasional presence of dew in the  
445 canopy. This peak is followed by a gradual drop after sunrise (at about 6AM), concurrent with the onset  
of photosynthesis and transpiration, as well as an increase in vapour pressure deficit (i.e. an increase in  
atmospheric water demand). As a result, dew quickly evaporates and the vegetation starts losing more  
water through transpiration, thus depleting canopy water content. Around noon, some equilibrium is  
reached between plant water losses and plant water supply so that VOD becomes relatively stable. In the  
450 evening, plant rehydration causes VOD to rise back.

A minor peak in VOD is observed at around 3pm, but remains difficult to explain without further  
evidence. That peak might indicate a brief period of canopy rehydration, documented for instance in  
Douglas firs (Cermak et al., 2007, their Figure 6), resulting from midday stomatal closure (Xiao et al.,  
2021). The associated “midday depression” of transpiration and photosynthetic rates has been widely  
455 documented (e.g. Faria et al., 1996;Kamakura et al., 2011). However, theory (Fig. 2b) also predicts that  
VOD could slightly increase in response to higher canopy temperature, which would peak at about that  
time of the day. In Section 5.2, we present an attempt to disentangle these two possible contributions.

Overall, our results agree with previous observations of a diurnal cycle in VOD and backscatter (e.g.  
460 Konings et al., 2017b;Holtzman et al., 2021;Vermunt et al., 2021;Prigent et al., 2022). Such diurnal VOD  
changes are consistent with our knowledge of canopy water storage dynamics, as derived from either  
continuous direct measurements (Zhou et al., 2018), or from the imbalance between plant water losses  
(i.e. transpiration) and plant water supply (i.e. measured with sap flow sensors) (Kocher et al.,  
2013;Cermak et al., 2007). The leaf samples collected on the site in October also confirm that some intra-  
465 day variability exists in relative leaf water content (Fig. 9b). Monitoring the diurnal cycle of plant water  
status is interesting because it can provide key information on plant hydraulic traits (Konings and Gentine,  
2016) and enables disentangling the effects of limitations in root water uptake, plant transpiration, and  
water redistribution within the plant (Konings et al., 2021). In Fig. 9c, we investigate whether our method  
would be able to monitor such physiologically-relevant changes, and in particular here, seasonal changes  
470 in pre-dawn versus midday water status. We find midday VOD to be almost always lower than pre-dawn  
VOD, a behaviour that is entirely consistent with field observations of pre-dawn and midday leaf water

potentials (Martínez-Vilalta et al., 2014). Seasonally, both pre-dawn and midday VOD start to decrease in September with the start of a very dry period during which VPD remains high even during the night. Pre-dawn and midday VOD are significantly correlated with each other ( $r = 0.79$ ), as is frequently  
475 observed with leaf water potential, however, we note that this might also occur (at least partly) because VOD is sensitive not only to relative changes in water content but also to potential seasonal changes in the absolute amount of biomass present in the canopy (Momen et al., 2017). These mixed contributions from both absolute biomass and its relative water content are even better illustrated in Fig. 9d, where we  
480 find that the amplitude of the diurnal cycle in VOD becomes larger as denser sections of the canopy are considered.

485 **Figure 9.** (a) Average diurnal cycle for the month of August. Average VOD (black) is shown at a 15-minute sampling rate with shaded areas delineating the 25<sup>th</sup> and 75<sup>th</sup> percentiles. VPD and surface wetness data from the TCCON weather station have hourly resolution. (b) Average diurnal cycle for the month of October compared with in-situ measurements of relative leaf water content. (c) Daily pre-dawn and midday VOD, calculated using all observations within the window 4AM-6AM and 12PM-2PM respectively. (d) Diurnal VOD anomaly (centred around zero) measured for progressively denser classes of canopy (based on the long-term VOD average, see Fig. 5b).

## 5. Retrieval of canopy density and water content

### 490 5.1 Approach and algorithm

In the following, we demonstrate an approach to retrieve changes in canopy density and water content at hourly resolution based on the transmissivity model presented in section 2.3. Combining Eq. 1, 4, 5, and 8 we obtain the following expression for modelled  $VOD$ :

$$VOD_t = 2k_e h = 2 \frac{2\pi}{\lambda_0} [-\Im\{\sqrt{\varepsilon_{veg_t}}\}] v_{veg_t} h \quad (15)$$

495 Canopy height  $h$  is 7 meters, and  $\lambda_0$  is the free-space wavelength. This leaves as free parameters:  $v_{veg_t}$ , the time-dependent vegetation volumetric density (in  $m^3/m^3$ ), and  $\varepsilon_{veg_t}$ , the time-dependent bulk dielectric constant of the vegetation, which is itself a function of the (measured) temperature, (unknown) water content ( $m_g$ ) and (unknown) salinity of the plant water (Ulaby and El-rayes, 1987). A similar expression may be found for instance in Kerr and Wigneron (1995) or Guglielmetti et al. (2007).

500 Here, we use the canopy-averaged processed VOD time series (i.e., Fig. 7b) as the observed VOD. This means that canopy density and water content are assumed to evolve homogeneously over the whole canopy. If the forest canopy is very heterogeneous, this might not be a suitable approximation. For instance, some groups of trees may evolve at different speeds, or individual trees may exhibit different responses to water stress. If this is suspected, a retrieval may be performed for each individual tree,  
505 potentially at the cost of retrieval accuracy since less observations will be available. In practice, this would mean separating the field of view of the antenna into sub sectors (for instance based on data similar to Fig. 4) and computing a processed VOD time series for each sub sector. However, and for the sake of simplicity, this is not done here, and we perform only one retrieval for the whole canopy.

Disentangling the effects of changes in overall biomass density ( $v_{veg}$ ) versus variations of its water  
510 content ( $m_g$ ) is one of the main challenges when trying to interpret and better understand VOD (Momen et al., 2017; Konings et al., 2019). Because changes in biomass tend to unfold at a much slower pace than changes in relative water content, a common strategy has been to assume that long-term changes in VOD are mostly related to biomass, while short-term changes (and especially a diurnal signal) are most likely due to variations in water content (e.g. Konings et al., 2016). In the retrieval detailed below, we will make  
515 use of this assumption and allow  $v_{veg}$  to contain only low-frequency (long-term) changes. We also

assume that the temperature of the canopy can be approximated by the air temperature. While leaf and air temperatures are not necessarily equal, as documented by many field studies, an error of a few degrees is negligible for the purpose of calculating  $\epsilon_{veg}$  (Fig. 2b) and our main purpose is only to gain a reasonable representation of the seasonal and diurnal effects of temperature on the dielectric constant. We also note  
520 that these temperature impacts on the dielectric are often neglected in other studies.

Finally, the plant water salinity is also unknown in our case, but most likely within a range of about 1 to 11 psu according to previous experience (Ulaby and Long, 2014). In the absence of any other data, we assume that salinity is constant over the whole time period. In our retrieval algorithm, a range of a priori values for vegetation water salinity is tested and the value yielding the best overall (season) fit to the  
525 observed VOD data is selected as the most plausible. We note that salinity, in the context of the dielectric model of Ulaby and El-rayes (1987), is meant to account for the ionic conductivity of the plant water (due to both sugars and salts). Thus, the salinity yielding the best fit might not necessarily reflect the actual (NaCl) salinity of the plant water.

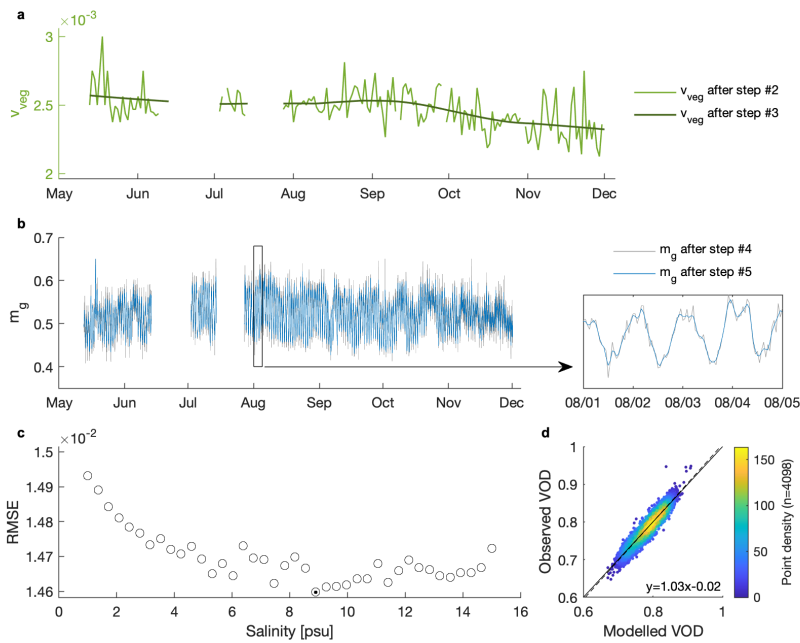

Below, we summarize the retrieval algorithm step by step. The root mean square error between modelled  
530 and observed VOD is always used as the cost function and optimization at steps #2 and #4 is carried with a simplex search method. We define the search space for  $m_g$ , the gravimetric moisture content (water mass / fresh mass), as [0.3, 0.7]. This is guided by the average values measured at the site ( $m_g = 0.45 \pm 0.02$  g g<sup>-1</sup>), and also by data from Scoffoni et al. (2014) for *quercus agrifolia* in the Los Angeles area ( $m_g = 0.48$  g g<sup>-1</sup>). The search space for  $v_{veg}$  (volume of vegetation material per m<sup>3</sup>) is loosely defined as  
535 [0.0001, 0.01 m<sup>3</sup> m<sup>-3</sup>] based on the indications of Ulaby and Long (2014).

#### Algorithm

1. Select an a priori value for salinity.
2. For each 24-hour period, optimize  $v_{veg}$  (1 value for the entire 24-hour period) together with  $m_g$   
540 (24 hourly values). The result is a time series of daily  $k$  and hourly  $m_g$  covering the whole season (Fig. 10a).

3. Filter the time series of  $v_{veg}$  with a low-pass filter. Here we use a local regression filter (LOESS) with  $\pm 30$  days width (Fig. 10a).
4. Optimize  $m_g$  using the new  $v_{veg}$  values obtained at step #3 (Fig. 10b).
- 545 5. Filter the time series of  $m_g$  to reduce the high-frequency noise. Here we use a LOESS filter with  $\pm 2$  hours width (Fig. 10b).
6. Evaluate the agreement between the modelled and observed canopy-averaged VOD time series (with  $v_{veg}$  and  $m_g$  from steps #3 and #5) and determine an optimal salinity (Fig. 10c).

550 Because  $v_{veg}$  is kept constant only for the duration of a day, there is some high-frequency variability in the  $v_{veg}$  time series that is obtained after step #2 (Fig. 10a). These sudden and unrealistic jumps of  $v_{veg}$  also contaminate the estimates of  $m_g$  (not shown). These problems are alleviated in step #3, where daily estimates of  $v_{veg}$  are low-pass filtered, consistent with the assumption that changes in biomass usually occur at a relatively slow pace. Note that although calibrating  $v_{veg}$  over a time period longer than a day  
555 would also smooth the estimate, we found that optimizing  $v_{veg}$  at a daily time step and then applying a low-pass filter was much more effective in mitigating the influence of outliers. A new hourly time series of  $m_g$  is then obtained based on the filtered  $v_{veg}$  time series in step #4 (Fig. 10b). Because the  $m_g$  time series is contaminated by some noise inherited from the VOD observations, some mild smoothing is applied to  $m_g$  in step #5 (Fig. 10b). Steps #2 to #5 are repeated for different values of salinity and  
560 retain the optimum of the cost function as the most likely value (Fig. 10c). Here we find an optimum with a salinity of 8.9 psu, which is a physically plausible value.

565 **Figure 10. (a) Time series of  $v_{veg}$  after steps #2 and #3. (b) Time series of  $m_g$  after steps #4 and #5 with a zoom on a short period for better visibility. (c) Root mean squared error obtained for various salinity values. (d) Scatter plot of the modelled versus observed VOD. The data shown in (a), (b) and (d) is based on a salinity of 8.9 psu.**

570 Before we interpret these results, some limitations to the presented approach need to be emphasized. First, the dielectric model of Ulaby and El-rayes (1987) was originally developed for leaves, however, it is clear that branches and stems also contribute to canopy extinction. To our advantage however, Kurum et al. (2009a) have determined with numerical simulations (at L-band) that leaves do have a significant impact on extinction, while branches have a dominant contribution only in terms of backscatter, and trunks have a negligible impact on extinction. Steele-Dunne et al. (2012) arrived at similar conclusions and concluded that leaf moisture is by far the dominant control on vegetation transmissivity at L-band for both

a supprimé: may

a supprimé: (

polarizations. (but see Ferrazzoli and Guerriero (1996) for a different perspective). Observations by Mätzler (1994) in a deciduous forest also showed a clear dependence of the transmissivity to the presence or absence of leaves in the canopy. It is assumed that the dielectric model of leaves and its sensitivity to moisture, temperature, and salinity provides a sufficient approximation for the behaviour of the whole crown (branches and stems included). However, the impact of intercepted water (due to dew deposition or rainfall) is not explicitly represented and will thus be compensated for by an overestimation of the retrieved gravimetric moisture content. There is unfortunately not enough empirical data in our case to also retrieve intercepted water independently.

## 5.2 Results and interpretation

In Fig. 11a, the retrieval of gravimetric moisture content ( $m_g$ ) is compared against observations of leaves taken at the site on October 18. There is a bias of  $0.04 \text{ g g}^{-1}$  between the retrieval and the observations, a surprisingly good performance given the assumptions made during the retrieval of  $m_g$ , and the fact that a few leaf samples are not necessarily representative of the entire canopy. The relative difference between dawn and daytime values (about  $0.03 \text{ g g}^{-1}$ ) is consistent between the retrieval and the observations. We also find that the relationship between retrieved hourly  $m_g$  and VPD becomes narrower (Fig. 11b) compared to the relationship between hourly VOD and VPD (Fig. 11c). Even though this does not provide any formal validation of the  $m_g$  retrieval, it does suggest that the retrieval is somewhat successful in concentrating in  $m_g$  a response to atmospheric water demand that is consistent with observed plant stomatal behaviour (e.g. Grossiord et al., 2020).

595

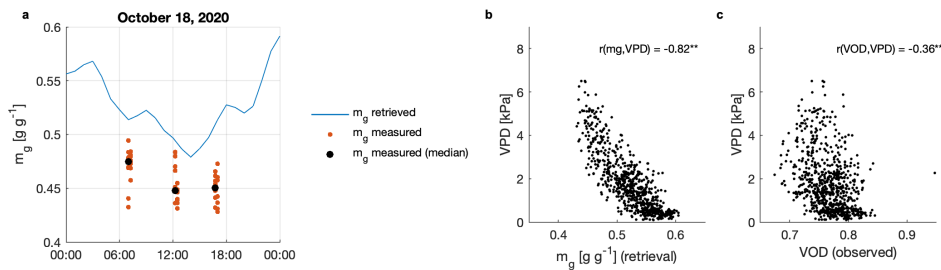

Figure 11. Retrieved and measured values of gravimetric moisture content ( $m_g$ ) on October 18 (a). Scatter plots of the hourly values of  $m_g$  (b) and VOD (c) against vapour pressure deficit (VPD), for the month of October (both correlations significant at  $p < 0.01$ ).

600 Dry aboveground biomass (AGB,  $\text{kg m}^{-2}$ ) can be calculated by multiplying the retrieved volume of the  
 vegetation material ( $v_{veg} \cdot h$ ,  $\text{m}^3 \text{m}^{-2}$ ) with the average density of the dry leaf material ( $\rho_{dry}$ ). Here we use  
 leaf density to remain consistent with the model's assumptions, but it is unknown if the density of leaves,  
 branches, wood, or some weighted average of all three would be more relevant at this stage. We use a  
 value of  $\rho_{dry} = 630 \text{ kg m}^{-3}$  reported by Scoffoni et al. (2014) for *quercus agrifolia*.

605

$$AGB = v_{veg} h \rho_{dry} \quad (16)$$

Canopy water content (CWC) is then calculated as follows.

610

$$m_g = \frac{\text{water weight}}{\text{fresh weight}} = \frac{CWC}{CWC + AGB} \quad (17)$$

$$CWC = \frac{AGB m_g}{(1 - m_g)} \quad (18)$$

The resulting time series are shown in Fig. 12a. For AGB, we obtain a mean value of  $10.9 \text{ kg m}^{-2}$  with  
 very little seasonal variations, as may be expected for an evergreen forest. Note that this estimate should  
 615 be interpreted with the awareness that VOD-based estimates of AGB likely do not weigh all canopy  
 constituents evenly. While L-band VOD is sensitive to leaves, the sensitivity to branches and trunks  
 increases at lower leaf moisture content (Steele-Dunne et al., 2012), or if leaves are entirely absent of  
 course. Because in situ estimates of AGB are not available at our experimental site, we can only put this  
 value in context with the literature. Several studies have empirically linked VOD observations to global  
 620 AGB datasets that are based on satellite data and forest inventories (Avitabile et al., 2016). For instance,  
 using the exponential relationship calibrated at L-band by Vittucci et al. (2019), we obtain (for an average  
 VOD value of 0.79 at our site) an AGB of  $13.8 \text{ kg m}^{-2}$ , not so far from our estimate. Other results from  
 Brandt et al. (2018) suggest a linear relationship between AGB and L-band VOD, with a sensitivity of

a supprimé: primarily

a supprimé: can also

about 133 Mg ha<sup>-1</sup> per unit VOD, which would yield an AGB of 10.5 kg m<sup>-2</sup> at our site. Thus, existing empirical relationships between VOD and AGB would suggest that the results obtained with the retrieval algorithm and its simple model are reasonable.

630 In terms of canopy water content (CWC), which is a function of both  $m_g$  and AGB, we find a long-term mean of 12.1 kg m<sup>-2</sup> at our site. As for AGB, it's important to keep in mind that the CWC estimate does not weigh all canopy constituents evenly. In particular, our retrieval assumes that the attenuation is dominated by small canopy elements, even though the contribution of large elements (like large branches or trunks) to CWC is likely not negligible. Comparisons with other studies are quite difficult here because the relationship between VOD and vegetation water content is poorly known for forests. Many studies  
635 over grasslands and croplands have demonstrated an empirical linear relationship of the form  $VOD = b \cdot CWC$ . However,  $b$  is also known to be vegetation- and time-dependent (Jackson and Schmugge, 1991; Van de Griend and Wigneron, 2004) and it has been argued that such a linear relationship is not necessarily appropriate for forests (Kurum et al., 2012; Le Vine and Karam, 1996). A mean CWC of 12.0 kg m<sup>-2</sup> is in broad agreement with the few studies which measured forest CWC. Recently, Kurum et al. (2021)  
640 reported 7.3 – 25.6 kg m<sup>-2</sup> across various plots of a deciduous broadleaf forest in Manitoba (Canada) with mean height of 10.9 m. Yilmaz et al. (2008) estimated CWC values ranging from about 2 to 10 kg m<sup>-2</sup> for a deciduous forest in Iowa (USA). In the SMAP soil moisture retrieval algorithm, vegetation water content values are estimated from NDVI (Chan et al., 2013). Their resulting (unvalidated) global map suggests a range of 6 to 18 kg m<sup>-2</sup> for various types of forest biomes.

645 In Fig. 12b-c, we investigate the temporal consistency (over the whole season) between the retrieved CWC values at our site and satellite observations of the Normalized Difference Water Index (NDWI) from Sentinel 2 (Gao, 1996; Claverie et al., 2018). NDWI is a good proxy for vegetation water content and is based on optical and near-infrared measurements, thus providing fully independent observations with respect to our retrieval. There are 24 days when NDWI observations are available, not flagged for  
650 cloud cover, and concurrent with a CWC estimate (Fig. 12b). We find a relatively good agreement between CWC and NDWI ( $r = 0.70$ ), higher than the agreement between observed VOD and NDWI ( $r = 0.63$ ). Interestingly, this agreement is quite dependent on the timing of the in-situ CWC (or VOD) measurement (Fig. 12c). For instance, comparing the 10:30 AM NDWI with the 12:30 PM CWC (or

VOD) would yield a substantially lower (and statistically non-significant) correlation of  $r = 0.30$  (0.32 for  
655 VOD). This time-dependence of the agreement is a good indication that the diurnal cycle of CWC is well  
captured and that VOD alone is not fully representing its dynamics.

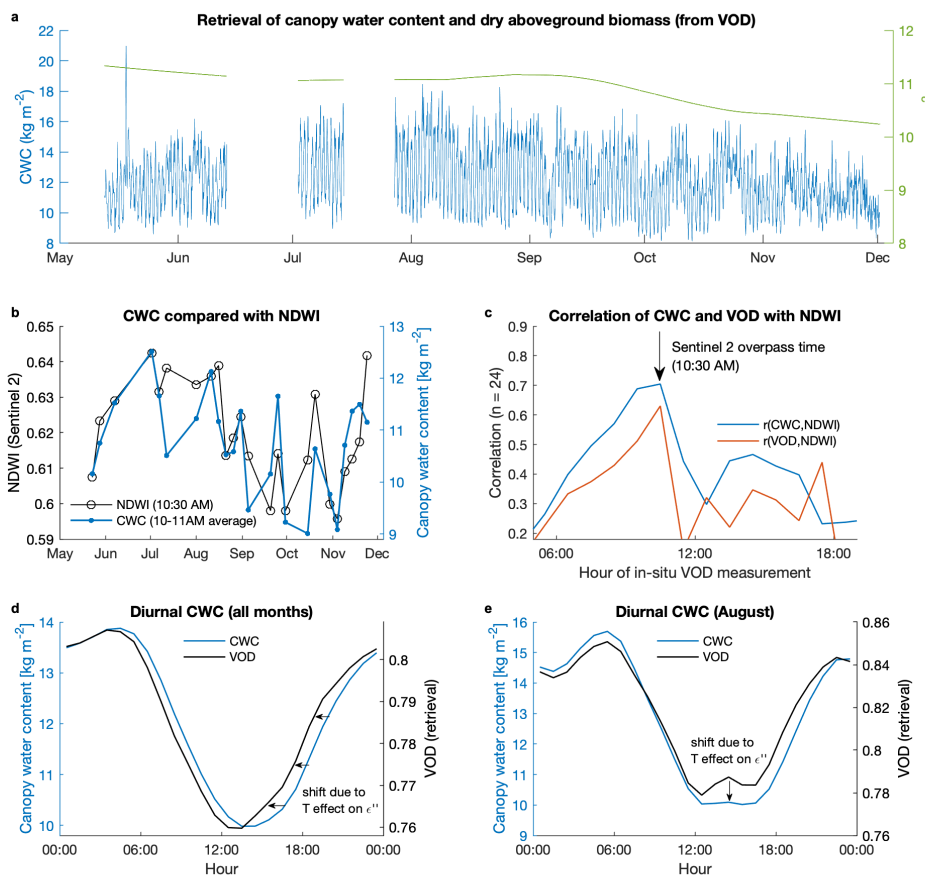

The diurnal dynamics of CWC are particularly strong, with a diurnal amplitude of  $3.8 \text{ kg m}^{-2}$  on average,  
meaning that 28% of the pre-dawn CWC is depleted over the course of the day (Fig. 12d). Such diurnal  
variations may seem important for a forested ecosystem but are not entirely inconsistent with other  
660 studies. Over a corn field in the Netherlands, (Vermunt et al., 2022) observed that midday vegetation  
water content was decreased by 10-20% on average compared to pre-dawn levels and even by 35.4% on  
a particularly warm day. The results of Mirfenderesgi et al. (2016), who investigated the transpiration and  
sap flow dynamics of oaks in New Jersey with a hydrodynamic model, suggest a diurnal amplitude of  
about 15% for just stem water storage. Matheny et al. (2017) also reconstructed a diurnal amplitude of  
665 14.6% to 22.3% of the stem water storage from in situ sap flow measurements of red maple in Michigan.  
Since our estimate of CWC also likely incorporates an additional contribution from dew (discussed in the  
next section), an average CWC amplitude of 28% would not be unexpected.

We find that our retrieval of CWC is slightly lagged compared to the diurnal average VOD cycle (Fig.  
670 12d). This lag is due to the diurnal cycle of temperature and its effect on the dielectric loss (and thus on  
VOD), as represented in the dielectric model (Fig. 2b). The effect can also be seen in Fig. 10e which  
focuses on the month of August. Here a minor peak in VOD can be observed at about 3PM, in the centre  
of the midday depression (also see Fig. 8a). Our retrieval suggests that at least some of this peak is in fact  
not related to rehydration but to a peak in diurnal temperature. In Fig. 13, we use the transmissivity model  
675 (Eq. 15) to explore the influence of moisture and temperature on modelled VOD (by enforcing a  
seasonally constant value for temperature and gravimetric moisture respectively). As temperature  
increases during the day, it increases the dielectric loss and leads to a higher modelled VOD (Fig 13a),  
thus counteracting the effect of moisture content changes to some extent. This effect was particularly  
pronounced during the heatwave which struck the area from September 5<sup>th</sup> to 6<sup>th</sup> (Fig 13b). Here it can be  
680 seen that there is relatively little response in terms of VOD during the heatwave, with even a minor  
increase on September 5. Because it is taking the response of the dielectric loss to temperature into

account, the retrieval algorithm compensates the effect of temperature with a marked CWC drop over that period (e.g. see Fig. 10a), which makes sense from a physiological standpoint. Indeed, the record-breaking heatwave was accompanied by VPD values of up to 8kPa on both days (compared to an average of 1kPa the week before) and it would be very unlikely to see no response of CWC (and VOD) to such a level of stress.

This modelled response of VOD to high temperatures emerges directly from the dielectric model of Ulaby and El-rayes (1987). It is also predicted by another semi-empirical dielectric model of leaves proposed by Matzler (1994), who confirmed such a temperature dependency with seasonal observations made in a beech forest (although they did not control for potential moisture changes as a covariate). It is very important to note that, at L-band, the magnitude as well as the direction of the dielectric loss's dependence on temperature is dependent on the temperature itself (Fig. 2b). For instance, at temperatures between 0 and 20°C the sensitivity of L-band VOD to temperature is negative (e.g. Schwank et al., 2021). We note that this temperature dependency can be quite crucial when interpreting water stress from VOD measurements. As water stress conditions often correlate with warm temperatures, one must be careful in interpreting VOD time-series over a large dynamic range of canopy temperatures as VOD alone might lead to unphysical interpretations, in our case an increase of canopy water in the middle of a heat wave.

710 **5.3 Rainfall interception and dew**

The only significant rainfall event during the measurement period occurred on May 18<sup>th</sup> (Fig. 14a). A  
 cumulated precipitation amount of 10.2 mm was measured on that day which coincided with an increase  
 in VOD of about 20% compared to the usual diurnal cycle. Within a few hours following rainfall, this  
 excess VOD quickly subsided but did not fully disappear until the day after. We could also establish that  
 715 signal strength was likely not affected by the presence of intercepted water on the antenna itself  
 (Supplementary Figure S2). These results indicate that L-band VOD is quite sensitive to intercepted  
 rainfall, ~~as has been shown with X-band VOD observations from the AMSR-E satellite (Xu et al., 2021)~~  
~~and from an in-situ radiometer (Schneebeli et al., 2011).~~ The VOD anomaly also lasted longer compared  
 to the surface wetness measurements taken at the reference station (Fig. 14a). This is likely because the  
 720 surface wetness instrument is exposed to sunlight and an open atmosphere, such that its surface water  
 evaporates much faster compared to what happens in a forest canopy. If future research at eddy-  
 covariance tower sites can demonstrate that such VOD measurements are a good proxy for intercepted  
 water, this may provide a useful constraint to the partitioning of evapotranspiration fluxes into different  
 sources (i.e. evaporation versus transpiration).

- ~~a supprimé:~~ satellite
- ~~a supprimé:~~ observations
- ~~a supprimé:~~ or
- ~~a supprimé:~~ data

For completeness, we also investigate the effect of dew on our measurements in Fig. 14b-c. Unlike rainfall events, dew events have smaller impacts on VOD and are more difficult to isolate from other sources of variability. Thus, we focus on the retrieved CWC time series, as it is less influenced by day-to-day variability in temperature compared to the VOD measurements (as discussed in the previous section). To  
735 diagnose some possible effects of dew on CWC, we separate a two-month observational subset into two samples based on the daily maximum relative humidity ( $RH_{\max}$ ). We use a threshold of 70% relative humidity to distinguish nights with and without a potential for dew formation (Ritter et al., 2019). We then calculate the average diurnal CWC cycles for each of these two subsets (Fig. 14b) and compare their relative difference against the surface wetness measurements taken at the reference site (Fig. 14c).  
740 Because the surface wetness sensor tends to saturate relatively quickly, we exclude nights where the wetness sensor is stuck at its maximum value. While this does remove some nights where a lot of dew deposition is occurring, it has the advantage of preserving the proportionality between CWC and the wetness sensor measurements. We find a relatively good agreement between CWC and the wetness sensor data (Fig. 14c), suggesting that dew deposition is reflected in our CWC retrieval. This finding is of  
745 importance since dew deposition, even in southern California, would then influence and potentially bias calculated differences between midnight and mid-day satellite-based VOD, which have been used to interpret plant hydraulic behaviour (Konings and Gentine, 2016). The two-peaked structure in Fig. 14c seems to be arising from the combination of individual dew accumulation events occurring either after sunset or before sunrise. It is important to note that because the transmissivity model does not represent  
750 surface water in a dedicated way (Schneebeil et al., 2011), the data in Fig. 14c should not be used to derive actual dew amounts. Here we can only conclude that L-band VOD is likely influenced by dew deposition, unlike Holtzman et al. (2021) who found no evidence for the impact of dew on VOD measurements in an oak forest, but in agreement with conclusions from several other studies (Xu et al., 2021; Schneebeil et al., 2011; Khabbazan et al., 2022).

(c) Difference in CWC based on (b) compared against wetness sensor measurements (taken at the reference site).

## 6. Conclusions

760 In this paper we have demonstrated that a pair of GNSS receivers can be used to continuously measure  
 L-band VOD in a forest stand. Thanks to the diversity of GNSS satellite orbits, a hemispheric scan of the  
 canopy can be obtained, offering the opportunity to individually monitor specific trees, groups of trees,  
 or classes of canopy density. While continuous changes in GNSS orbit patterns and constellation  
 configurations complicate the analysis of raw observations, we provide here a relatively straightforward  
 765 solution to alleviate this problem and produce credible VOD time series. Pooling observations from the  
 four largest GNSS constellations (GPS, GLONASS, BeiDou, and Galileo), we show that VOD anomalies  
 can be resolved at hourly resolution. In particular, our approach is able to identify a diurnal cycle in VOD  
 which appears consistent with what has been reported in previous recent studies (Holtzman et al.,

2021; Vermunt et al., 2021; Konings et al., 2017b). Here, obtaining such high-frequency (e.g. hourly) VOD  
770 time series comes at the cost of angular resolution, since measurements taken at all azimuths and elevation  
angles are aggregated into hourly averages. Because of the configuration of the GNSS orbits, users face  
a trade-off between obtaining VOD estimates at high angular resolution (e.g. Figure 5b) versus obtaining  
VOD time series at high temporal resolution (e.g. Figure 7b).

In a further step, we use existing simple models of canopy microwave transmissivity and vegetation  
775 dielectric parameters (Ulaby and Long, 2014) to demonstrate the feasibility of using such GNSS-based  
VOD observations to derive information on canopy water content and aboveground dry biomass (future  
work could certainly explore more complex formulations). Owing to the limited number of ancillary in  
situ measurements, this retrieval algorithm was not evaluated against long-term ground truth observations  
and should be seen as a proof-of-concept. Still, the resulting dry aboveground biomass and CWC  
780 estimates agree with what has been reported in similar studies. In addition, we show that the CWC  
estimates are in good agreement with satellite observations of the research site (NDWI from Sentinel 2),  
but only if the hourly CWC estimates are taken precisely at the time of the Sentinel-2 overpass. This  
dependency of the agreement on the observation timing provides convincing and independent evidence  
that the CWC time series derived from GNSS-based VOD contains valuable information. We also  
785 investigate the potential effects of diurnal changes in temperature on the dielectric constant of the  
vegetation and its impact on L-band VOD and the retrieved CWC. We show that temperature effects on  
the vegetation dielectric at L-band are predicted to play a minor but non-negligible role and can modulate  
VOD variability, especially for the case of diurnal variability as well as during extreme events such as  
heatwaves. Our results suggest that diurnal variability in VOD due to water content could be dampened  
790 and in some cases even be reverted by the variability in temperature. This is because temperatures  $> 20^{\circ}\text{C}$   
cause an increase of the dielectric loss in saline water, causing VOD to increase over the day, in a direction  
opposite to the expected effect of diurnal canopy dehydration. The magnitude of this temperature effect  
is dependent on the microwave frequency and the ionic conductivity of the plant water according to the  
empirical model of Ulaby and El-rays (1987). Finally, we provide some evidence that GNSS-based VOD  
795 is sensitive to surface canopy water, for the cases of both rainfall interception and dew deposition.

Future work may focus on various aspects. Future deployments of GNSS-based measuring systems like the one proposed here will be made at heavily monitored ecohydrological research sites in order to facilitate cross-comparisons with other in situ data. At the time of writing, we have recently equipped  
800 three forested FluxNet eddy-covariance sites with pairs of GNSS sensors, one in the U.S. (US-MOz) and two in Switzerland (CH-Lae and CH-Dav). Based on these new deployments, we provide below a few recommendations. The total cost to equip an existing research site was of about 2000 USD, with two thirds of that amount dedicated to acquiring the scientific instruments. The reference instrument may be placed at the top of a flux tower or at some other close location (i.e. < 5 km away) with the clearest  
805 possible view of the sky. Positioning the subcanopy antenna is not subject to strong restrictions. It can even be placed on the ground (without a tripod) as long as it is level and free from obstructions. We suggest placing the antenna in direct view of frequently monitored trees and not too close to strong reflectors (large tree trunks, buildings). The sampling characteristics discussed in section 3.2 and reported in Fig. 6a may be helpful in guiding new installations. Over flat terrain, the maximum extent of the  
810 observation footprint is dependent on the height of the vegetation (minus the subcanopy antenna height). Assuming that measurements with an elevation angle lower than  $10^\circ$  are discarded, the footprint may be roughly estimated as a circle with a radius of  $r = h/\tan(10^\circ)$ , i.e.  $r \approx 57$  m for  $h = 10$  m. We provide further recommendations in Supplementary Table S1. Other future objectives should include an evaluation of GNSS-based VOD estimates against other VOD measurements made by a tower-mounted  
815 radar or radiometer. In particular, the degree to which GNSS-VOD at RHCP-polarization agrees with other VOD estimates at horizontal (H) or vertical (V) polarization is unknown. For instance, previous studies over forests have shown that H-pol VOD can differ from V-pol VOD, even though temporal dynamics are similar (Schwank et al., 2021; Guglielmetti et al., 2008; Kurum et al., 2009b). Even though our observations do not suggest it, we cannot yet exclude the possibility that GNSS-based VOD has some  
820 type of bias compared to these other types of measurements (which do not constitute a reference per se). The question of how to best process the GNSS data in order to obtain VOD time series also remains to be explored. The initial solution provided in Section 3.3 may likely be refined to further reduce some of the noise still present in sub-hourly GNSS-based VOD time series. Some additional information may also be gained by using GNSS signals at multiple frequencies (we used here the most common signal, which is

825 emitted at around 1.57 GHz, but individual constellations also broadcast signals at lower frequencies, up  
to 1.17 GHz).

The results presented here suggest that GNSS-VOD may have the potential to fill a key research gap in  
terms of linking satellite-based L-band VOD observations to ground observations. This contribution could  
830 take place in several ways. For example, arrays of GNSS receivers deployed within the spatial footprint  
of a satellite VOD grid cell (i.e. about 30 km) may serve to estimate a regional average VOD that would  
be suitable as ground truth for the satellite products. In addition, long-term in-situ VOD observations  
performed at existing ecohydrological research sites may serve to develop and evaluate retrieval  
algorithms that aim to transform VOD into other relevant quantities of interest like aboveground biomass,  
835 canopy water content, or leaf water potential. To the benefit of these research sites, GNSS-VOD provides  
a useful proxy to upscale and gap-fill time series of the time-consuming and labour-intensive  
measurements of leaf water status and biomass. The ability to detect rainfall interception and dew  
deposition at the scale of a whole canopy may also provide some key information to improve our  
understanding of water, energy, and carbon fluxes at these sites. While GNSS-based monitoring of the  
840 Earth system remains a relatively diverse and emerging research field, remote sensing of GNSS-VOD  
appears as a particularly promising application, because of its ability to address a series of research  
objectives at a modest cost.

#### **Code and data availability**

Raw and processed GNSS data files are freely available upon request. Weather data is publicly available  
845 at <http://tccon-weather.caltech.edu/> and <https://dpw.lacounty.gov/wrd/rainfall/>. Harmonized Sentinel-2  
data is publicly available at <https://hls.gsfc.nasa.gov/>. The tecq software is publicly available at  
<https://www.unavco.org/software/data-processing/teqc/teqc.html>.
