**Abstract.** Ocean acidification (OA) is expected to negatively affect many ecologically important organisms. Here we explored the response of Caribbean benthic foraminiferal assemblages to naturally discharging low-pH waters similar to expected future projections for the end of the 21<sup>st</sup> century. At low-pH ~ 7.8 sw pH units and low calcite saturation ( $\Omega < 4$ ), the relative abundance of agglutinated and symbiont-bearing species increased, indicating higher resistance to potential carbonate chemistry changes. Diversity and other taxonomical metrics (i.e., richness, abundance, and evenness) declined steeply with decreasing pH despite exposure of this ecosystem to low pH conditions for millennia, suggesting that tropical foraminifera communities will be negatively impacted under acidification scenarios SSP3-7.0 and SSP5-8.5. The species *Archaias angulatus*, a major contributor to sediment production in the Caribbean was able to calcify at conditions more extreme (7.1 pH units) than those projected for the late 21<sup>st</sup> century, but the calcified tests were of lower density than those exposed to high-pH ambient conditions (7.96 pH units), indicating that reef foraminiferal carbonate budget might decrease. Smaller foraminifera were highly sensitive to decreasing pH and our results demonstrate their potential use to monitor increasing OA conditions.

## 1 Introduction

With anthropogenic carbon emissions steadily increasing since the beginning of the industrial age, atmospheric carbon dioxide (CO<sub>2</sub>) is now higher than it has been in the past 800 thousand years (Petit et al., 1999; Lüthi et al., 2008). Global emissions are annually increasing and leading to a proportional increase of CO<sub>2</sub> uptake by the oceans and consequently decreases of surface ocean pH ( $-0.0181 \pm 0.0001$  decade<sup>-1</sup>, Lida et al., 2021) and carbonate ion concentrations [CO<sub>3</sub><sup>2-</sup>], a process known as ocean acidification (OA) (Doney et al., 2020). Based on the Coupled Model Intercomparison Project Phase Six (CMIP6), a further decrease of surface ocean pH is expected for all Shared Socioeconomic Pathways (SSPs) at the end of the 21<sup>st</sup> century (Kwiatkowski et al., 2020; IPCC, 2021). As the carbonate system has major control on biogenic calcification efficiency this process is expected to negatively affect many ecologically important calcifying organisms such as corals (Kroeker et al., 2013; Crook et al., 2013; Hughes et al., 2017), foraminifers

40 (Uthicke, Momigliano, and Fabricius, 2013; Kawahata et al., 2019), and coralline crustose algae (Penã et al., 2021).

Among these, foraminifera are dominant members of both planktonic and benthic communities with widespread distribution in the oceans. They are vital to calcium carbonate (CaCO<sub>3</sub>) cycling, especially through calcification (Langer et al., 1997; Langer, 2008). On a global scale, they are estimated to contribute  
45 a total of 14 billion tons of CaCO<sub>3</sub> per year, which accounts for about 25 % of current total CaCO<sub>3</sub> production (Langer, 2008). Due to their ability to consume substantial amounts of organic matter, they are also relevant for organic carbon cycling (Moodley et al., 2000), being part of a key link in marine food webs. After death, their tests become important contributors to sediment mass accumulation in many ecosystems (Yamano, Miyajima, and Koike, 2000; Doo et al., 2016) and are also relevant for the carbon  
50 burial flux in the ocean (Schiebel, 2002). With ongoing OA and future scenarios projecting rapid changes (Kwiatkowski et al., 2020; IPCC, 2021), it is vital to understand how foraminifera will be affected for assessing biological feedbacks and changes in biochemical cycles. Many studies under controlled conditions often document the association of low-pH with decreased calcification, weight, size, and taxonomical metrics (Nehrke et al., 2013; Kawahata et al., 2019; Narayan et al., 2021, and references  
55 therein). However, some studies have also demonstrated either resilience (Engel et al., 2015; Pettit et al., 2015; Stuhr et al., 2021), or even positive effects on foraminifera, such as enhanced calcification (Fujita et al., 2011) and enzymatic calcification activity (Prazeres et al., 2015), which demonstrate the complexity of interspecific responses to OA. Additionally, relatively little is known about how foraminifera respond in natural low-pH low carbonate saturation waters, which is crucial for determining if and how communities  
60 have the potential to acclimate.

In situ investigations have been performed in natural CO<sub>2</sub> vents in the Mediterranean Sea (Dias et al., 2010; Pettit et al., 2015), Papua New Guinea (Uthicke, Momigliano, and Fabricius, 2013), the northern Gulf of California (Pettit et al., 2013) and coastal springs in Puerto Morelos (PM), Mexico (Martinez et al., 2018). In the latter, recruitment and early succession (Crook et al., 2016), acclimatization potential (Crook et al.,  
65 2013), and the responses of calcifying communities were studied (Crook et al., 2012; Martinez et al., 2018), demonstrating that despite general deleterious effects, some organisms were able to calcify under OA conditions. A study focused on Large Benthic Foraminifera (LBF) has shown that porcelaneous, chlorophyte-bearing foraminifera, (e.g., *Archaias angulatus*), were relatively less impacted (Martinez et al., 2018). Study sites such as coastal springs allow the investigation of foraminiferal communities under  
70 projected future conditions more realistically, helping to decrease the uncertainty in global-scale models. However, a detailed survey considering community-wide responses (i.e., including smaller foraminifera) is necessary to ascertain a wider range of potential impacts.

As CO<sub>2</sub> emissions continue to grow despite emerging climate policies (Peters et al., 2020), global awareness has demonstrated a strong interest in research focused on potential impacts for mitigative action. To build  
75 on and expand the findings at PM we aimed to (i) explore the mid-term (i.e., multidecadal) responses of foraminifera species using total assemblages, (ii) investigate the effects of OA on both large and small foraminiferal assemblages for acidification scenarios projected to the end of the 21<sup>st</sup> century (Kwiatkowski et al., 2020; IPCC, 2021), (iii) explore the taphonomical and ecological implications of *post mortem*

alterations for reef ecosystems, and (iv) investigate possible acclimation patterns in the shell structure of the species *A. angulatus*. Specifically, an examination of assemblage structure, taxonomic metrics, assemblage test size, preservation potential and an X-ray micro-CT analysis in the species *A. angulatus* was employed.

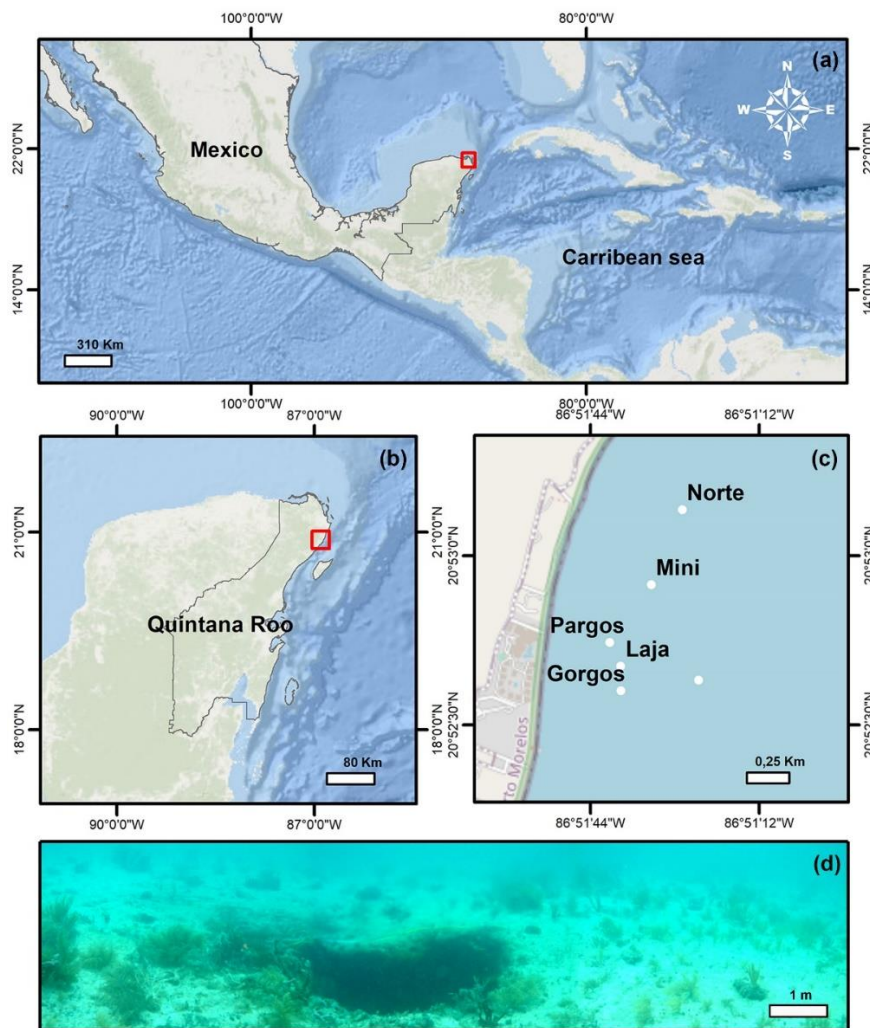

## 2 Methods

### 2.1 Study site and data retrieval

The Yucatán Peninsula is a karstic region in Southern Mexico (Fig. 1a). The Tertiary limestones is underlain by an ejecta/evaporite complex, where several structural and tectonic features strongly influence and divide the area into six distinct physiographic regions (Back and Hanshaw, 1970). Among these, Puerto Morelos reef lagoon is part of the Holbox Fracture Zone–Xel-Ha region, which is characterized by >100 km long chain of elongated depressions referred as ‘sabanas’ (Perry, Velazquez-Oliman, and Marin, 2002). In this area, rainwater infiltrates the porous karstic limestone of Quintana Roo (Fig. 1b) and flows towards the ocean through interconnected caves and fractures where the groundwater mixes with seawater in the underground aquifers before discharging between the shore and the offshore barrier reef (Beddows et al., 2007; Null et al., 2014). Flowing through the limestones and interacting with the strata through processes of dissolution, precipitation, and mixing, the groundwater conditions change and finally discharge along the Mexican coast as low-pH, low carbonate-saturation-state ( $\Omega$ ), and high inorganic C content waters (Back and Hanshaw, 1970; Perry, Velazquez-Oliman, and Marin, 2002; Crook et al., 2012, 2013, 2016; Martinez et al., 2018, 2019; Hernandez-Terrones et al., 2021). These waters discharge at submarine springs, which structure ranges from long “fractures” to small circular depressions “seeps” (Fig. 1d, spring Agua), (Crook et al., 2012). The discharge of the springs is relatively constant throughout the year (Crook et al., 2016), and the lagoon circulation is not significantly affected by tides (av. 17 cms), and currents due to the microtidal regime of the region (Coronado et al., 2007) and their location in the protected back-reef. The waves overtopping on the reef and the resulting flow is the main driving factor of circulation, which in general is slow (av. 2–3 cm s<sup>-1</sup>), with faster (av. 20 cm s<sup>-1</sup>) flow restricted to the northern and southern channels where the water exits the lagoon (Coronado et al., 2007). At the springs, the discharged slightly lower salinity waters mainly flow vertically and not towards the sediment due to the buoyancy effect. The beach sediments are composed of coarse (~0.258 mm) carbonate sands of biogenic origin (Escudero et al. 2020).

Surface sediment samples (< 1 cm depth) were retrieved using a plastic spoon at various distances from the center of six submarine springs (Fig. 1c, Gorgos, Laja, Mini, Norte, Agua, and Pargos) in October 2011. In the laboratory, samples were weighed, washed with deionized water through a 63  $\mu$ m sieve mesh, and dried at 50 °C for 24 hours. Discrete water samples near the sites of sediment collection were also retrieved for water chemical analysis. The carbonate chemistry, temperature, and salinity data from seven samples reported in Martinez et al., 2018 was complemented with 20 additional samples collected at the same day following the protocols described by the authors. Briefly, the samples were filtered (0.2  $\mu$ m) and split into aliquots for the analysis of salinity, total inorganic carbon ( $C_T$ ) and total alkalinity ( $A_T$ ), following the protocols of Dickson, Sabine and Christian (2007). The  $C_T$  was measured on a CM5011 Carbon Coulometer

(UIC, Inc.; analytical measurement error:  $\pm 3 \mu\text{mol kg}^{-1}$ ) and  $T_A$  using an automated open-cell, potentiometric titrator (Orion model 950; analytical measurement error:  $\pm 2 \mu\text{mol kg}^{-1}$ ). Salinity was measured using a portable salinometer (Portasal Model 8410, Guild Line). Seawater temperature was measured in situ with a handheld YSI micro-processor (Yellow Springs model 63). The pH (Seawater scale), carbonate ion concentration ( $\text{CO}_3^{2-}$ ) and calcite saturation state ( $\Omega$ -Calcite) were calculated using the program CO<sub>2</sub>Sys (Pierrot, Levis and Wallace, 2006), considering the CO<sub>2</sub> dissociation constants of Lueker, Dickson and Keeling (2000); KHSO<sub>4</sub> – Dickson, Sabine and Christian (2007); B concentration – Upström, 1974. Certified CO<sub>2</sub> reference material (from A. Dickson lab at UC San Diego, batch 112) was used to calibrate all instruments.

**Figure 1** (a) Location map of the Yucatán Peninsula, (b) Quintana Roo, and (c) the six submarine springs (Gorgos, Laja, Mini, Norte, Pargos and Agua) studied at Puerto Morelos reef Lagoon (National Marine Park), (d) Spring agua, which structure presents a small circular depression.

## 130 2.2 Foraminiferal analysis

The dry weight of sediments was recorded, and samples were split to make them more suitable and efficient to pick. The specimens found in each pre weighted sediment aliquot were counted under a Zeiss STEMI 2000 stereomicroscope until a minimum of 250 specimens were obtained from each sample. Foraminiferal tests were identified to the lowest possible taxonomic level and assigned to informal species categories for diversity analyses. The taxonomic classification was based on the specialized bibliography of Cushman (1929), Jones (1994), and supplementary taxonomic studies (Milker and Schmiedl, 2012; Abu-Zied, Al-Dubai, and Bantan, 2016; Sariaslan and Langer, 2021). Each species and genus were verified against WoRMS to ensure the use of the most recent nomenclature.

The samples were stained in rose Bengal to consider the living counts, while most test were at least partially stained the proportions of fully stained specimens were small (~3 %) hence total (live plus dead) assemblages were used. We expect that the sample represents accumulation over several decades. This approach allows us to assess the mid-term responses of foraminiferal assemblages since the generational accumulation of tests in the sediments integrate the effects of stressors over time (Hallock et al., 2003), and averages out seasonal fluctuations, therefore documenting the foraminifera responses to prevailing marine conditions (Scott and Medioli, 1980). We note that the low live percentage is a common pattern as most reef-dwelling taxa tend to live on phytal or hard substrates rather than directly on the sediments (Martin, 1986; Barbosa et al., 2009, 2012; Stephenson, Hallock and Kelmo, 2015). Shannon-Weiner Diversity Index ( $H'$ ), and Pielou's evenness ( $J'$ ) were calculated considering the standardized foraminifera density at  $1 \text{ cm}^3$ . These taxonomic metrics were calculated as follows: Shannon-Weiner Diversity Index with the equation  $H' = -\sum(P_i \cdot \log(P_i))$ , where  $P_i$  is the proportion of individuals per species; Pielou's evenness with the equation  $J' = H' / \log(S)$ , where  $H'$  is the Shannon-Weiner Diversity Index and  $S$  the species richness. Assemblage distributions were assessed according to differences in functional groups, i.e., symbiont-bearing and opportunistic, and test type groups, i.e., small miliolids, small rotaliids, and agglutinated that do not present an opportunistic behavior. This approach is used by Amergian et al. (2022) in nearby settings, based on categories designed by Hallock et al. (2003) for sensitivity/stress-tolerance taxa and Murray (2006) for different test compositions.

### 2.3 Taphonomy and assemblage test size analysis

To improve the understanding of the extent to which tests have been taphonomically altered foraminifera tests were classified into three categories 'optimally' (i.e., pristine tests), 'well' (i.e., tests with weak taphonomic signals), and 'poorly' (i.e., strongly abraded or fragmented tests) preserved, following the descriptions of Yordanova and Hohenegger, 2002. Discoloration patterns were analyzed to investigate the vertical mixing and exposure of relict tests. In general, if colored black (with iron/manganese sulfides) the tests indicate relict sediments deposited under reducing conditions, whereas a brown coloration indicates the oxygenation of iron through the reworking of the sediments (Maiklem, 1967) and white tests indicate lack of significant sediment burial and alteration. For a complete survey of the assemblage test size distribution, the surface area of all individuals was calculated using the ImageJ software (Schneider, Rasband, and Eliceiri, 2012). All specimens picked were placed on the dorsal side in common brass picking trays and photographed under the same magnification and camera settings using an adapter for a microscope

camera as Prazeres et al. (2015), to trace surface area changes (i.e., gain or loss) in large benthic  
170 foraminiferal species under low-pH conditions. The parameter of surface area was the most suitable for the  
analysis since it identifies the size of the foraminifera tests in a standard way, considering the high  
taxonomical and consequently morphological diversity of PM samples.

#### 2.4 X-ray MicroCT

An X-ray MicroCT analysis was employed in four individuals from ambient (7.96 pH units) and low-pH  
175 conditions (7.11 pH units). To ensure that the analyzed tests represent living conditions, only tests in  
excellent condition, and therefore, not influenced by *post mortem* processes of dissolution and transport  
were selected. For the X-ray microCT acquisition, a V/TOMEX/M (GE Measurement and Control  
Solutions, Wunstorf, Germany) was used. The microCT parameters for the acquisition included a voltage  
of 60 kV, current of 100  $\mu$ A, 5 frames, and an Al filter with a thickness of 0.5 mm. The geometry had a  
180 magnification of 31.81 and pixel size of 6.28  $\mu$ m. Certified calcite standards were used to calibrate the  
density for this material. The 3D reconstructions were performed using the Phoenix Datos X Reconstruction  
software, in which the slice alignment, beam hardening correction was implemented, and a mathematical  
edge-enhancement filter was applied to achieve a higher contrast between the edges. For the 3D  
visualization, VG Studio Max v 3.0 and Avizo 2020.3 softwares were used. For calcite density analysis,  
185 the CTAnalyser v. 1.18.4.0 software was used. Calcite density was assessed by the calcite density  
distribution calculated from the CT number that was calculated based on the X-ray attenuation coefficient  
of each sample (Iwasaki et al., 2019). In addition, the estimation of morphometric parameters such as total  
volume and chamber wall thickness distribution was performed.

#### 2.5 Statistical analysis

A BIO-ENV procedure (9999 permutations) and global BEST test (statistical significance) was used to  
190 identify the set of explanatory environmental parameters that produced a Euclidean matrix that best  
correlated (Spearman method) the species assemblage similarity matrix and normalized environmental  
variables. Polynomial models (second order) were performed to investigate the relationships between  
carbonate chemistry and the taxonomical metrics ( $n = 26$ ). They were compared according to their  
195 contribution to the model's Akaike Information Criterion (AIC), and the models with the lowest AIC value  
(i.e., highest fit) were selected for the analysis. For comparison of *A. angulatus* microstructure parameters  
between high and low-pH the student's t-test ( $n = 8$ ) was used for variables with normal distributions and  
homogenous variances. When these conditions were not met, Welch's t-test was performed. We used the  
Kruskal-Wallis test to assess differences between functional groups, taxonomic metrics, and assemblage  
200 test size. For the latter, the stations were separated into four groups considering the following pH gradients  
in respect to future projections: 8.1–8.05 pH units as present-day conditions ( $n = 4$ ); 8.01–7.9 pH units  
surveying low-intermediate acidification scenarios SSP1-2.6 and SSP2-4.5 ( $n = 11$ ); 7.8–7.7 surveying high  
acidification scenarios SSP3-7.0 and SSP5-8.5 ( $n = 4$ ); 7.6–7.2 surveying acidification conditions beyond  
those predicted to the end of 21<sup>st</sup> century ( $n = 7$ ). Data normality and variance homogeneity were tested  
205 using Shapiro-Wilk and Levene's Test. The BIO-ENV and global BEST procedure were performed in

Primer v.6 software (Clarke and Gorley, 2006). Student's t-test, Welch's t-test, Kruskal-Wallis test, and data visualization were performed using R software (version 4.0.2; <http://www.Rproject.org>, R core team, 2020).

### 3 Results

#### 210 3.1 Water chemistry

Seawater carbonate chemistry (Table 1) contrasted strongly between samples. Obtained ranges were as follows: pH = 7.2–8.1 units,  $\Omega$ -Calcite = 1.3–6.2,  $CO_3^{2-}$  = 52–240  $\mu\text{mol}/\text{kg}^{-1}$ ,  $T_A$  = 2044–3108  $\mu\text{mol}/\text{kg}^{-1}$ , and  $C_T$  = 1725–3197  $\mu\text{mol}/\text{kg}^{-1}$ . The temperature was consistent among sites from 26.1–27.9, while salinity decreased with proximity to the springs, ranging from 28–37. The BIOENV analysis and global BEST test  
215 revealed that the best combination (p-value = 0.01) of environmental variables with species abundance was observed when considering pH,  $CO_3^{2-}$ ,  $\Omega$  Calcite and T ( $\rho$  = 0.55), in which  $CO_3^{2-}$  and pH were the environmental variables matching the highest correlation ( $\rho$  = 0.5) and salinity ( $\rho$  = 0.33) and temperature ( $\rho$  = 0.038) the lowest ( $\rho$  = 0.038). With respect to the taxonomic metrics the multiple regression analysis presented similar results. For diversity, richness, and evenness the pH model presented the lowest AIC  
220 value (26.96, 196.65, -67.05, respectively), indicating the central influence of this variable on the communities, while salinity (43.77, 209.71, -54.79, respectively) and temperature (59.46, 224.28, -40.65, respectively) were less influential. Interestingly, the  $T_A$  and  $C_T$  were the most important variables for foraminiferal density (AIC=401.79, and 401.99). The salinity (AIC = 406.34) and temperature (AIC = 409.03) were also not significant for foraminifera density. The weighting by relative likelihood (Akaike weights), log-likelihood, significance and level of variation explained by each of the environmental  
225 parameters ( $R^2$ ) are available in Table S1. Considering its predominant influence, pH will be mainly used to discuss the potential impacts of changing carbonate chemistry.

**Table 1** Carbonate chemistry parameters of discrete water samples collected near the substrate at the time of sediment collection.  $T_A$  = total alkalinity;  $C_T$  = total inorganic carbon;  $CO_3^{2-}$  = carbonate ion  
230 concentration;  $\Omega$  Calcite = calcite saturation-state; T = temperature.

### 3.3 Taphonomical and assemblage test size analysis

High-pH stations (~8.1 pH units) at PM are relatively pristine with optimally and well preserved tests  
235 representing approximately 80% of the assemblage, however, this gradually changes as the effects of spring  
water increase (Fig. 2b). In general, dissolution was not homogenous between species, but mainly  
associated with the occurrence of LBF, specifically, *Archaias angulatus*, which was able to individually  
explain 73% of highly dissolved tests occurrence ( $R^2 = 0.73$ , Fig. 2c). The small, less robust calcifiers (e.g.,  
*Rosalina* spp, *Elphidium* spp) were rare but when found they were mainly in pristine conditions. Regarding  
240 color patterns, only two specimens with brown color were found at spring Laja, indicating little reworking  
of sediments and therefore, mixing of pristine and relict tests. Overall, we observed that the specimens are  
in good conditions, composed of well-preserved time-averaged assemblages, which still provides a good  
representation of the present-day biocoenosis (Yordanova and Hohenegger, 2002). However, at 7.7 pH  
units and lower, high levels of taphonomical alteration started to occur (Fig. 2b-c, Dashed lines), when  
245 poorly preserved tests comprised ~ 50 % of total assemblage.

Along the gradient of changing carbonate chemistry, a significant change in foraminiferal assemblage test  
size was observed (Kruskal-Wallis, chi-squared = 16, df = 3, p-value = < 0.05). A gradual decrease in the  
abundance of tests with smaller surface area and a relative increase of larger tests is observed towards low-  
pH sites (Fig. 2a,  $R^2 = 0.73$ , p-value = < 0.05), whereas an abrupt increase was observed at 7.8 pH units.  
250 The post hoc Dunn's test reveals that only the differences between present-day and extremely low-pH  
conditions, which are beyond the predicted to the end of the 21<sup>st</sup> century was significant ( $z = -2.7$ , p-value  
= < 0.05). Specifically, the average test size in the assemblage more than tripled when compared to present-  
day conditions (from  $0.33 \pm 0.2$  to  $0.87 \pm 0.14$  mm<sup>2</sup>). This abrupt change can be visualized in Fig. 2a, likely  
responding to changes in faunal composition rather than interspecific changes in species size. As observed  
255 in taphonomical analysis, linear correlation with respect to dominant taxa coverage, i.e., the species *A.*  
*angulatus*, shows a high and significant correlation to changes in average assemblage test size (Fig. 2c,  $R^2$   
= 0.89, p-value = < 0.05). Raw data of assemblage average test size, and taxonomic metrics are available in  
table S2.

260 **Figure 2** (a) The density plot of assemblage test size, (b) area plot of foraminifera taphonomical status  
 against changing pH, and (c) variation of poorly preserved tests and average assemblage test size against  
*Archaia angulatus* relative contribution. The black lines represent the second-order polynomial model fits  
 along with the R<sup>2</sup> value and p-value (c).

### 3.2 Foraminiferal analysis

265 The assemblages (live + dead, table S3) found at PM exhibit similar composition to previous studies  
 conducted in nearby coastal settings (Gischler and Möder, 2009), Caribbean eastern islands (Wilson and  
 Wilson, 2011), and the Gulf of Mexico (Stephenson, Hallock and Kelmo, 2015; Amergian et al., 2022). A  
 total of 8564 foraminifera from 141 species were identified, belonging to 4 orders, 37 families, and 73  
 genera. Agglutinated species contributed with 6.4 % (9 species), porcelaneous 61 % (86 species), and  
 270 hyaline 32.6 % (45 species) of the total species richness. For total assemblages the species *A. angulatus*  
 (9.4 %), followed by *Rotorbinella rosea* (9.3 %), *Asterigerina carinata* (6.9 %), and the *Rotorbis auberii*  
 (4.7 %) were the most important contributing taxa, whereas for living counts *Rosalina globularis* was the

most important taxa (11 %). The species that contributed at least 3 % of total abundance are shown in Fig. 3.

In general, the species *Quinqueloculina tricarinata*, *A. angulatus*, *Amphistegina gibbosa*, *Valvulina oviedoiana*, *Cyclorbiculina compressa* increased towards low-pH, high  $C_T$ , and  $T_A$  values, presenting an increased relative abundance and lower sensitivity to OA. On contrary, high sensitive species were presented by *Thochulina* sp, *Sorites marginalis*, *Quinqueloculina subpoeyana*, *R. auberii*. The species *Rotorbinella rosea*, *Clavulina angularis*, *Quinqueloculina disparilis*, *Lachlanella carinata*, and *Schlumbergerina alveoliniformis* present decrease in abundance towards low pH at a lower rate compared to the species on the right suggesting more tolerance.

300 The symbiont-bearing taxa (Fig. 4a,  $R^2 = 0.54$ , p-value  $\leq 0.05$ ) presented lower sensitivity to OA conditions increasing in relative abundance towards low-pH. The small miliolids (Fig. 4c,  $R^2 = 0.42$ , p-value  $\leq 0.05$ ), opportunistic (Fig. 4d,  $R^2 = 0.28$ , p-value  $\leq 0.05$ ), and small rotaliids taxa (Fig. 4e,  $R^2 = 0.36$ , p-value  $\leq 0.05$ ) decreased in relative abundance towards low-pH conditions, presenting higher sensitivity. Kruskal-Wallis analysis reveal that the observed variation was statistically significant for most functional groups: Symbiont-bearing (chi-squared = 13, df = 3, p-value  $\leq 0.05$ ), small miliolids (chi-squared = 12, df = 3, p-value  $\leq 0.05$ ), opportunistic (chi-squared = 16, df = 3, p-value  $\leq 0.05$ ), and small rotaliids (chi-squared = 9, df = 3, p-value  $\leq 0.05$ )  $\ddagger$ . Specifically, post hoc Dunn test reveals that significant changes occurred mainly between present day ( $\sim 8.1$  pH units) and extremely low-pH conditions ( $\leq 7.6$  pH units) representing conditions beyond those predicted by the end of 21<sup>st</sup> century: Symbiont-bearing ( $z = -2.38$ , p-value = 0.01), small miliolids ( $z = 2.7$ , p-value  $\leq 0.05$ ), and opportunistic ( $z = 2.4$ , p-value = 0.01). For small rotaliids taxa the significance was observed between low-intermediate acidification scenarios ( $\sim 7.9$  pH units), at which the group presented a higher contribution, and extremely low-pH conditions ( $\leq 7.6$  pH units) where a strong decrease was observed with the other metrics ( $z = 1.7$ , p-value  $\leq 0.05$ ). No significance was observed for agglutinated foraminifera (chi-squared = 2, df = 3, p-value = 0.5), which also did not present significant correlation with changing pH (Fig. 4b,  $R^2 = 0.11$ , p-value = 0.1).

315

Raw data of functional and test type group are in table S4 and the distribution of functional groups against changing pH is in Fig. 4.

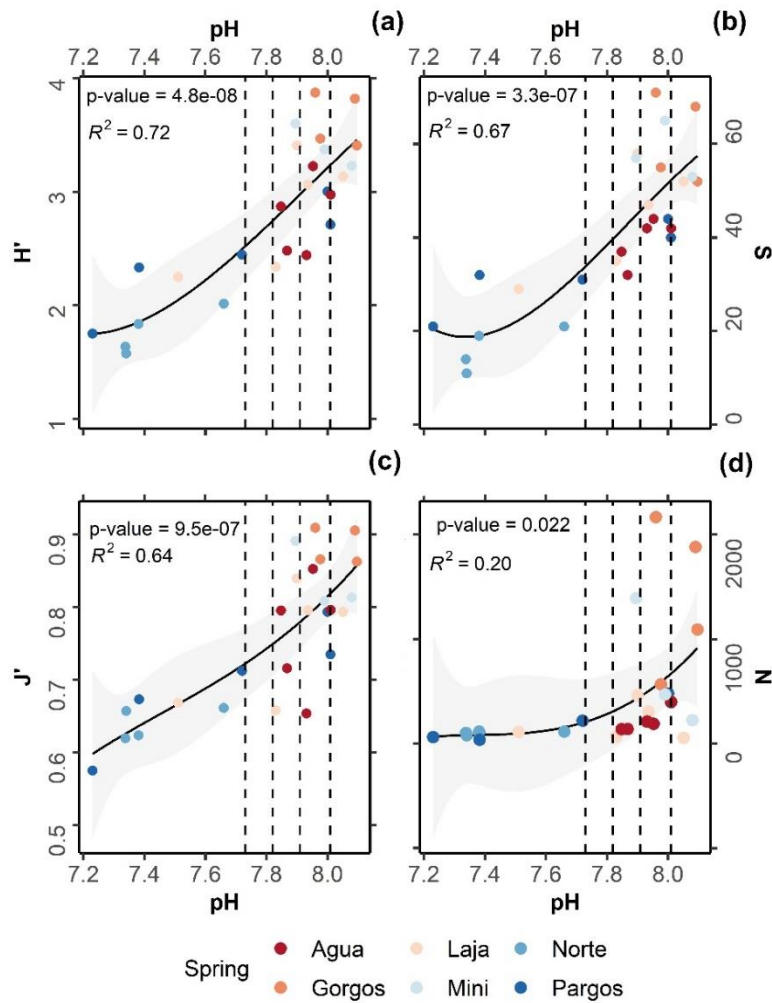

**Figure 4** Variation of functional groups against changing pH. The black line represents the second-order polynomial model fits along with the  $R^2$  value and the blue line represents the raw values obtained from in situ assemblages. Dashed lines demark predicted pH values at the end of this century following the Coupled Model Intercomparison Project Phase Six (CMIP6) predictions for Shared Socioeconomic Pathways (SSP1-2.6: 8.01 pH units; SSP2-4.5: 7.91 pH units; SSP3-7.0: 7.82 pH units, and SSP4: 7.73 pH units). SB = symbiont bearing, Agg = agglutinated, SM = small miliolids, OP = Opportunistic, SR = small rotaliids.

325 All taxonomic metrics presented a gradual decrease towards the springs (Fig. 5a-d). On average,  $H'$  ranged from 3.9 to 1.6 (Fig. 5a,  $R^2 = 0.72$ ,  $p\text{-value} = 4.8 \cdot 10^{-8}$ );  $S$  from 71 to 11 (Fig. 5b,  $R^2 = 0.67$ ,  $p\text{-value} = 3.3 \cdot 10^{-7}$ );  $J'$  from 0.9 to 0.6 (Fig. 5c,  $R^2 = 0.64$ ,  $p\text{-value} = 9.5 \cdot 10^{-7}$ ), and foraminifera density from 2167 to 36 ind./cm<sup>3</sup> (Fig. 5d,  $R^2 = 0.22$ ,  $p\text{-value} = 0.02$ ). Kruskal-Wallis analysis revealed that the observed variation was statistically significant for all taxonomic metrics:  $N$  (chi-squared = 14.5,  $df = 3$ ,  $p\text{-value} \ll 0.05$ ),  $S$  (chi-squared = 20,  $df = 3$ ,  $p\text{-value} \ll 0.05$ ),  $J'$  (chi-squared = 15,  $df = 3$ ,  $p\text{-value} \ll 0.05$ ) and  $H$  (chi-squared = 19,  $df = 3$ ,  $p\text{-value} \ll 0.05$ ). However as observed for functional and test type groups, the post hoc Dunn test revealed that significant changes occurred mainly between present day and extremely low-pH conditions:  $N$  ( $z = 2.2$ ,  $p\text{-value} = 0.02$ ),  $S$  ( $z = 3.4$ ,  $p\text{-value} \ll 0.05$ ),  $J$  ( $z = 3.1$ ,  $p\text{-value} \ll 0.05$ ), and  $H$  ( $z = 3.4$ ,  $p\text{-value} \ll 0.05$ ). No significant difference was observed for any taxonomic metric at low-intermediate acidification scenarios (SSP1-2.6 and SSP2-4.5), and only  $S$  differed significantly between present day and high acidification scenarios (Fig. 5b, SSP3-7.0 and SSP5-8.5,  $z = 2.1$ ,  $p\text{-value} = 0.03$ ).

330

335

**Figure 5** Relationships between pH and (a) Shannon-Weiner Diversity Index ( $H'$ ), (b) foraminiferal density (N), (c) Pielou's evenness ( $J'$ ), and (d) species richness (S). The black lines represent second-order polynomial model fits, and grey areas mark 95 % confidence intervals. Dashed lines demark predicted pH values at the end of this century following the Coupled Model Intercomparison Project Phase Six (CMIP6) predictions for Shared Socioeconomic Pathways (SSP1-2.6: 8.01 pH units; SSP2-4.5: 7.91 pH units; SSP3-7.0: 7.82 pH units, and SSP4: 7.73 pH units).

Considering the consistency in the data analyses, we observed that under the most conservative projections (SSP1-2.6; SSP2-4.5) foraminifera assemblages did not display considerable changes in taxonomic metrics, relative to assemblages living at present-day conditions. For projections SSP3-7.0 and SSP5-8.5 the analyzed assemblages presented a significant decrease in richness S, indicating that foraminifera assemblages are likely to be affected under high acidification scenarios. To species level, the symbiont-bearing taxa presented relatively higher resistance, when compared to other functional groups, while agglutinated foraminifera were not measurably influenced by changes in pH. For conditions beyond the

predicted for the late 21<sup>st</sup> century, foraminifera density decreased abruptly and high taphonomical alteration was observed.

### 3.4 X-ray MicroCT

The X-ray MicroCT (Fig. 6a-d) analysis revealed that despite having a similar size ( $0.80 \pm 0.05 \text{ mm}^3$ ), and volume ( $0.06 \pm 0.02 \text{ mm}^3$ ) the specimens present at low-pH conditions (7.1 pH units) were on average 46 % less dense ( $2.4 \pm 0.2$  to  $1.30 \pm 0.03 \text{ g/cm}^3$ ) than the specimens present at high-pH conditions (Welch Two Sample t-test,  $t = 8.1204$ ,  $df = 3.0808$ ,  $p\text{-value} = 0.0035$ ). Yet, no significant (Two Sample t-test,  $t = -1.4378$ ,  $df = 6$ ,  $p\text{-value} = 0.2$ ) difference in chamber wall thickness was observed ( $0.050 \pm 0.006 \text{ mm}^3$ ). The differences in internal density (Fig. 6a and 6b) represent 2 specimens living in high and low-pH conditions, respectively. The external differences of these same individuals are represented in the 3D volume (Fig. 6c and 6d). Raw data of test density, chamber wall thickness, test volume, and test diameter measured in *A. angulatus* individuals are listed in table S5.

**Figure 6** - Comparison between X-ray microCT images with color code as a function of calcite density.

The specimen living at  $\sim 7.96$  pH units (a) presents a higher calcite density (more green) when compared with low  $\sim$  pH 7.11 individual (more blue) (b). The 3D volume rendering in function of calcite density for

the same individuals living at the high (c) and low-pH conditions (d). Note that individual at “d” living under low pH presents a test with incomplete parts and blurred edges, which demonstrates a lower density.

#### 4 Discussion

##### 370 4.1 Foraminiferal resistance to intermediate pH lowering conditions

Under the two most conservative acidification projections (Fig. 5a-d) foraminifera assemblages in PM did not display considerable changes, while at high acidification scenarios a significant decrease in species richness was observed. These results indicate that benthic foraminifera are unlikely to be affected by pH decreases of ~ 0.2, but certainly respond adversely to higher acidification levels (~ 0.4 pH units). These  
375 findings are consistent with previous observations from other naturally high pCO<sub>2</sub> sites in which taxonomic metrics decreased significantly with declining pH (Bernhard et al. 2009; Dias et al. 2010; Pettit et al., 2015; Dong et al., 2019, 2020). It is noteworthy, however that changes in assemblage composition did not follow the same pattern observed in these previous studies. Whereas the proportion of calcareous species usually decline with decreasing pH, they remained dominant (~90 %, mainly SB, Fig. 4a) under all projections in  
380 PM, suggesting a relatively higher resistance for these shallow-reef benthic assemblages.

Considering the mid-range pH (~ 7.9 pH units), small rotaliids are more resilient; the chemical conditions at PM, along with the physiology of calcification in foraminifera may explain the lack of sensitivity of the species. Recent calcification models demonstrate that hyaline foraminifera can manipulate pH to control the speciation of inorganic carbon parameters during calcification (De Nooijer et al., 2009; Toyofuku et al.,  
385 2017; De Goeyse et al., 2021; Geerken et al., 2022). Specifically, the proton-pumping based model (Toyofuku et al., 2017) shows that at the external environment, a decrease in pH (~ 6.9 pH units) induces the transformation of CO<sub>3</sub><sup>2-</sup> and bicarbonate (HCO<sub>3</sub><sup>-</sup>) into CO<sub>2</sub>, whereas at the site of calcification the elevated pH (~ 9 pH units) results in the opposite shift into CO<sub>3</sub><sup>2-</sup>. As foraminifera induce pH changes exceeding the predicted to SSP1-2.6 and SSP2-4.5, intermediate acidification scenarios are unlikely to  
390 impair foraminiferal calcification. In fact, the higher abundance of small rotaliid (Fig. 4e) and resistance of SB species (e.g., *Amphistegina*) supports the hypothesis that they might, at least to a certain extent, benefit from the extra dissolved inorganic carbon (Toyofuku et al., 2017, De Goeyse et al. 2021). Evidence for this hypothesis is that carbonic anhydrase plays a key role in the biomineralization process of some rotaliids, possibly concentrating inorganic carbon for calcification by converting HCO<sub>3</sub><sup>-</sup> into CO<sub>2</sub> (De Goeyse et al.  
395 2021). As such, these models suggest that increased CO<sub>2</sub> might favor foraminifera calcification by increasing C<sub>T</sub>, which is notably higher towards the springs in PM (Table 1).

The higher C<sub>T</sub> and T<sub>A</sub> might also induce CO<sub>2</sub> fertilization effects in SB species, increasing the activity of symbionts (Fujita et al., 2011; Uthicke and Fabricius, 2012; Martinez et al., 2018). This could explain why symbiont-bearing species including (A) *Ar. angulatus* (chlorophyte-bearing), increased in relative  
400 abundance from 11-15 % to 21 % from ~ 8 to 7.72 pH units (e.g., Pargos spring). This behavior was also observed for *Amphistegina gibbosa* (diatom-bearing), from 16-19 % to 23 %, and (C) *Cyclorbiculina compressa* (chlorophyte-bearing) that presented low contribution ~ 1 % at high-pH stations but also increased in relative contribution to 3.2 % at intermediated pH. These findings are supported by laboratory-controlled experiments demonstrating that both *Ar. angulatus* (Stuhr et al., 2021) and *Amphistegina* sp.

405 (McIntyre-Wressnig et al., 2013; Prazeres et al., 2015) can calcify and live under relatively low-pH conditions (~ 7.6 pH units).

This behavior, however, was not observed for all SB. For example, the species *H. depressa* was documented to be resilient in laboratory-controlled conditions (Vogel and Uthicke et al., 2012; Schmidt, Kucera and Uthicke, 2014), but in PM it presented a strong decline towards low-pH waters. A possible explanation is  
410 that although salinity is considered to not be a significant factor controlling the overall foraminiferal communities (AIC, BIO-ENV/global BEST analysis), salinity may have specifically affected the occurrence of select species close to the springs, which are known to be typically stenohaline, e.g., larger rotaliids (30–45, Hallock, 1986). However, this cannot be very important since salinity at the springs is > 30 over 90 % of the time and does not drop below 27 (Crook et al., 2012; Martinez et al., 2018). Other  
415 parameters, such as heavy metals could also influence the abundance of certain species, but concentrations of the metals (Paytan unpublished) were not significantly higher at the springs when compared to sites at > 1m distance from the water discharge. Hence, we do not attribute the changes in foraminifera assemblages to impacts of heavy metals. We note that the springs furthest analyzed sites are just a few meters apart hence other parameters such as light, eutrophication, and pollution are identical.

420 Additionally, the high  $C_T$  and  $T_A$  might also raise local pH and carbonate saturation during photosynthesis, even if only on the scale of an individual organism at the foraminiferal shell surface. A diffusive boundary layer of increased pH (up to 8.9) has been documented at the underlying surface of symbiont bearing foraminifera (Koehler-Rink and Kuehl, 2000; Glas et al., 2012), and although insufficient to compensate future decreases of ambient seawater pH, it might increase the symbiont-bearing resistance in PM.  
425 Correspondently, the symbioses between seagrasses and foraminifera has also been suggested a key factor in the resilience of epiphytic species (e.g., *A. angulatus*, *C. compressa* and *A. gibbosa*). Although no significant effect (Fabricius et al., 2011; Pettit et al., 2015) has been reported for some species, *Marginopora vertebralis* was observed to maintain its growth when associated with its common algal host, *Laurencia intricata* in laboratory conditions (Doo et al., 2020). In respect to observations in the present  
430 study, the epiphytic species *R. globularis* was the most important taxa for living counts (11 %), and although not the primary objective of the present study, it gives important insights about short-term foraminifera responses. Specifically, this finding is in agreement with the observed resilient behavior of Rosalinids in the natural, low-pH venting sites of Panarea (Di Bella et al., 2022). However, considering the low occurrence of fully stained tests future analysis on phytal substrates in PM would be necessary to confirm  
435 this trend. Lastly, the ability of foraminifera to function and calcify near the springs may also be related to the site-specific natural pH variability to which the species are exposed. For many coastal/transitional areas characterized by high pCO<sub>2</sub> variability, foraminifera seem to be more resilient and acclimated to changing conditions including low-pH (Haynert et al., 2012; Charrieau et al., 2018). By discharging low-pH waters for millennia (Back et al., 1979) the foraminifera living near the spring have experienced a pH variability  
440 over a much longer timespan than the life span of individual organisms (Martinez et al., 2018). Specifically, as reef-dwelling organisms, the foraminifera in PM experience a wide range of pH on daily and seasonal scales which might physiologically increase the species resilience to low-pH waters (Price et al., 2012).

#### 4.1 High pH acidification scenarios

445 Previous data from recruitment and succession experiments in PM showed that foraminifera were able to calcify and increased in weight over the investigated period (14 months) at low (~ 7.8) pH conditions (data from Laja and Gorgos springs, Crook et al., 2016). Two years later, Martinez et al. (2018) documented the occurrence of calcareous tests at PM even at extreme acidification levels (~ 7.1 pH units). In agreement, we observed that despite the strong decrease in foraminifera density calcareous foraminifera still remained relatively dominant in PM (~90 %, mainly *A. angulatus* and *A. gibbosa*) at expected future conditions for 450 the end of the 21<sup>st</sup> century and beyond.

For high acidification scenarios (SSP3-7.0 and SSP5-8.5), the in-situ occurrence of calcifying foraminifera has only been reported in the deep-sea near extensive CO<sub>2</sub> vents in the Wagner Basin (Pettit et al., 2013). At this site, a rich food supply and stable temperatures were considered to offset the effects of OA and a shift towards opportunistic assemblages was reported. The springs from PM also have relatively high 455 nutrient concentrations compared to the open waters in the region (Null et al., 2014; Crook et al., 2016), however, near the springs, assemblages did not change towards opportunistic dominated assemblages, suggesting that the nutrient availability does not exert a major control at this site. Rather, the high-pH assemblages heavily dominated by small calcareous forms were replaced by larger symbiont-bearing species near the springs (Fig. 4a-e). Such species are known to be sensitive to high nutrient loading, likely 460 because of changes in turbidity/light regimes and their dependence on algal symbionts to enhance growth and calcification (Hallock et al., 2003; Prazeres et al., 2020; Girard et al., 2022). However at PM despite higher nutrient levels the waters at the springs are clear and light regimes are not reduced.

To better understand the resilient response towards the springs (Fig. 4a-d) and investigate possible acclimation patterns that could explain the observation of relatively higher SB occurrence, we employed an 465 X-ray microCT analysis in *A. angulatus* specimens living under high and low pH conditions. The analysis revealed that despite having similar size ( $0.80 \pm 0.05 \text{ mm}^3$ ), volume ( $0.06 \pm 0.02 \text{ mm}^3$ ), and chamber wall thickness ( $0.050 \pm 0.006 \text{ mm}^3$ ) the specimens found at low-pH conditions (7.1 pH units) were on average 46 % less dense ( $2.40 \pm 0.2$  to  $1.30 \pm 0.03 \text{ g/cm}^3$ ) than the specimens present at high-pH conditions (7.96 pH units). This demonstrates that the species could calcify in low-pH conditions beyond those predicted 470 for the late 21<sup>st</sup> century albite at lower density. The lower density however indicates that *Archaias* individuals were not capable to acclimate sufficiently to maintain ambient present day calcification efficiency. These results agree with Knorr et al. (2015) that observed a 50 % decrease in *A. angulatus* size at 7.6 pH units, and a consequent decrease of 85 % in the production of high-Mg calcite by this species, and also with the documented for other SB species such as *Peneroplis* spp (pH 7.4, approximately 25 % 475 lower, Charrieau et al., 2022), and *Amphistegina* spp (pH 7.6, approximately 20 % lower, Prazeres et al., 2015). We acknowledge that post-mortem dissolution may also contribute to the observed lower density, but only pristine tests were analyzed, so this influence must be minimum. Future analysis of B isotopes and B/Ca ratios could provide more information about the documented trends in the present study. Since *A. angulatus* showed lower density close to the low-pH springs and hence is negatively impacted by the low- 480 pH, the species increase in relative increase towards the springs is probably associated with the high preservation potential of its tests. The tests of *A. angulatus* are large, thick, and reinforced by internal partitions (pillars), therefore more likely to be preserved in the sediment (Martin, 1986; Cottey and Hallock,

1988). This is confirmed by the performed regression analysis as the species relative contribution explains 88 % of assemblage test size and 73 % of high dissolved test occurrence in the samples (Fig. 2c). In fact, changes were so abrupt that shifts in the assemblage test size and functional groups were clearly observed at ~7.7 pH units (Fig. 2a), when the symbiont-bearing taxa relative contribution also started to increase (Fig. 4a). At this point preservation thresholds of smaller taxa seemed to be crossed, and their decrease in relative abundance near the springs is likely related to higher rates of breakage and dissolution (Present study, Martinez et al., 2018).

Considering that foraminifera are a crucial component of reef sediment production (Langer et al., 1997; Langer, 2008), including *A. angulatus* in the Caribbean region, our results support previous findings that reef-building carbonate production and accumulation are likely to decrease under future scenarios, even in the tropics (Knorr et al., 2015; Eyre et al., 2018; Kuroyanagi et al., 2021). Specifically, we also observed a decrease in foraminifera density (Fig.5d) and therefore in carbonate accumulation as foraminifera tests in the sediments. As OA intensifies, symbiont-bearing taxa, which demonstrated higher resistance to low-pH (> 7.8 pH units), will likely still represent major contributors in the Caribbean and Gulf of Mexico sediments where species like *A. angulatus* may dominate (Culver and Buzas, 1982). In contrary, the high sensitivity of *Quinqueloculina* spp, *Triloculina* spp, *Articulina* spp, and *Miliolinella* spp to low pH highlighted their lower fitness in response to OA, demonstrating that changes in abundance of small taxa can be used as bioindicators to monitor the effects of OA.

The relative contribution of agglutinated foraminifera slightly increased towards low-pH (Fig. 4b), but they did not compensate for the decline in calcareous species (Fig. 4a-e), even at extreme low pH conditions. Since the particles available for the agglutinated tests are made of carbonate and under low- $\Omega$  waters are also prone to dissolve that could affect the agglutinated species. Interestingly, agglutinated foraminifera also presented species-specific responses to acidification like calcareous foraminifera. For example, *Valvulina oviedoiana* increased in relative abundance towards low pH, while *Textularia agglutinans* presented a strong decrease. Since acidification is expected to have little direct effect on agglutinated foraminifera the observed interspecific behavior is also probably associated with preservation potential. The variation of agglutinating material (e.g., mucopolysaccharide), structure (e.g., fibrous, strands, foam-like masses), and size of granular particles (e.g., fine, and coarser) are essential to determine the preservation and accumulation of agglutinated tests (Bender and Hemleben, 1988). The most important agglutinated species, in our study e.g., *T. agglutinans*, *C. angulata*, and *V. oviedoiana* use calcite cement as the agglutinating material of particles, which probably assigns a higher resistance to dissolution (Bender, 1995). Among these, *T. agglutinans* lower resistance likely responds to its smaller size, which implies higher dissolution (Bender, 1995). Altogether, we observe that until ~7.8 pH units foraminifera physiology was a main driver of foraminifera distribution, whereas at  $\leq 7.7$  pH units (Fig. 2b) the preservation potential became an important factor affecting the distribution of both calcareous and agglutinated tests.

Hence, we cannot exclude the possibility that a higher accumulation of *A. angulatus* tests could be responsible for an overestimation in symbiont-bearing taxa density. In this case, species richness would be more reliable to the interpretation of assemblage responses, which was the only parameter to decrease significantly at < 7.7 pH units (Fig. 5b), suggesting that overall foraminifera are less likely to acclimate

under high acidification scenarios. These results bring serious implications as SSP3-7.0 and SSP5-8.5 scenarios also predict substantial increases of sea surface temperature (Kwiatkowski et al., 2020), which combined to surface OA might critically decrease the tolerance of foraminifera (reviewed in Kawahata et al., 2019). Recently, Bernhard et al. (2021) observed that foraminiferal assemblages presented the lowest number of species and abundances under a triple-stressed (low-pH/O<sub>2</sub> and high temperature) treatment demonstrating the synergetic effects of these variables. As observed in PM, agglutinated foraminifera were relatively more resistant than calcareous taxa.

In general, for emissions beyond the predicted to the end of 21<sup>st</sup> century (< 7.7 pH units) all taxonomic metrics decreased significantly, and calcareous species with higher preservation potential like *C. compressa* and *A. angulatus* comprised up 50–60 % of assemblage composition. This was expected since a drop in the  $\Omega$  aragonite < 3.2 would increase foraminifera dissolution (Yamamoto et al., 2012), but these calcareous taxa were still found at the center of discharge where the surface sediments were still composed by carbonate. We attribute this to high T<sub>A</sub> levels, which was also considered to likely limit the dissolution rates of *A. angulatus* and other porcelaneous tests in the springs at the coast of Florida, where numerous spring-fed rivers emerge from Eocene and Oligocene limestone and dolostone substrata (Amergian et al., 2022). The high T<sub>A</sub> may also provide a calcification optimum within the polyhaline (22-30) waters of the Springs at the Florida Coast, where a similar range of salinity to PM was observed. This hypothesis could explain the observed resistance of *A. angulatus* in the present study, and the higher association of foraminifera density to T<sub>A</sub>. Nevertheless, if we restricted the analysis to only pristine, well-preserved tests, the taxonomic metrics at 7.7-7.2 (Fig. 5) would be much lower and more similar to those presented by Uthicke, Momigliano, and Fabricius (2013), in which foraminifera were almost absent at sites with  $\leq 7.9$  pH units.

## 5 Conclusion

Despite their life-long exposure to low-pH conditions, benthic tropical foraminifera species could be negatively affected under the high acidification scenarios (SSP3-7.0 and SSP5-8.5) for the end of the 21<sup>st</sup> century. Species-specific responses in foraminiferal assemblages were observed and as the oceans become more acidic, reef foraminiferal assemblages might gradually shift towards larger, symbiont-bearing species and agglutinating foraminifera. The species *A. angulatus*, which is known to be dominant in warm, oligotrophic areas of the Caribbean and Gulf of Mexico can calcify at pH conditions lower than those projected by SSP5-8.5, however, the observed lower density of the pristine tests suggests that reef carbonate budget might decrease as this species represent a major carbonate producer at these areas. Considering the observed trends of increasing average assemblage test size, our results demonstrate the key role smaller foraminifera have as bioindicators to monitor the effects of OA, as their high sensitivity to dissolution makes them first responders to ongoing OA.

## 6 Data availability

All data related to this study are given in the Supplement data files that accompany this paper.

## 7 Author contribution

DF, AP and CFB conceived of and designed the study. DF performed the faunal and statistical analysis. OMA and RTL conducted the Micro-CT experiments. DF, AP and CFB analyzed the data. DF, AP, CFB  
560 prepared the original draft of the manuscript with writing, and OMA and RTL reviewed and edited.

## 8 Competing interest

We declare that this manuscript has no conflict of interest.

## 9 Acknowledgments

This study was funded by the National Science Foundation-1040952 (to AP). DF thanks the scholarship of  
565 the National Council for Scientific and Technological Development (CNPq) No. 132210/2020-7. The funders had no role in the study design, data collection, and analysis, decision to publish, or preparation of the paper. DF thanks Pamela Hallock, Heitor Evangelista, Sven Uthicke and the anonymous reviewers for their helpful comments and suggestions.
