Abstract. The sinking of zooplankton fecal pellets is a key process in the marine biological carbon pump, facilitating the export of particulate organic carbon (POC). Here, we analyzed zooplankton fecal pellets collected by two time-series sediment traps deployed on mooring TJ-A1B in the northern South China Sea (SCS) from May 2021 to May 2022. The results show a seasonal variability in both fecal pellet numerical (FPN) flux and fecal pellet carbon (FPC) flux, with peaks in November to April and June to August. It implies that the fecal pellet flux is largely regulated by the East Asian monsoon system. Vertical analysis further shows that FPN and FPC fluxes are higher at 1970 m than at 500 m water depth, with larger pellets occurring in the deeper water, indicating a significant influence of mesopelagic/bathypelagic zooplankton community and lateral transport on deep-sea fecal pellet carbon export. However, the biovolume of amorphous pellets decreases significantly from 500 m to 1970 m water depth, implying that these fecal pellets are broken and fragmented during the sinking process, possibly due to zooplankton grazing and disturbance by deep-sea currents. The contribution of fecal pellets to total POC export in the northern SCS is in average 3.4% and 1.9% at 500 m and 1970 m water depths, respectively. This study highlights that the sinking fate of fecal pellets is regulated by marine surface productivity, deep-dwelling zooplankton community, and deep-sea currents in the tropical marginal sea, thus providing a new perspective for exploring the carbon cycle in the world ocean.

1 Introduction

The marine biological carbon pump (BCP) is a process whereby marine organisms mediate the transfer of carbon from the atmosphere to the deep ocean. Marine organisms inhabiting the upper water column can fix atmospheric CO₂ through photosynthesis, producing particulate organic carbon (POC) in the euphotic zone. Subsequently, a series of processes transport the POC, including phytoplankton cells, zooplankton fecal pellets, molts, carcasses, and aggregates, from surface to deeper layers of the ocean, representing a significant component of the global carbon cycle (Fowler and Knauer, 1986; Steinberg and Landry, 2017). As a key process in the BCP, zooplankton fecal pellets can reduce the dissolution and degradation of organic matter during the sinking process and subsequently increase the particle sinking flux in the mesopelagic and bathypelagic zones (Wilson et al., 2008; Turner, 2015). During the sinking process, most zooplankton fecal pellets are susceptible to being

30 ingested by other zooplankton or degraded by bacteria. Several studies have revealed that the concentration of fecal pellets in
the deep sea is significantly lower compared to the production rate of fecal pellets in the surface waters, and the presence of
amorphous fecal pellets has been observed, indicating significant consumption during the sinking process (Juul-Pedersen et
al., 2006; Wilson et al., 2008; Goldthwait and Steinberg, 2008; Kobari et al., 2010, 2016; Stukel et al., 2013; Miquel et al.,
35 2012; Turner, 2015). Noji et al. (1991) categorized copepod behavior in fecal pellet consumption into three different types:
coprorhexy, coprophagy, and coprochaly. These processes are thought to reduce the carbon export of fecal pellets in the deep
sea (Noji et al., 1991). However, the repackaging of larger zooplankton inhabiting the mesopelagic zones, accompanied by
their in-situ production of large fecal pellets, may contribute to an increasing flux of deep-sea fecal pellets (Urrère and Knauer,
1981; Shatova et al., 2012; Manno et al., 2015; Belcher et al., 2017). As a key component of the carbon cycle, fragmentation,
40 decomposition, and repackaging of fecal pellets may affect the POC export and regulate the efficiency of the BCP.
Numerous studies have been conducted in the global ocean to explore the biogeochemical mechanisms of zooplankton fecal
pellets during production, sinking, degradation, and recycling processes (González et al., 2000; Gleiber et al., 2012; Belcher
et al., 2017; Le Moigne, 2019). Previous studies have observed obvious differences in fecal pellet flux with increasing water
depth, mostly showing a decreasing trend (Viitasalo et al., 1999; Wexels Riser et al., 2007). However, in certain regions, such
45 as the Northeast Pacific, Mediterranean Sea, Sargasso Sea, and Southern Ocean, fecal pellet fluxes tend to increase in the deep
layer (Urrère and Knauer, 1981; Fowler et al., 1991; Wassmann et al., 2000; Shatova et al., 2012; Manno et al., 2015; Belcher
et al., 2017). This variation in the trend of fecal flux with water depth is influenced by the composition of local zooplankton
community and efficiency of the BCP. Different shapes and sizes of fecal pellets have different sinking rates, which contribute
differently to the POC export (Wilson et al., 2008; Manno et al., 2015; Turner, 2015; Steinberg and Landry, 2017; Qiu et al.,
50 2018). In the high-latitude eutrophic seas, fecal pellets tend to exhibit a high contribution to the total POC flux (Juul-Pedersen
et al., 2006; Wilson et al., 2008; Manno et al., 2015). However, the contribution in the subpolar mesotrophic seas and low-
latitude oligotrophic seas is significantly lower. Pilskaln and Honjo (1987) reported that fecal pellets account for less than 5–
10% of sinking flux in tropical and subtropical regions. Taylor (1989) also reported that fecal pellets contribute a minimal
fraction (6%) of the POC flux in the central North Pacific. Roman and Gauzens (1997) suggested that the contribution of fecal
55 pellets to the total carbon flux was quite small in the tropical Pacific, and that most fecal pellets produced in the surface waters
were ingested during sinking.

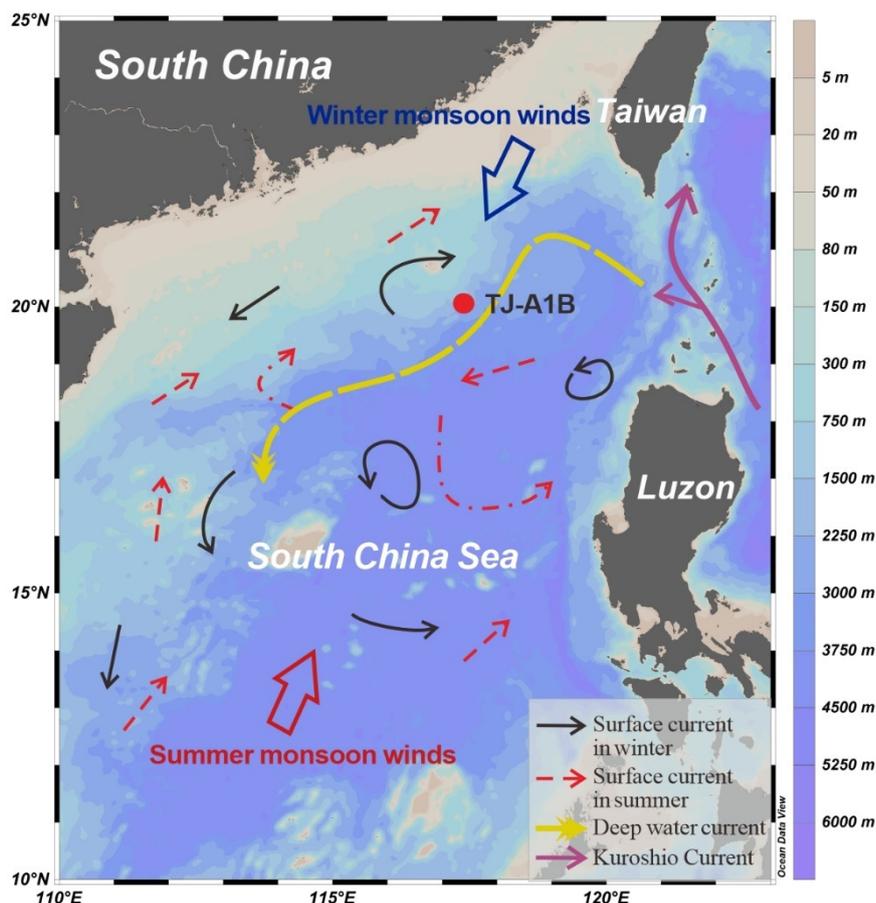

The South China Sea (SCS) is considered as an oligotrophic tropical sea and a source of CO₂ (Su, 2004; Cao et al., 2020).
Owing to its unique geographical and physicochemical characteristics, the organic carbon flux and its regulatory processes in
the SCS are subject to significant spatiotemporal variability. Previous studies have investigated the composition and flux of
60 sinking POC in the northern and central SCS, which vary with the East Asian monsoon system. Notably, the peak occurrence
of sinking POC has been observed during the northeast monsoon period (Chen et al., 1998; Liu et al., 2007; Li et al., 2017;
Zhang et al., 2019, 2022; Blattmann et al., 2018, 2019). Based on the C/N ratio and stable/radiocarbon isotope analyses, the
vertical vector of modern POC turns out to be 87% ± 4% of the sinking POC in the northern SCS, with the lateral vector

accounting for the remaining 13% (Zhang et al., 2022). The contribution of laterally supplied POC becomes more significant
65 with increasing depth, which is largely derived from lithogenic organic carbon transported by the deep-sea currents and
resuspension of slope sediments (Blattmann et al., 2018; Zhang et al., 2022). In the southern SCS, Li et al. (2022) conducted
the first study of zooplankton fecal pellet characteristics, numerical fluxes, and carbon fluxes in the tropical marginal sea,
showing that fecal pellets contribute 0.4–30.0% to the total POC flux. Despite the dominance of marine-origin organic carbon
in sinking POC in the northern SCS, detailed studies of the rapidly sinking particles are sparse, and the contribution of fecal
70 pellets to the total carbon flux remains uncertain. To better understand the efficiency and biogeochemical cycling of the BCP
in the northern SCS, we collected sinking zooplankton fecal pellets from mesopelagic and bathypelagic waters using two
sediment traps to quantify the role of fecal pellets in POC export. By analyzing the shape, quantity, internal composition, and
carbon content of zooplankton fecal pellets, we gained more specific insights into the sinking fate of these pellets in tropical
marginal seas and highlighted the importance of fragmentation during the sinking process in determining the carbon flux
75 transferred to the deep sea.

2 Study area

The SCS is a large marginal sea with an area of about 3.5×10^6 km² and an average depth of about 1350 m (Wang and Li, 2009).
The study area is located in the northern SCS, where a warm and humid southwest monsoon prevails in summer (June to
August), while a dry and cold northeast monsoon prevails in winter (November to April) (Chu and Wang, 2003) (Fig. 1).
80 Hydrological system of the northern SCS is complex due to the seasonal shift of the East Asian monsoon winds and the
interplay of waters from the Kuroshio Current (Su, 2004; Caruso et al., 2006). Surface circulation of the northern SCS also
shows a seasonal shift from a large cyclonic gyre in winter to a weak cyclonic gyre in summer (Su, 2004). Contour currents
have been found to dominate sediment transport processes on the deep-sea slope at 1600–2400 m water depth, transporting
Taiwan-sourced sediments westward (Zhao et al., 2015; Liu et al., 2010, 2016). Combination of strong winter winds, water
85 mixing, and surface cooling in the northern SCS drives winter convective overturning, leading to higher primary productivity
during the winter monsoon than during other periods (Liu et al., 2002; Chen, 2005; Tseng et al., 2005). Rainfall in the northern
SCS is seasonally variable, with increased rainfall during the summer (Zhang et al., 2019). Typhoons, mesoscale eddies, and
other dynamical processes are also well developed in the northern SCS (Su, 2004; Wang and Li, 2009).

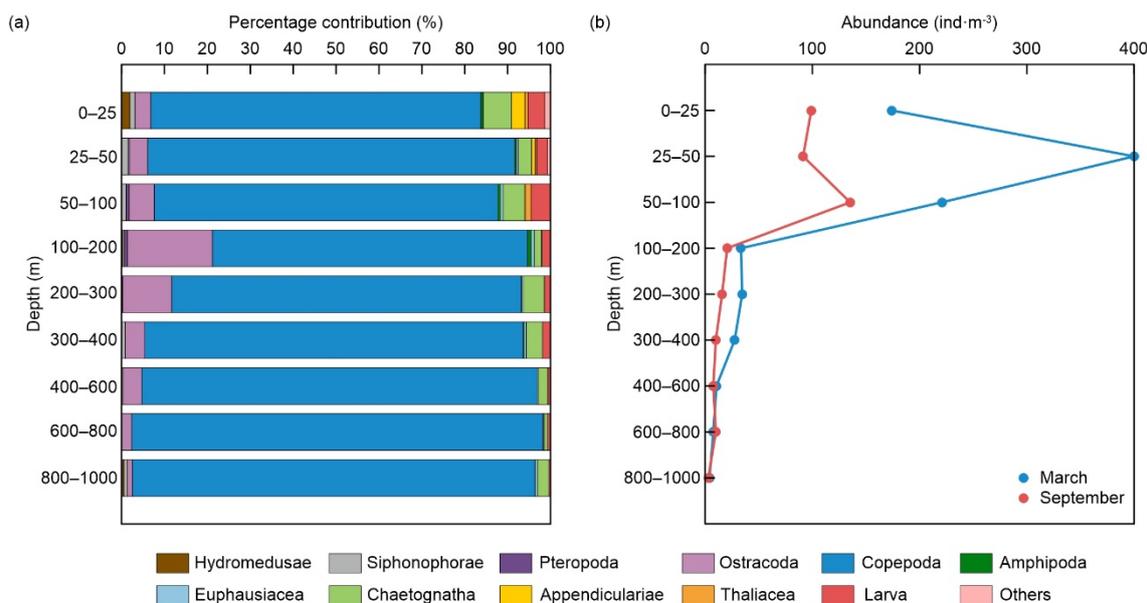

90 **Figure 1.** Monsoon and current systems in the South China Sea (SCS) (after Liu et al., 2016). Location of the sediment trap mooring TJ-A1B is indicated. Ocean Data View software was used to generate the map (Schlitzer, 2023).

Zooplankton species in the northern SCS mainly include Hydromedusae, Siphonophorae, Pteropoda, Ostracoda, Copepoda, Amphipoda, Euphausiacea, Chaetognatha, Appendiculariae, Thaliacea, and larvae (Fig. 2a; Li et al., 2021; Gong et al., 2017).

95 Among these, copepods have the largest number of species, contributing 30% of the total identified species (Ren et al., 2021; Ge et al., 2021). Copepods are also the most abundant group, contributing about 80% of the total abundance, followed by ostracods and chaetognaths (Fig. 2a). Zooplankton abundance is the highest between 0–100 m water depth and consistently decreases with increasing depth (Fig. 2b; Gong et al., 2017; Li et al., 2021). The average zooplankton biomass is 35 mg m⁻³, with a slight increase at 350–600 m water depth (Gong et al., 2017). Below 300 m, there is a noticeable increase in the
100 proportion of copepods to the total abundance, with some copepod species (including *Calanoides carinatus*, *Bradyiditus armatus*, *Chiridius gracilis*, and *Euchirella curticauda*) only found at 450–1000 m water depth (Du et al., 2014; Li et al., 2021).

Furthermore, on a seasonal scale, zooplankton abundance in the northern SCS increases significantly during the winter monsoon period, while it declines during the inter-monsoon period (Li et al., 2004; Li et al., 2021).

105 **Figure 2.** Vertical distribution of (a) species richness percentage and (b) total abundance of zooplankton from 0 to 1000 m depths in the northern SCS. Data from Li et al. (2021).

3 Material and Methods

3.1 Sediment trap deployment

110 Samples were collected by sediment traps deployed on mooring TJ-A1B (20.06°N, 117.39°E, 2000 m water depth) in the northern SCS (Fig. 1). Two traps (UP and DW) were deployed at 500 m and 1970 m water depths, respectively, each with a sampling area of 0.5 m². Samples were collected at 18-day intervals from May 2021 to May 2022 (except for the first sample, which covered only three days), resulting in a total of 42 samples (21 samples for each trap). Prior to deployment of the traps, each sample bottle was pre-filled with 0.6 g (for the trap at 500 m) or 0.3 g (for the trap at 1970 m) HgCl₂, along with 33.3 g NaCl per 1000 ml of deionized water to prevent microbial activity and ensure the reliability of organic geochemical analysis.

115 3.2 Sample analysis

The samples were wet sieved using a 1 mm mesh to remove swimmers. The small fractions (<1 mm) were then equally aliquoted using a splitter, and one wet portion was used for the analysis of zooplankton fecal pellets. POC content and flux were determined using the methods outlined in detail by Li et al. (2022). The wet samples were filtered through a 20 μm Nitex © mesh, followed by rinsing on a gridded petri dish. These samples were examined under a Zeiss Stemi 508 stereomicroscope

120 coupled to a Zeiss Axiocam 305 digital camera. Fecal pellets were photographed and counted by shape to obtain the fecal
pellet numerical (FPN) flux (Li et al., 2022). Pellets were classified into four shapes: ellipsoidal, cylindrical, spherical, and
amorphous. Biovolumes of the first three fecal pellet shapes were calculated from the formulas for an ellipsoid, cylinder, and
sphere (Sun and Liu, 2003), while the biovolume of amorphous fecal pellets was estimated through best-fit ellipsoid
calculations (Kumar et al., 2010). The fecal pellet biovolume was then converted to carbon content to determine the fecal pellet
125 carbon (FPC) flux and its contribution to the POC flux, by using the conversion factor of $0.036 \text{ mg C mm}^{-3}$ measured in the
southern SCS (Li et al., 2022), which is similar to the conversion factor commonly used in tropical and subtropical marginal
seas (Urban-Rich et al., 1998; Kobari et al., 2010).

Fecal pellets selected from eight samples at two different depths were prepared for scanning electron microscopy (SEM) and
energy-dispersive spectrometry (EDS) to identify their internal structure and to determine elemental composition. 6–7 fecal
130 pellets of different shapes (ellipsoidal, cylindrical, spherical, and amorphous) and aggregates were randomly selected from
each sample.

3.3 Hydrological parameters

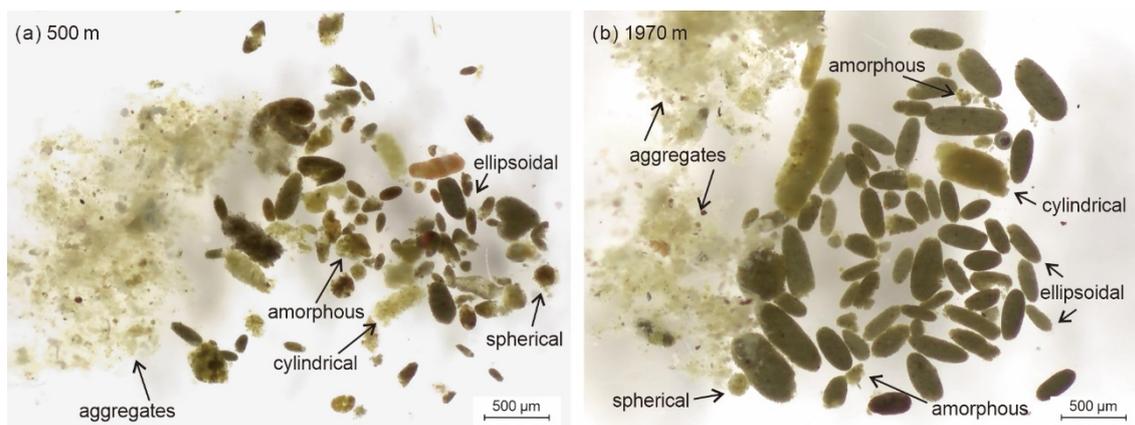

To investigate the environmental factors regulating the sinking and export of fecal pellets, we analyzed several relevant
physical and biogeochemical parameters. For daily wind speed (10 m zonal and meridional components of surface wind), data
135 were derived from the Atmospheric Composition Reanalysis 4 product
(<https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-reanalysis-eac4>), with a spatial resolution of $0.25^\circ \times 0.25^\circ$.
Daily sea surface temperature (SST) data were retrieved from the Copernicus Climate Change Service
(<https://cds.climate.copernicus.eu/cdsapp#!/dataset/satellite-sea-surface-temperature>), which provides SST data with a
horizontal resolution of $0.05^\circ \times 0.05^\circ$. For daily ocean mixed layer depth (MLD) defined by potential density anomaly and
140 surface water velocity, data were retrieved from the Operational Mercator global ocean analysis and forecast system
(https://data.marine.copernicus.eu/product/GLOBAL_ANALYSISFORECAST_PHY_001_024/description), with spatial
resolutions of $0.25^\circ \times 0.25^\circ$ and $0.083^\circ \times 0.083^\circ$, respectively. Daily net primary production (PP) data of biomass expressed as
carbon per unit volume in sea water with a spatial resolution of $0.25^\circ \times 0.25^\circ$ were obtained from the Operational Mercator
Ocean biogeochemical global ocean analysis and forecast system
145 (https://data.marine.copernicus.eu/product/GLOBAL_ANALYSIS_FORECAST_BIO_001_028). Daily precipitation data
with a horizontal resolution of $1.0^\circ \times 1.0^\circ$ were provided by the Global Precipitation Climatology Project
(<https://cds.climate.copernicus.eu/cdsapp#!/dataset/satellite-precipitation>).

4 Results

4.1 Fecal pellet characteristics

150 Microscopic analysis of the sediment trap samples revealed fecal pellets of various shapes (ellipsoidal, cylindrical, spherical, and amorphous). All shapes were found both at 500 m (Fig. 3a) and 1970 m (Fig. 3b). Among them, ellipsoidal, cylindrical, and spherical pellets were intact with smooth edges, while amorphous pellets were degraded with broken edges. Notably, their peritrophic membranes were partially absent. Fecal pellets were often brown in appearance, which were significantly different between the two depths. Ellipsoidal, cylindrical, and spherical pellets sizes were larger at 1970 m, whereas amorphous fecal
155 pellets sizes were larger at 500 m (Fig. 3, detailed photographs can be found in Supplementary Figs. S1–S21). In addition to zooplankton fecal pellets, a number of transparent and flocculent aggregates were also present in the samples, which were more common in the winter samples (Fig. 3, Figs. S1–S21).

160 **Figure 3.** Light microscopy photographs of four morphological types of zooplankton fecal pellets and aggregates collected from (a) 500 m and (b) 1970 m water depths of sediment trap mooring TJ-A1B in the northern SCS.

The internal components of the fecal pellets were mainly composed of diatoms, e.g., *Coscinodiscus* (Fig. 4a and 4e), *Thalassionema* (Fig. 4h), *Hemiaulus* (Fig. 4g), and *Nitzschia* (Fig. 4g), as well as coccoliths (Fig. 4d) and lithogenic particles (Fig. 4h and 5b). In contrast, the aggregates had a looser structure, and consisted mainly of radiolarians, diatoms, sponge
165 spicules, and foraminifers (Fig. 4i). The major elements composing of the fecal pellets were O, Si, C, and Ca, with minor proportions of Al and K, indicating that terrigenous minerals such as quartz and clay minerals may also be important components of fecal pellets (Fig. 4h and 5b).

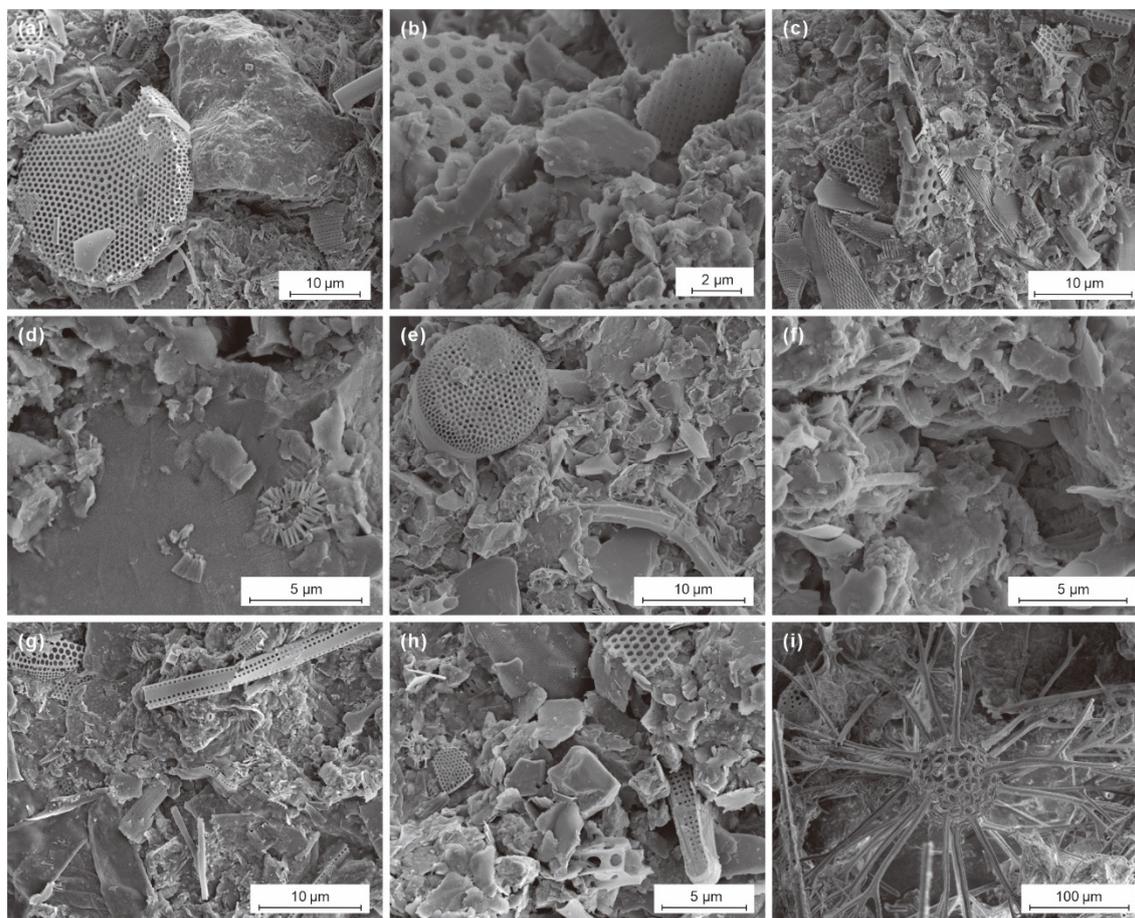

Figure 4. Scanning electron microscopy (SEM) observations of internal components of zooplankton fecal pellets and aggregates collected from the sediment trap mooring TJ-A1B in the northern SCS: (a, b) ellipsoidal pellet, (c, d) cylindrical pellet, (e, f) spherical pellet, (g, h) amorphous pellet, and (i) aggregates.

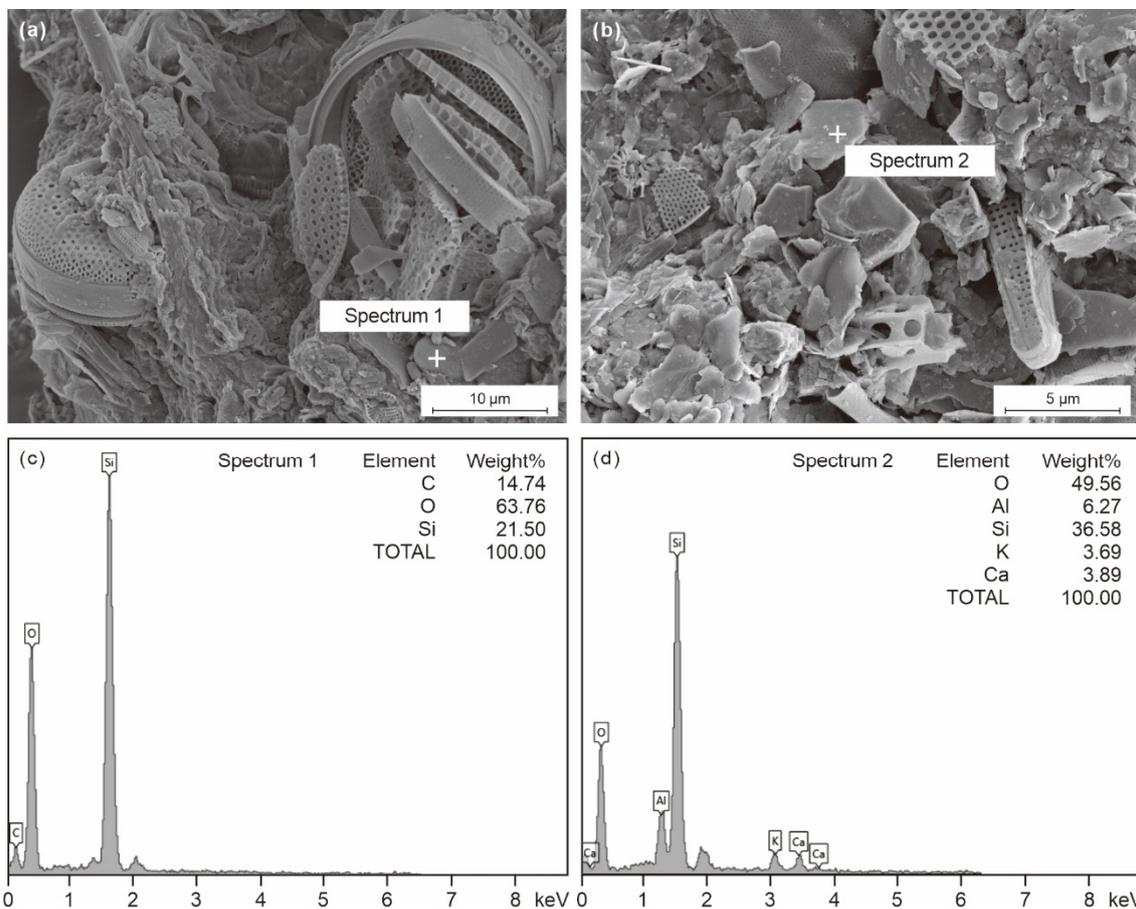

Figure 5. SEM coupled EDS analysis for internal structure and elemental composition of zooplankton fecal pellets in the sediment trap mooring TJ-A1B in the northern SCS. Panels (a) and (c) for one fecal pellet, and panels (b) and (d) for another fecal pellet.

Fecal pellets varied considerably in biovolume among the four types (Table 1). Ellipsoidal pellets had average biovolumes of 1.96 and $3.02 \times 10^6 \mu\text{m}^3$ at 500 and 1970 m depth, respectively. The average biovolumes of cylindrical pellets were $13.31 \times 10^6 \mu\text{m}^3$ at 500 m and $13.55 \times 10^6 \mu\text{m}^3$ at 1970 m, which were 10 times larger than other pellet types. Spherical pellets were the smallest, with a mean biovolume of only $0.90 \times 10^6 \mu\text{m}^3$. The biovolume of amorphous pellets ranged from 0.04 to $35.89 \times 10^6 \mu\text{m}^3$ and the average value was two times larger at 500 m ($2.23 \times 10^6 \mu\text{m}^3$) than at 1970 m ($0.92 \times 10^6 \mu\text{m}^3$). Two patterns of biovolume change from 500 m to 1970 m were observed for different fecal pellet types. Specifically, the average biovolume of ellipsoidal, cylindrical, and spherical pellets increased from 500 m to 1970 m, where the average biovolume of amorphous pellets decreased at 1970 m to only half of that at 500 m.

Table 1. Biovolume, numerical flux, numerical percentage, carbon flux, and carbon percentage of four types of zooplankton fecal pellets in the sediment trap mooring TJ-A1B in the northern SCS.

Depth (m)	Fecal pellet type	Number measured	Biovolume ($\times 10^6 \mu\text{m}^3$)	Numerical flux ($\times 10^3 \text{m}^{-2} \text{d}^{-1}$)	Numerical percentage (%)	Carbon flux ($\text{mg C m}^{-2} \text{d}^{-1}$)	Carbon percentage (%)

4.2 Fecal pellet flux

190 Fecal pellet numerical (FPN) flux and fecal pellet carbon (FPC) flux at different depths were summarized in Table 1 and Fig. 6. FPN flux varied considerably throughout the year, from a minimum of 216 pellets $\text{m}^{-2} \text{d}^{-1}$ to a maximum of 2518 pellets $\text{m}^{-2} \text{d}^{-1}$ at 500 m, while at 1970 m, this value spanned a range of 597–4573 pellets $\text{m}^{-2} \text{d}^{-1}$. FPC flux varied between 0.0021 and 0.1148 $\text{mg C m}^{-2} \text{d}^{-1}$ at 500 m (Table 1; Fig. 6b). At 1970 m, the range was 0.0108 to 0.1697 $\text{mg C m}^{-2} \text{d}^{-1}$ (Table 1; Fig. 6d). The most apparent temporal trend in the FPN and the FPC fluxes was a distinct seasonal variation (Fig. 6). There was a double
 195 seasonal peak, with a primary (higher) peak in November–April and a secondary peak in June–August (Fig. 6). In particular,

the FPC flux increased slightly in June 2021 before declining sharply over the next 3 months (Fig. 6), and then increasing again with a primary peak from November to April. An anomalously high value of FPC flux was detected at 500 m in April–May 2022, caused by a large increase in cylindrical pellets (Fig. 6b). Moreover, both FPN and FPC fluxes increased from 500 m to 1970 m, with values at 1970 m twice as high as those measured at 500 m (Table 1).

200

Figure 6. Temporal variations of FPN and FPC fluxes of fecal pellets at the sediment trap mooring TJ-A1B in the northern SCS. (a) FPN flux at 500 m; (b) FPC flux at 500 m; (c) FPN flux at 1970 m; (d) FPC flux at 1970 m.

The total fecal pellet flux consisted of four morphological pellet types, with each type making a distinct contribution to the total FPN and FPC fluxes (Table 1; Fig. 6). Typically, ellipsoidal and amorphous pellets dominated the numerical flux, accounting for 80% of the total FPN flux. Cylindrical and spherical pellets were minor contributors to the FPN flux. In terms of the dominance of different types of fecal pellets, there were notable differences between the two depths (Table 1; Fig. 6). Amorphous pellets accounted for around 45% of the FPN flux at 500 m, while ellipsoidal pellets became most prominent at 1970 m. Cylindrical and spherical pellets had a relatively constant but low numerical percentage. Regarding FPC flux, amorphous pellets contributed on average 40% of the total FPC flux at 500 m, followed by cylindrical pellets (on average 29%) with larger size compared to the other types, despite their relatively low numerical flux. Ellipsoidal pellets contributed on

210

215 average 26%, while spherical pellets contributed only 4%. At 1970 m, ellipsoidal and cylindrical pellets dominated the FPC flux throughout the time series. Carbon percentage of amorphous pellets declined to 2–26%, while spherical pellets still remained the lowest (1–15%) (Fig. 6b and 6d). Notably, ellipsoidal, cylindrical, and spherical pellets exhibited higher FPN and FPC fluxes at 1970 m than at 500 m. However, amorphous pellets had lower carbon fluxes and carbon percentages at 1970 m due to their significantly lower biovolumes.

4.3 Contribution of fecal pellets to total POC flux

220 The POC flux in the northern SCS ranged from 0.11 to 5.31 mg C m⁻² d⁻¹ at 500 m, while it varied between 1.08 and 8.19 mg C m⁻² d⁻¹ at 1970 m (Fig. 7). A high seasonal variability of the POC flux was observed, with maxima in the winter monsoon period and minima in the inter-monsoon period at two depths (Fig. 7). This seasonal variation of the POC flux matched that of the FPC flux, with a higher peak from November to April, a lower peak from June to August, and a minimum value from September to October (Fig. 7). In addition to the temporal variation, the POC flux also varied significantly at different depths. On average, the POC flux at 500 m was only ~50% of that measured at 1970 m, and the minimum POC flux at 1970 m was one order of magnitude higher than that observed at 500 m.

225 The contribution of fecal pellets to the POC flux (FPC/POC ratio) ranged from 0.3% to 15.7% at 500 m, with the highest contribution occurring in April-May (Fig. 7). The FPC/POC ratio was generally low from May to July (<4%) and fluctuated between 1%–8% from August to December. During the winter monsoon period, this ratio remained fairly constant (~2%), and then it increased sharply in April-May. At 1970 m, the FPC/POC ratio varied from 0.5% to 5.7%, with a smaller range compared to that of 500 m. It was generally low except for May and August 2021(5.7% and 4.8%, respectively), and the 230 minimum occurred in January 2022. In general, the FPC/POC ratio is relatively higher at 500 m and lower at 1970 m, with average percentages of 3.4% and 1.9%, respectively (Fig. 7).

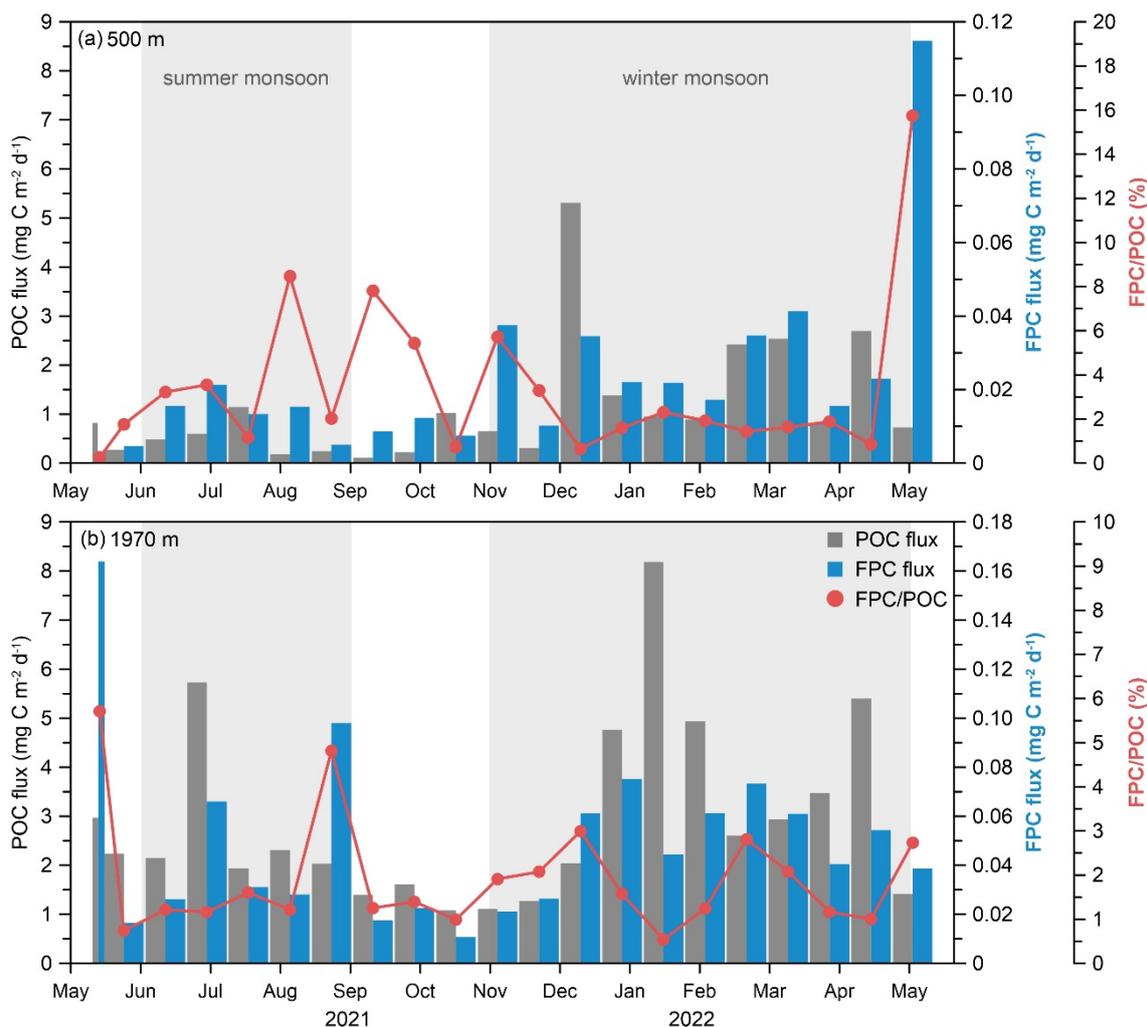

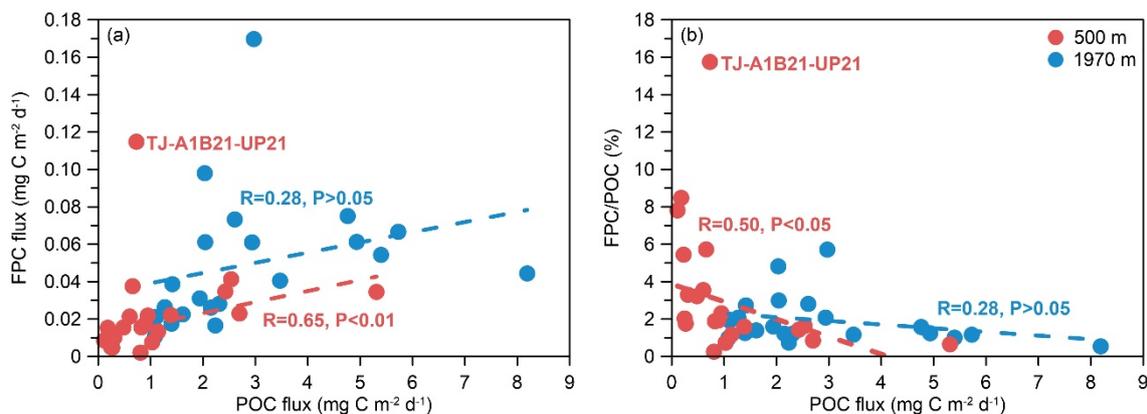

Figure 7. POC flux, FPC flux and FPC/POC ratio at water depths of (a) 500 m and (b) 1970 m at the sediment trap mooring TJ-A1B in the northern SCS.

235

Positive linear correlations were observed between the POC flux and the FPC flux (Fig. 8a). Sample TJ-A1B21-UP21, which contained a substantial quantity of cylindrical fecal pellets measuring up to 1.5 mm in size but low POC flux, was removed from the fitted relationship. Meanwhile, there were negative linear relationships between the POC flux and the FPC/POC ratio (%) (Fig. 8b). Besides, the negative linear relationship was weaker at 1970 m compared to 500 m.

240

5 Discussions

5.1 Seasonal variation of POC and FPC export

245 Temporal patterns of the POC and the FPC fluxes in the northern SCS exhibited clear seasonal signals with well-defined winter peaks (November–April). The POC flux during this period constituted over 75% of the total POC flux (Fig. 9a). The FPC flux also elevated, and the average flux during this period was 2 to 4 times higher than the average flux over the whole deployment period (Fig. 9b). Wind speed was also the highest during this period, reaching 8–10 m s⁻¹ (Fig. 9c). Meanwhile, the sea surface temperature (SST) declined continuously after November, reaching a minimum (24°C) in January and March (Fig. 9d). During

250 the winter monsoon period, cooling of surface water, along with the strong northeasterly winds resulted in the enhanced vertical mixing, which can be reflected in the variation of the mixed layer depth (MLD). MLD was typically shallow (<40 m) during spring and summer, increased in autumn and reached its maximum (95 m) in late December (Fig. 9e), even deeper than the upper nutricline (Wong et al., 2015; Du et al., 2017). High concentrations of primary productivity (PP) also indicated that the subsurface water provided adequate nutrients to the upper layer, which stimulated the growth of phytoplankton (Fig. 9f). In

255 the northern SCS, Chen et al. (2009) also reported a winter phytoplankton bloom (including *Picoeukaryotes*, *Synechococcus*, and *Prochlorococcus*). The significant increase in PP provided an enhanced food supply and supported high zooplankton biomass, thus resulting in twice the average zooplankton abundance compared to the other seasons (Fig. 2; Li et al., 2004; Tseng et al., 2005; Li et al., 2021). This pattern was consistent with studies in the southern SCS, where higher FPN and FPC fluxes were recorded during the East Asian winter monsoon (Li et al., 2022). Therefore, changes in phytoplankton community

260 structure and zooplankton abundance influenced by the northeast monsoon resulted in a significant increase in the POC and the FPC fluxes. Similarly, in the northern Arabian Sea, fecal pellets were the dominant contributor to particulate matter during the northeast monsoon (Roman et al., 2000; Ramaswamy et al., 2005). In the northeastern Mediterranean Sea, the FPC flux

also showed spring peaks during phytoplankton blooms (Carroll et al., 1998). Therefore, though in the oligotrophic seas, the monsoon system can increase the sea surface productivity, which allows for increased zooplankton biomass and promotes the export of carbon from their fecal pellets.

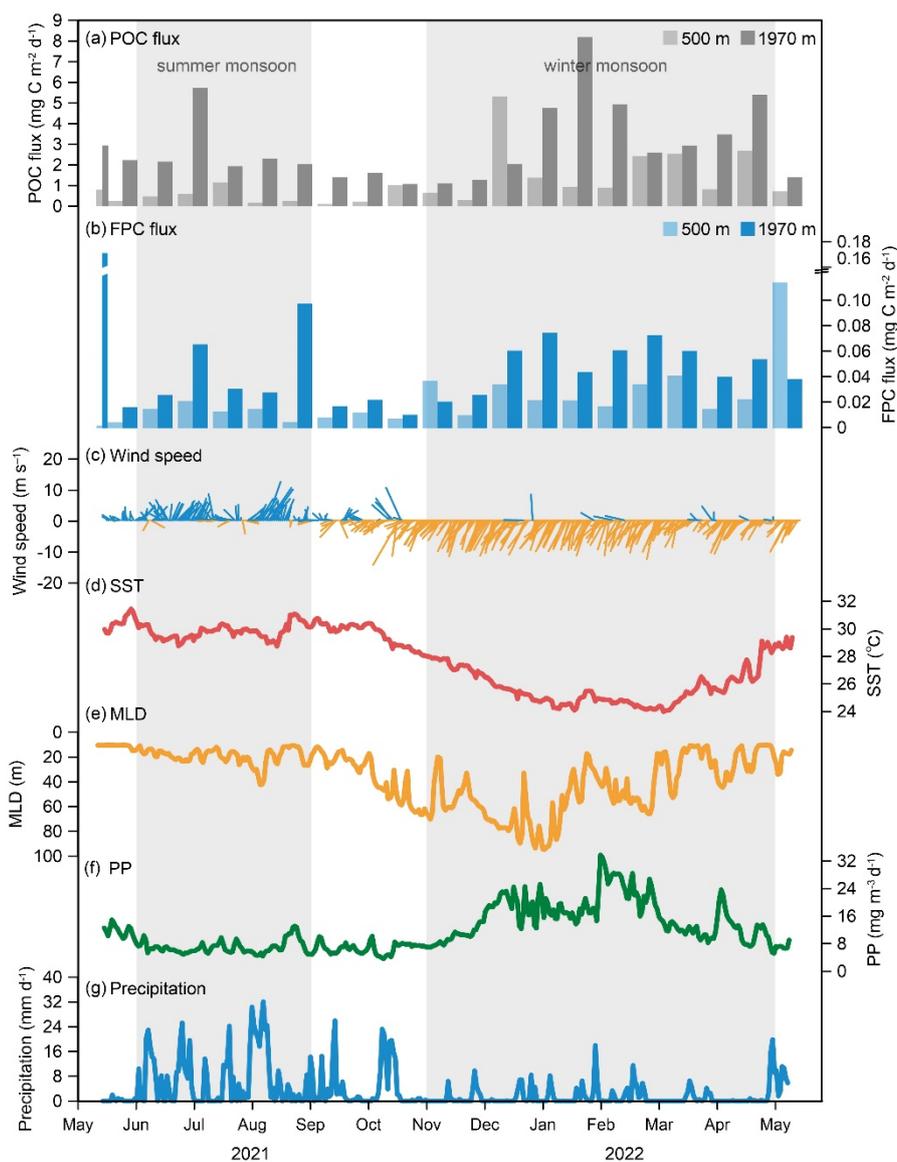

Figure 9. Seasonal variability of POC flux, FPC flux, and five hydrological parameters at the sediment trap mooring TJ-A1B in the northern SCS. (a) POC flux; (b) FPC flux; (c) wind speed; (d) sea surface temperature (SST); (e) mixed layer depth (MLD); (f) net primary production (PP) of biomass; (g) precipitation.

Secondary peaks in the POC and the FPC fluxes occurred in summer (June–August) (Fig. 9a and 9b). The southwest monsoon, typically accompanied by strong winds in the SCS, was a potential driver. However, from June to July 2021, mean wind speed decreased from 6.7 to 5.4 m s⁻¹ (Fig. 9c), with generally high SST (>28°C), which intensified the upper layer stratification. At this time, the MLD was less than 45 m, which was probably insufficient to transport subsurface nutrients to the euphotic layer.

275 Therefore, the observed increase in the POC and the FPC fluxes cannot be attributed solely to the summer monsoon, but also to rainfall and terrestrial nutrient inputs. Indeed, precipitation in the northern SCS was highly seasonal, with up to 70% concentrated between June and September (Fig. 9g; Zhang et al., 2019). Summer precipitation can bring terrestrial organic matter from land into the ocean through rivers, and this additional nutrient can lead to an increase in zooplankton biomass (Fig. 9g; Meyers, 1997; Vizzini et al., 2005; Chen et al., 2017). In addition, the notably high FPC fluxes at 500 m and 1970 m were

280 observed in May 2021 and May 2022, respectively (Fig. 9b). Previous studies have highlighted the annual occurrence of a diatom bloom peak in southwestern Taiwan waters in April (Chen et al., 2016). This may have led to an obvious increase in zooplankton biomass, which produced a large number of fecal pellets (Carroll et al., 1998). These fecal pellets from southwestern Taiwan have been transported to the northern SCS by deep-sea currents, which coincided with the previously reported high FPC flux recorded in May 2014 (Gao et al., 2020). In summary, the POC and the FPC fluxes in the northern

285 SCS exhibited obvious seasonal variations, which were primarily controlled by the East Asian monsoon system and seasonal precipitation.

5.2 Role of zooplankton repackaging in fecal pellet export

Assemblage of different types and sizes of fecal pellets varied with depth, providing an indication of the repackaging of deep-dwelling zooplankton in the water column (Wilson et al., 2008). To better understand the fecal pellet carbon export to the deep

290 sea, the biovolume of fecal pellets was converted into carbon content in the following discussion. Cylindrical pellets had the highest carbon content (on average 0.07 μg C pellet⁻¹), which was up to 10 times higher than other pellet types (Fig. 10). The maximum carbon content of cylindrical pellets at 1970 m was 10.62 μg C pellet⁻¹, which was 2.5 times higher than the maximum value recorded at 500 m (4.26 μg C pellet⁻¹). The average carbon content of ellipsoidal pellets increased from 0.01 μg C pellet⁻¹ at 500 m to 0.02 μg C pellet⁻¹ at 1970 m (Fig. 10). Spherical pellets were the smallest, and they also had higher

295 carbon contents at 1970 m than at 500 m (Fig. 10). These larger pellets may result in a twofold increase in the FPC flux at 1970 m (Table 1; Fig. 9b), which might come from the in-situ production of fecal pellets by deep-dwelling zooplankton communities. According to the literatures, ellipsoidal pellets could be attributed to copepods, pteropods, appendicularia, and larvae (González et al., 1994, 2004; Wilson et al., 2008; Wexels Riser et al., 2010; Gleiber et al., 2012). Cylindrical pellets are produced by copepods and euphausiids, and spherical pellets are produced by amphipods, ostracods and small copepods

300 (Beaumont et al., 2002; Wexels Riser et al., 2007; Phillips et al., 2009; Köster et al., 2011). The origin of amorphous fecal pellets is still under debate, as they could be produced by chaetognaths (Wilson et al., 2008) or result from the fragmentation of other-shaped intact fecal pellets (Svensen et al., 2012). In the northern SCS, copepods are the dominant group, with some species (*Chiridius poppei*, *Heterorhabdus abyssalis*, *Scolecithricella valens*, and *Calanoides carinatus*) occurring only

between 450 and 1000 m depth (Gong et al., 2017; Li et al., 2021). Larger individuals are mainly distributed in the deeper
305 layers and produce larger fecal pellets (Paffenhöfer and Knowles, 1979; Li et al., 2021). This phenomenon of increased deep-sea fecal pellet flux due to mesopelagic and bathypelagic zooplankton is a common occurrence (Fower et al., 1991; Wassmann et al., 2000; Belcher et al., 2017). Although zooplankton distribution is primarily concentrated within the euphotic zone (0–200 m), the total zooplankton abundance in the mesopelagic zones may still be substantial due to the large depth extent of these layers (Gong et al., 2017). Therefore, it is likely that a large number of fecal pellet production still occurs in the
310 mesopelagic/bathypelagic zones to increase the export of fecal pellets to the deep sea, and these fecal pellets are characterized by strong cycling within the water column.

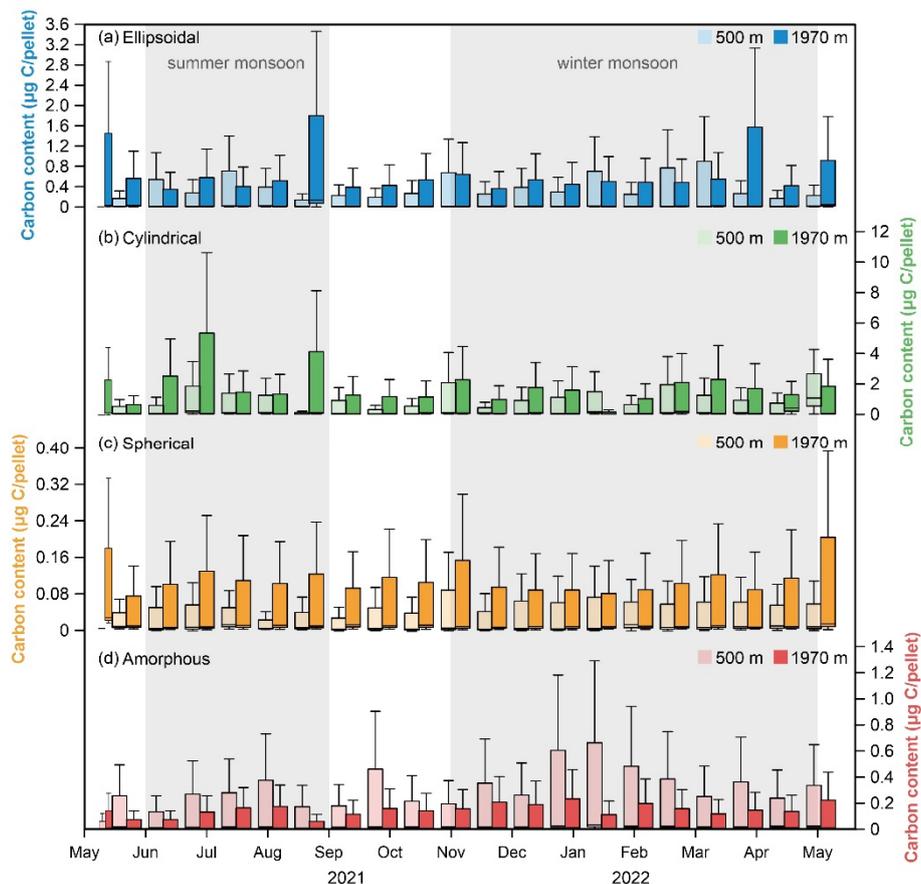

Figure 10. Carbon content of four types of fecal pellets at water depths of 500 m and 1970 m at the sediment trap mooring TJ-A1B in the northern SCS. (a) Ellipsoidal pellet; (b) cylindrical pellet; (c) spherical pellet; (d) amorphous pellet.

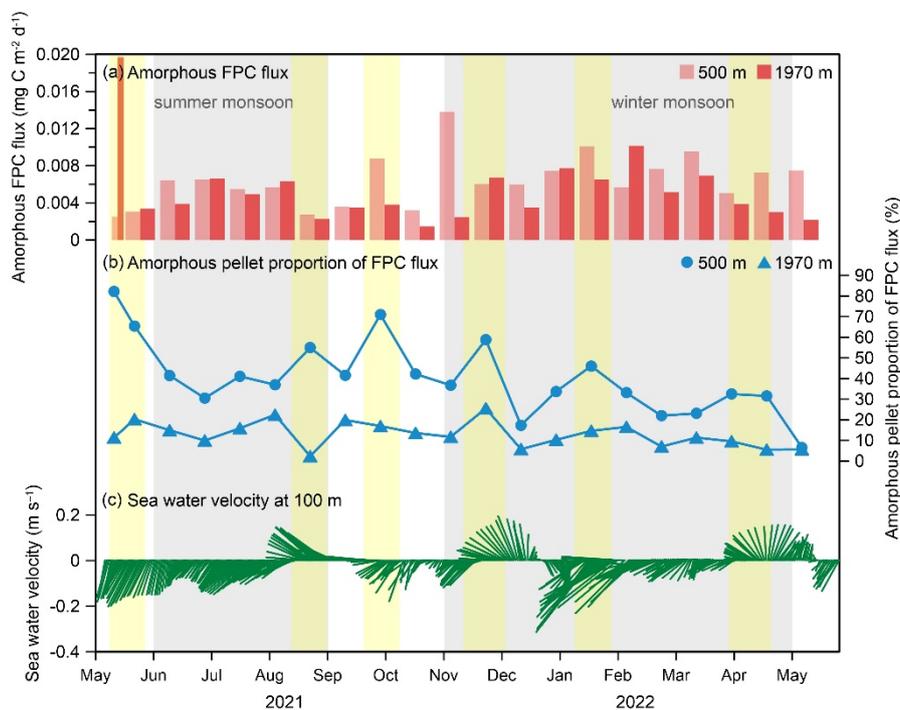

315

In addition to the influence of mesopelagic and bathypelagic zooplankton, lateral input by deep-sea currents may also be a significant factor in the increasing export of fecal pellets to the deep sea. Analysis of the internal composition of fecal pellet identified the presence of terrigenous minerals like quartz and clay minerals, with an elemental composition characterized

320 primarily by O, Si, C, Ca, Al, and K (Fig. 4 and 5). The weak correlation between the FPC flux and the POC flux at 1970 m
(Fig. 8) also suggested that POC export in the deep northern SCS was influenced by multiple factors including the input from
Taiwan rivers (Blattmann et al., 2018, 2019). Previous studies have demonstrated an increasing deep-sea POC flux in the
northern SCS due to laterally transported terrestrial organic carbon (Blattmann et al., 2018, 2019; Zhang et al., 2022). Therefore,
the significant increase in the POC flux and the FPC flux in deeper layers may be a result of lateral input via deep-sea currents
along the continental slope. This phenomenon has also been observed in the Panama Basin, where Pilskaln and Honjo (1987)
325 reported an increase in the FPC flux from $0.09 \text{ mg C m}^{-2} \text{ d}^{-1}$ at 1268 m to $1.50 \text{ mg C m}^{-2} \text{ d}^{-1}$ at 3769 m. They identified deep-
sea currents as a possible driver of the increase in the FPC flux. In summary, lateral transport of deep-sea currents is also likely
to lead to increased fluxes of deep fecal pellets.

Conversely, the biovolume and carbon flux of amorphous pellets were significantly reduced at 1970 m compared to the 500
m (Table 1). The average carbon content of amorphous pellets also showed a decrease from $0.02 \mu\text{g C pellet}^{-1}$ at 500 m to 0.01
330 $\mu\text{g C pellet}^{-1}$ at 1970 m (Fig. 10), indicating the fragmentation of fecal pellets during the sinking process. Previous studies
have shown that certain copepod species have distinct feeding behaviors on fecal pellets (Noji et al., 1991). For instance, the
species *Oithona similis* is known to frequently engage in coprorhexy or coprochaly (González and Smetacek, 1994). This
highly adaptable species, which is widespread throughout the northern SCS and found in all water layers (Gong et al., 2017),
may play a critical role in fecal pellet fragmentation. In the eastern Fram Strait, higher copepod FPC fluxes were detected in
335 the upper water column compared to the lower water column, indicating the effects of re-feeding and decomposition (Lalande
et al., 2016). Similarly, studies conducted at K2 station also provided evidence of fecal pellet fragmentation by repackaging of
mesopelagic sinking debris (Wilson et al., 2008). These phenomena further support the idea that deep-dwelling zooplankton
may play a significant role in the repackaging of fecal pellets. Additionally, increased current activity may also lead to
fragmentation of fecal pellets. As shown in Fig. 11, the amorphous FPC flux showed a trend of winter peak and summer sub-
340 peak, with the highest value occurring in May 2021. However, the temporal variation in amorphous pellet proportion to the
total FPC flux did not show consistency with the amorphous FPC flux (Fig. 11b). Notably, as current velocity increased, the
proportion of amorphous pellets to the total FPC flux was significantly higher (~40%), meaning that these pellets exhibited a
higher degree of fragmentation (Fig. 11b and 11c). Therefore, the fragmentation of fecal pellets in the northern SCS shows the
joint effect of zooplankton grazing and hydrodynamic changes.

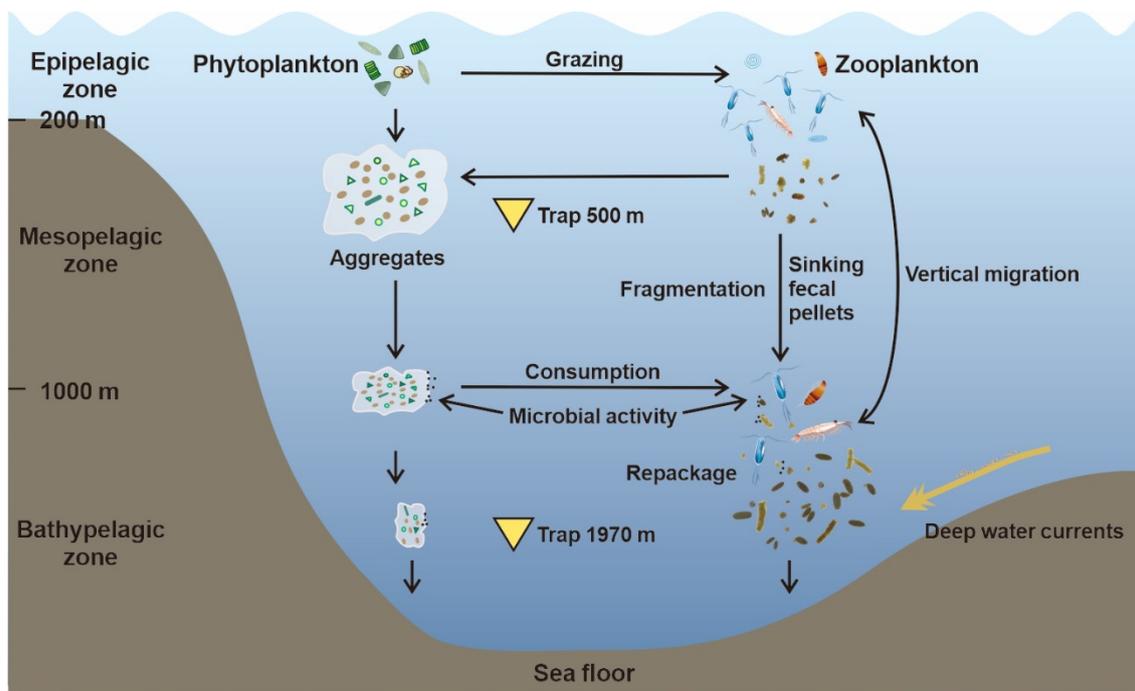

345

Figure 11. Correlation between (a) amorphous FPC flux, (b) amorphous pellet proportion to the total FPC flux, and (c) sea water velocity at 100 m at the sediment trap mooring TJ-A1B in the northern SCS. Yellow shadows display the period with a relatively high proportion of amorphous pellets to the total FPC flux.

5.3 Sinking fate of zooplankton fecal pellets

350 In the northern SCS, variable mechanisms affect the carbon export of zooplankton fecal pellets (Fig. 12). In the euphotic zone, zooplankton consume phytoplankton and egest sinking fecal pellets. Phytoplankton cells, zooplankton molts, and fecal pellets together form the larger aggregate. High FPC fluxes are observed during the northeast monsoon period and the summer rainy season. Presence of deep-dwelling zooplankton communities and lateral inputs from the slope into the deep basin tend to increase the export of fecal pellet to the deep sea. However, amorphous pellets are fragmented during the sinking process,
355 indicating that surface-produced pellets are likely to be consumed and reworked by zooplankton grazing and strong hydrodynamic activities. The evolving picture regarding the sinking fate of fecal pellets is therefore a coupling between the surface primary production, repackaging by mesopelagic and bathypelagic zooplankton, lateral input by deep-sea currents and hydrodynamically induced fragmentation.

360 **Figure 12.** Conceptual graph of the sinking processes regulating the carbon export of fecal pellets in the northern SCS. Yellow
365 triangles show the locations of sediment traps to collect fecal pellets in this study.

Zooplankton fecal pellets were a minor contributor to POC flux in the northern SCS. Fecal pellets contributed an average of 3.4% (range 0.3–15.8%) of the POC flux at 500 m, and 1.9% (range 0.5–5.7%) of the POC flux at 1970 m. These results are
365 similar to those from several other oligotrophic seas (Urrère and Knauer, 1981; Pilskaln and Honjo, 1987; Wassmann et al., 2000; Wilson et al., 2008; Goldthwait and Steinberg, 2008; Shatova et al., 2012). However, compared to the southern SCS (9.0%), the contribution of fecal pellets to the total carbon flux was comparatively lower in the northern SCS, possibly due to
370 their higher degree of fragmentation and degradation (Li et al., 2022). Even though 87% of the sinking POC in the northern SCS was from marine biospheric origin, the majority may have come from phytoplankton cells such as *Prochlorococcus* and *Synechococcus*, zooplankton molts, zooplankton carcasses, and large aggregates (Zhang et al., 2019, 2022). Negative correlations between the POC flux and the fecal pellet contribution were observed, indicating that during periods of low POC flux, fecal pellets may play a proportionally larger role in deep-sea carbon export (Fig. 8). In contrast, during periods of high POC flux, aggregates composed of diatoms, dinoflagellate flocs, fecal pellets, and other debris appeared to be the major contributors (Fig. 3). Wilson et al. (2013) found that during periods of low POC flux in the northeast Pacific, fecal pellets also
375 accounted for a greater proportion of deep-sea POC flux. This negative correlation between the FPC flux and the POC flux may be a common characteristic of particulate fluxes in the deep ocean (Wilson et al., 2013). In the northern SCS, the FPC

flux was relatively low, with a high abundance of amorphous pellets and significantly low FPC/POC ratios, which may indicate a low efficiency BCP with a weak carbon sink effect.

380 Although the contribution of fecal pellets to the total carbon flux in the northern SCS is quantitatively low (0.3–15.8%), detailed analyses of the spatiotemporal variations in fecal pellet fluxes can provide significant insights into the processes controlling fecal pellet production, sinking, and reworking. Linking fecal pellet fluxes to seasonal and oceanographic dynamics can provide new insights for investigating the efficiency of BCP in the SCS, and greatly enhance our understanding of the biogeochemical processes that influence the export of organic carbon to the deep sea. Additional research is needed to determine the presence of fecal pellets at the sediment-water interface, and to further explore the sinking and burial processes
385 of POC in the deep sea, from sinking particles to sediment cores.

6 Conclusions

Characteristics, internal structure, quantity, and carbon content of zooplankton fecal pellets were investigated in the northern SCS to quantify the numerical and carbon fluxes of fecal pellets and to explore the process of fecal pellet sinking in the tropical marginal sea. Our conclusions are as follows:

- 390 1. Seasonal variations in the FPN and the FPC fluxes showed distinct peaks from November to April and from June to August. Strong northeast monsoon and surface water cooling led to the mixing of the upper water column, importing nutrients from subsurface into the euphotic layer, stimulating phytoplankton growth and increasing FPC flux in winter. Additionally, the FPC fluxes were also high in summer due to heavy precipitation that brought terrestrial nutrients into the sea.
- 395 2. Zooplankton fecal pellet fluxes were twice higher at 1970 m than at 500 m. The occurrence of larger ellipsoidal, cylindrical, and spherical pellets at 1970 m provided evidence for repackaging and in-situ production of mesopelagic/bathypelagic zooplankton communities, and lateral input by deep-sea currents. Amorphous pellets were abundant and their biovolume decreased by half at 1970 m compared to 500 m, indicating that these fecal pellets were subject to fragmentation during sinking, possibly due to the impacts of zooplankton grazing and strong current disturbance.
- 400 3. The sinking process of fecal pellets is controlled by a combination of sea surface productivity, mesopelagic and bathypelagic zooplankton repackaging, as well as current activities. Although the contribution of fecal pellets to the deep-sea carbon flux is relatively low in the northern SCS, fecal pellets still play a variable but indispensable role in the vertical carbon export.

Data availability

The data involved in this study are underway of archiving at the PANGAEA database (<https://issues.pangaea.de/browse/PDI-35447>). They are provided as supporting materials during the reviewing process.
