20 **Abstract.** The coralligenous build-ups located in Mediterranean shelf in front of Marzamemi (SE - Sicily, Italy) represent
21 useful natural examples to study the relationship between skeletal organisms and non-skeletal components in marine
22 bioconstructions. Coralligenous build-ups are formed in open marine systems and their comparison with coeval
23 bioconstructions (biostalactites) of confined environments, like submarine caves, allows depicting the complex
24 interactions between metazoans and microbial communities in the formations of recent bioconstructions in different
25 Mediterranean settings. In this study, two coralligenous build-ups were characterized in terms of organisms and sediments
26 involved in their formation. The framework mainly consists of coralline algae and subordinate bryozoans and serpulids.
27 Sponges affect the general morphology of the bioconstructions both interacting with skeletonised organisms and through
28 bioerosion activity. The micrite or microcrystalline calcite is present in minor amount than other components that form
29 the build-ups and consists of two types: autochthonous (*in situ*) and allochthonous (detrital). Fine autochthonous micrite
30 mineralized directly inside the framework cavities and shows aphanitic or peloidal fabric, produced by
31 organomineralization processes of soft sponge tissues and microbial metabolic activity, respectively. The detrital micrite
32 occurring inside cavities derives from external sources or erosion processes of the bioconstructions themselves. This
33 component has been classified as organic or inorganic based on the organic matter contents deduced by UV-
34 Epifluorescence. A great amount of sponges lives in cavities of the coralligenous build-ups and compete with
35 carbonatogenic bacteria for the same cryptic spaces limiting the production of microbialites. The sharing of a similar
36 relationship between sponges and microbial communities by coralligenous concretion and biotic crusts of particular
37 submarine caves suggests that this competition is not habitat specific. On the contrary, it may develop in a range of
38 environmental settings, from open to cryptic systems, and could be used to clarify the role of metazoans *vs* microbialites
39 in palaeoecological reconstructions.

40 **Keywords:** Coralligenous reefs; Sponges; Micrites; Geobiology; Mediterranean.

41 **1. Introduction**

42 Bioconstructions consisting of in-place reef-building organisms in temperate waters of the Mediterranean Sea shelf are
43 known as Coralligenous (Pérès and Picard, 1964). The term Coralligenous (Coralligène) is derived from the French
44 literature (Marion, 1883; Pérès and Picard, 1964), and generally indicates mesophotic bioconstructions of the
45 Mediterranean Sea, primarily built by crustose coralline algae. However, in recent years, the definition of Coralligenous
46 is under review, also due to the exploration efforts in the deepest part of the shelf (Cerrano et al., 2019).

47 These structures are primarily made-up of calcareous red algae, which are able to develop algal-dominated frameworks
48 characteristic for this basin (*e.g.*, Ballesteros, 2006). Pérès and Picard (1964) consider the Coralligenous a climax
49 biocoenosis of the circalittoral zone, in which crustose coralline algae (CCA) and mineralized Peyssonneliales develop
50 on primary or secondary hard bottoms, in dim-light conditions. The crustose coralline algae have an excellent fossil record
51 from the Early Cretaceous onwards (Aguirre et al., 2010) but the fossil record of build-ups similar to Coralligenous dates
52 back only to the Quaternary (Sartoretto et al., 1996; Bertolino et al., 2017a, 2017b; Basso et al., 2022).

53 Due to its importance as hot spot of biodiversity the European Community considers the Coralligenous among the most
54 important habitats to be monitored and protected (see: Ballesteros, 2006; Gennaro et al., 2020), considering also its low
55 accretion rate of 0.06÷0.27 mm per year (Sartoretto et al., 1996; Di Geronimo et al., 2001; Bertolino et al., 2019; Basso
56 et al. 2022). Coralligenous is usually considered to be an association of several communities (Ballesteros, 2006; La
57 Rivière et al., 2021). Indeed, the external surface and the cavities of the build-ups host a rich association of calcareous
58 red algae, sponges, bryozoans, serpulids, molluscs, and corals (Pérès, 1982; Bellan-Santini et al., 1994; Di Geronimo et
59 al., 2002; Ballesteros, 2006; Rosso and Sanfilippo, 2009; Bertolino et al., 2017, 2019; Costa et al., 2019; Basso et al.,
60 2022; Bracchi et al., 2022; Cipriani et al., 2023). Coralligenous build-ups: (i) modify the seafloor and the seascape
61 (Laborel, 1961; Basso et al., 2007; Bracchi et al., 2015, 2017), (ii) promote the production of carbonate (Marchese et al.,
62 2020), and (iii) may be recognized in the sedimentary succession (Bosence and Pedley 1982; Carannante and Simone
63 1996; Basso et al., 2007, 2009; Titschack et al., 2008; Bracchi et al., 2014, 2016, 2019). The presence of the coralligenous
64 3D structure and the related high biodiversity and biomass also determine the increase of available resources. These attract
65 microorganisms such as ostracods and foraminifera which, while not contributing directly to the bioconstruction, raise its
66 biodiversity (*e.g.*, Hong, 1982; Ballesteros, 2006; Sciuto et al., 2023).

67 Unlike other aspects, geobiological features of the Coralligenous and the role of skeletonised and non-skeletonised (*e.g.*,
68 bacteria) communities in forming these build-ups have so far not been explored in detail. The lack of this information
69 produces a gap between the knowledge of the build-ups developed in the open settings of the Mediterranean Sea and
70 those forming in confined environments, like the “biostalactites” of submarine caves. Actually, “biostalactites” from
71 Apulia, Adriatic Sea (Onorato et al., 2003; Belmonte et al., 2009; Rosso et al., 2020; Guido et al., 2022), Sicily (Guido et
72 al., 2012, 2017a; Sanfilippo et al., 2015), Lesvos Island, Aegean Sea (Sanfilippo et al., 2017; Guido et al., 2019a, 2019b);
73 and Cyprus, Levantine Sea (Guido et al., 2017b; Jimenez et al., 2019) have been studied in detail and the biotic and abiotic
74 processes involved in their formation have been clarified. These studies showed the fundamental role of bacteria in
75 strengthening the bioconstructions, through the biomineralization processes of autochthonous micrite (Guido et al., 2013,
76 Gischler et al., 2017a). Like these systems, it is conceivable that also the high porous framework of the Coralligenous
77 could promote the development of non-skeletal biomineralization processes.

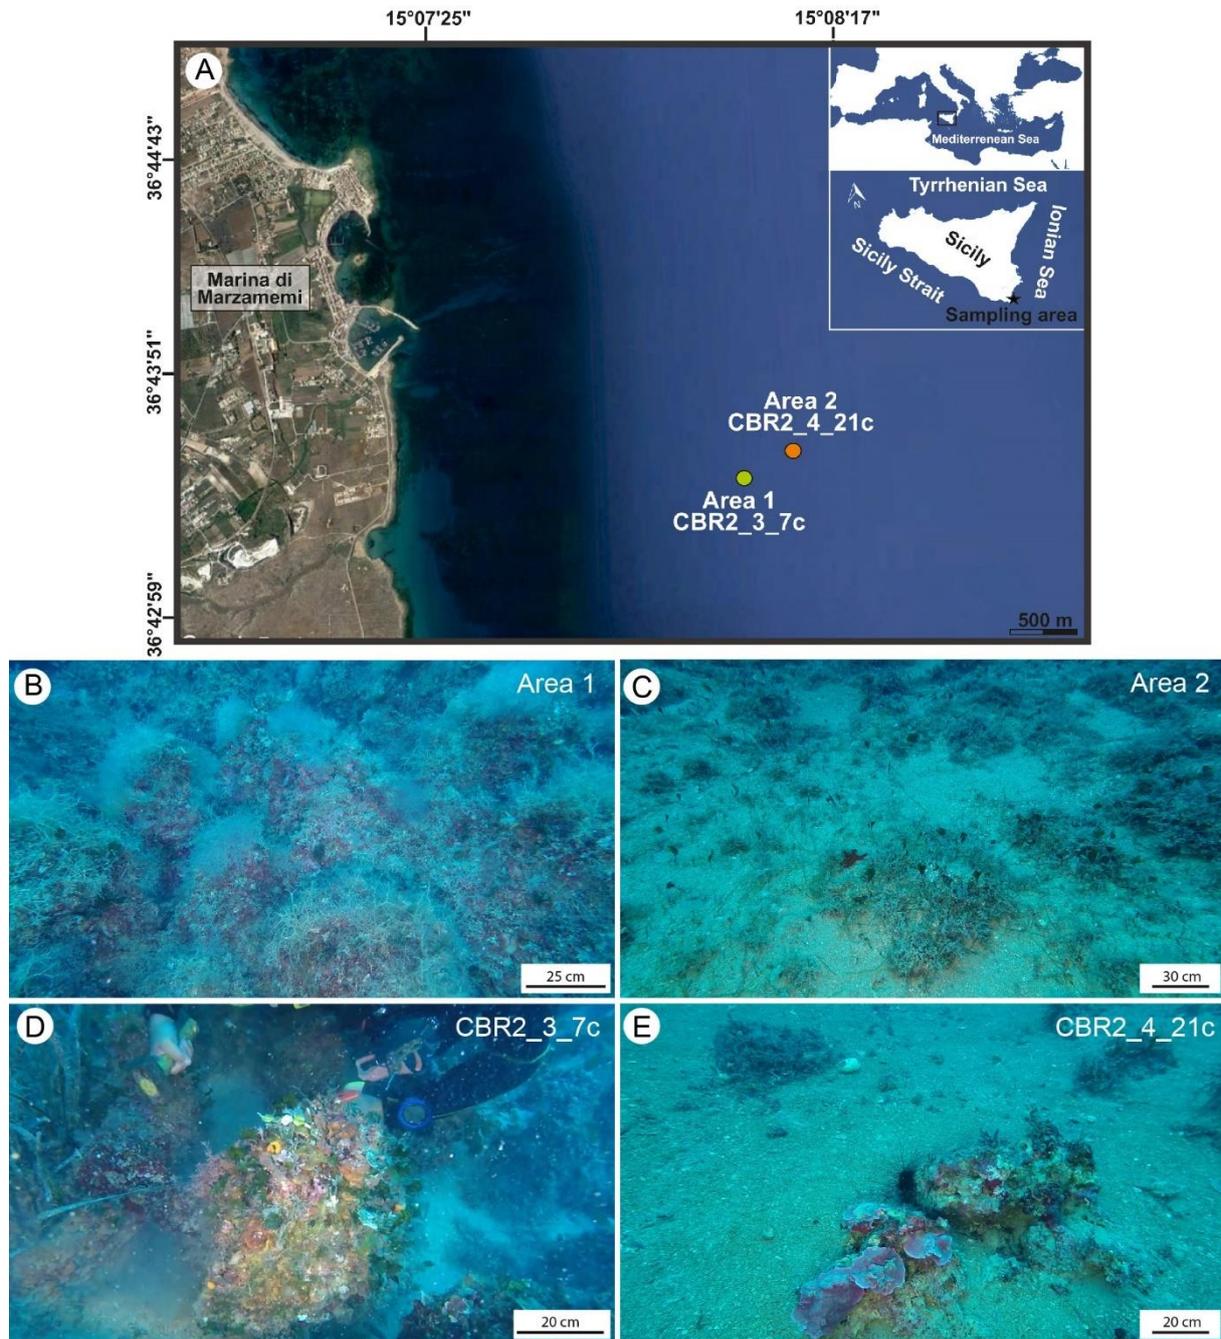

78 Biomineralization indicates a relationship between biotic activity or products and mineralization. Several
79 biomineralization processes have been extensively investigated mainly in carbonate rocks (Riding, 2000, 2011; Van
80 Driessche et al., 2019). Trichet and Défarge (1995) introduced the term organomineralization for mineral precipitation
81 mediated by non-living microbial organic substrates *via* acidic macromolecules of extracellular polymeric substances

82 (EPS). These macromolecules provide a template for biofilm organomineralization. Dupraz et al. (2009) later utilized the
83 term “organomineralization *sensu lato*” for not genetically controlled processes that mediate mineral precipitation on an
84 organic matrix, including in the definition both the active (biologically induced, mediated by living organic substrates)
85 and passive (biologically influenced, mediated by non-living organic substrates) processes. Summarizing, crystal
86 nucleation in biomineralization processes can be: (i) controlled directly by the organisms (Blakemore, 1975; Mann, 1983;
87 Mann, 2001; Weiner and Dove, 2003; Bazylinski and Frankel, 2004; Komeili, 2007; Altermann et al., 2009; Riding and
88 Virgone, 2020); (ii) induced by microbial communities (Lowenstam and Weiner, 1989; Perry et al., 2007; Altermann et
89 al., 2009; Dupraz et al., 2009; Borch et al., 2010; Phillips et al., 2013; Anbu et al., 2016; Riding and Virgone, 2020); or
90 (iii) influenced by the presence of cell surface organic matter (Trichet and Défarge, 1995; Perry et al., 2007; Altermann
91 et al., 2009; Dupraz et al., 2009). In all these cases, the formation of biominerals also depends on the chemical-physical
92 conditions of the environment (Riding and Liang, 2005; Riding, 2011). Here the autochthonous micrite (“automicrites”
93 *sensu* Wolf, 1965) was considered a product of induced or influenced biomineralization. To date no research has been
94 addressed to this topic and, in the frame of the project “CRESCIBLUREEF”, we aim to improve knowledge on the
95 Coralligenous: (1) describing the origin of the sediments filling the cavities of the skeletal framework; (2) investigating
96 the relationships between sponges and microbial processes through biomineralization-mediated processes; and (3)
97 comparing the Coralligenous, formed in open marine systems, with the bioconstructions of submarine caves developed
98 in confined marine settings.

99 **2. Materials and methods**

100 In the studied area coralligenous bioconstructions, mostly columnar-shaped and distributed in more or less dense clusters,
101 extend widely in a belt between ca 36 and 100 m depth. The image analysis and computed axial tomography reveals that
102 the bioconstruction’s framework is mainly formed of coralline algae and in minor amount of invertebrates (mostly
103 serpulids and bryozoans) and cavities filled with sediment (Bracchi et al., 2022; Varzi et al., 2023). The surfaces of the
104 studied build-ups were covered with a dense, up to 8–10 cm thick, canopy of fleshy algae and locally, also by subordinate
105 erect bryozoan colonies (Bracchi et al., 2022; Donato et al., 2022; Rosso et al., 2022, 2023; Sciuto et al., 2023). The most
106 abundant components are CCA and mineralized Peyssonneliales with a cover of up to about 61%. Fleshy algae are also
107 abundant, up to about 32%. The faunal groups have negligible covers, except for bryozoans reaching about 12% (Bracchi
108 et al., 2022).

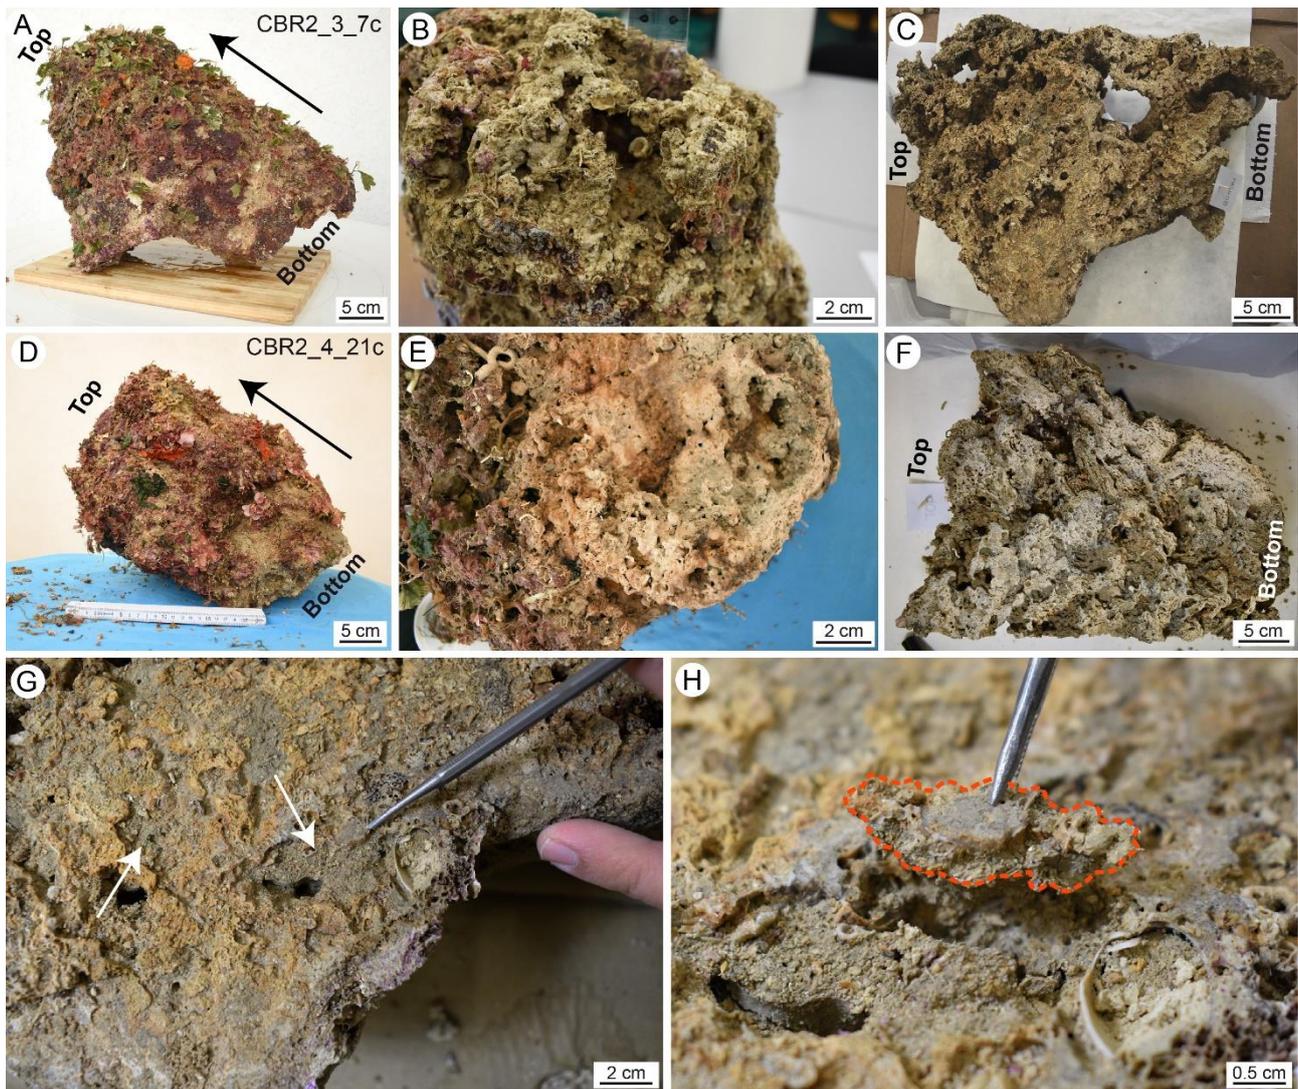

109 Two build-ups called CBR2_3_7c and CBR2_4_21c from this coralligenous field located in the Ionian Sea were collected
110 (Fig. 1). The build-up CBR2_3_7c (36° 43.394' N; 15°09.469' E) was sampled at 36,2 m depth in a zone covered by
111 coralligenous hybrid banks (Bracchi et al., 2017), made of distinct, though sometimes coalescent, coralligenous columnar
112 build-ups (Fig. 1B and D). The build-up CBR2_4_21c (36°43.454' N; 15°09.657' E) was collected at 36,7 m depth in an
113 area characterized by sparse and distinct build-ups growing on biogenic gravel and sand substrate (Fig. 1C and E).

114

115 **Figure 1:** (A) Location of the study areas off the coast of Marzamemi village in the Ionian Sea. (B-C) Underwater photos
 116 of the sampling sites. (D) Area 1, characterized by high coralligenous cover, from where the CBR2_3_7c build-up was
 117 collected at 37 m. (E) Area 2, showing sparse and isolated coralligenous columnar bioconstructions, from where
 118 CBR2_4_21c build-up was sampled at 36 m.

119 After drying, the build-ups were cut with a diamond saw following the putative grow direction of the structures (Fig. 2A,
 120 B, D and E). The cutting planes showed that the coralline algae framework forms a highly porous structure with cavities
 121 filled with sediments (Fig. 2C and H). Photos at macroscale were acquired at the University of Milano-Bicocca with a
 122 Nikon D3500 camera. Photos at mesoscale were acquired at the University of Catania through a stereomicroscope Zeiss
 123 Discovery V8A stocked with an AxioCam MRC and a system for automatic acquisition of the images (Axiovision). To
 124 investigate the role of sediment in the growth and stabilization of the skeletal components (at micro and nano-scale) small
 125 fragments (Fig. 2G and H) and thin sections (Fig. 3) were analysed at the Laboratory of Geobiology of the Department
 126 of Biology, Ecology and Earth Science, University of Calabria.

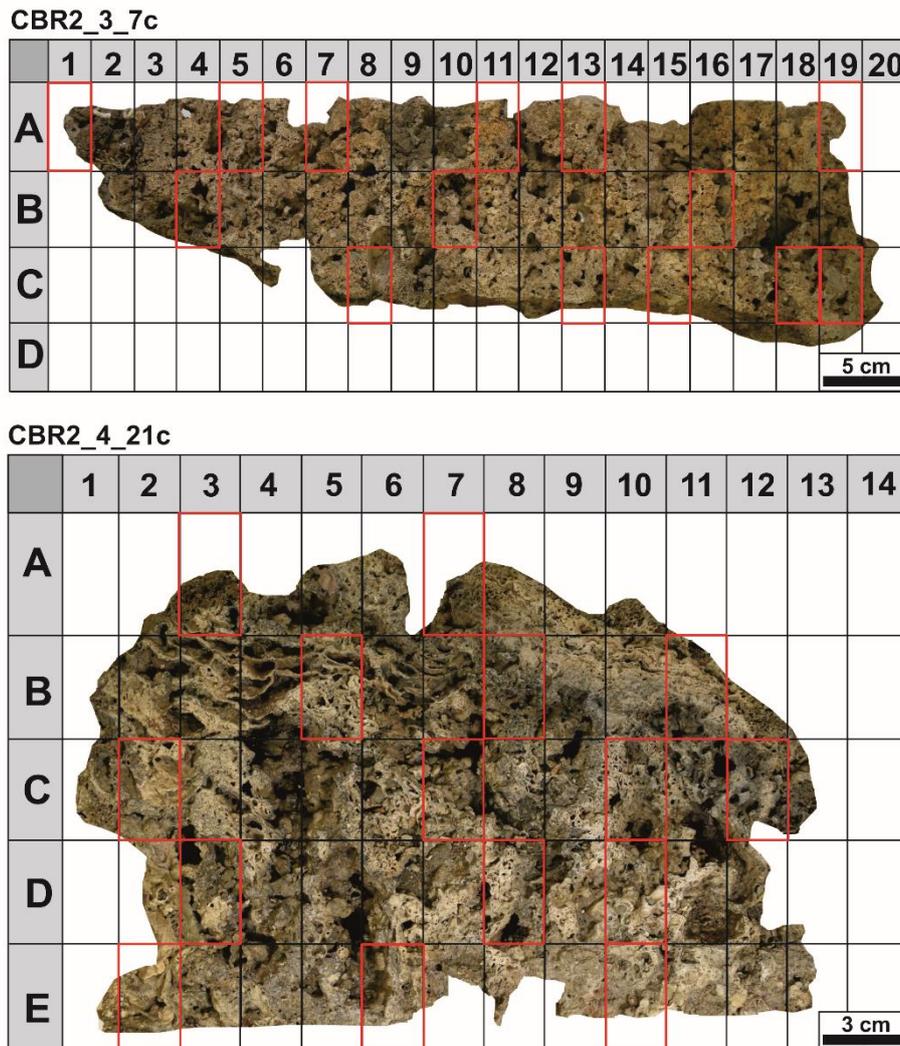

127

128 **Figure 2:** (A and D) Sampled coralligenous build-ups; note the high biogenic cover (largely consisting of soft-bodied
 129 organisms) on the external surfaces. Black arrows indicate the main growth direction. (B and E) Surfaces of detachment
 130 from the sea-bottom. (C and F) plane slab after the longitudinal cut of the build-ups showing the internal structure; note
 131 the high porous skeletal framework with cavities partly filled with sediment. (G and H) Selection and sampling of small
 132 micritic fragments from the cutting surfaces; (G) The white arrows point to cavities partly filled with sediment on a cutting
 133 plane of the CBR2_3_7c build-up; (H) detail of a fragment (red dotted line) sampled for the analyses. Bottom indicates
 134 the portion of build-ups detached from the substrate. A, C, and H from Cipriani et al. (2023).

135 A total of twenty-nine small blocks, selected following a grid with sides of 5x3 cm on the cutting plane, have been utilized
 136 for thin sections preparation (Fig. 3). The blocks have been chosen based on the mesoscopic aspect and relative amount
 137 of skeletal components and micrite sediments. The fragments and thin sections have been investigated using an optical
 138 microscope (Zeiss Axioplan Imaging II) at different magnifications (2.5x, 5x, 10x, 20x, and 40x). Thin sections were
 139 used for point counting analyses of the main components (skeletons, micrite and cavities). A total of 300 points per thin
 140 section were counted. Fluorescence intensity has been evaluated in incident light utilizing a Hg high-pressure vapour bulb
 141 and high-performance wide bandpass filters (band-pass filter 436/10 nm/long-pass filter 470 nm, no 488006, for the green
 142 light; and band-pass filter 450–490 nm/long-pass filter 515 nm, no. 488009, for the yellow light). UV-epifluorescence
 143 was used to discriminate the presence and distribution of organic compounds and to recognize, together with microfacies
 144 textures, biotic and abiotic components, especially in those cases showing a similar general aspect under reflected light
 145 (Neuweiler et al., 2000, 2003, 2023).

146 Selected fragments, used for Scanning Electron Microscopy (SEM) observations and EDS (Energy Dispersive X-ray
 147 Spectroscopy) microanalysis, were carbon coated. The SEM apparatus was used is Ultra High Resolution (UHR-SEM) –
 148 ZEISS CrossBeam 350 with the following condition: resolution 123 eV, high voltage 10 keV, probe current 100 pA and
 149 working distance 11 mm. Mineralogical and chemical compositions were investigated under high voltage 15 keV, probe
 150 current 60 mm, working distance 12 mm, take-off angle 40° and, live time 30 sec; the weight percentage (wt%) of the
 151 elements considered in this study were calibrated using the internal standard of the Microscopy and Microanalysis
 152 Laboratory Center, University of Calabria.

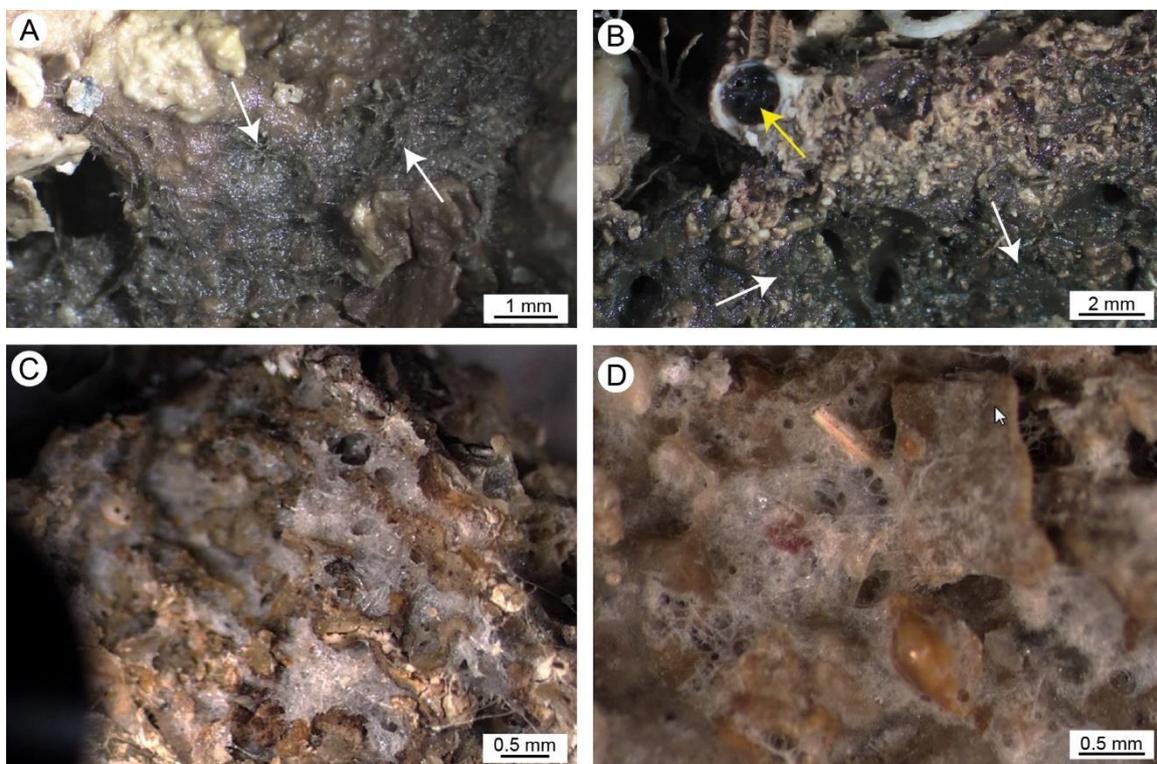

153
 154 **Figure 3:** Cutting plane of the coralligenous build-ups with the superimposed grids of 5x3cm sized rectangles. Cells
 155 selected for thin sections are rimmed in red.

156 **3. Results**

157 **3.1 Morphology and framework at mesoscale observation**

158 The CBR2_3_7c build-up is 56 cm high, with circumferences of 59 cm at the base, 78 cm at the top and a maximum of
 159 116 cm in between (Fig. 2A). The CBR2_4_21c build-up is 38 cm high, with circumferences of 71 cm at the base, 52.5
 160 cm at the top and a maximum of 112 cm in between (Fig. 2D). Both build-ups show a prevalent upward growth and a
 161 rough surface.

162 The surfaces of detachment (Fig. 2B and E, for CBR2_3_7c and CBR2_4_21c, respectively) and selected longitudinal
163 plane slabs (Fig. 2C and F, for CBR2_3_7c and CBR2_4_21c, respectively) highlight the internal framework of the two
164 build-ups, characterized by a primary skeletal framework forming a high porous structure, with cavities ranging from few
165 millimeters to ten centimeters. Sometime, the cavities surfaces are encrusted by skeletonized organisms, mainly serpulids
166 and bryozoans. In general, cavities show cylindrical-barrel shapes (like those produced by boring bivalves) or irregular
167 shapes and may be empty or (partially or totally) filled with sediment. This appears either brownish-greyish or greenish.
168 brown to grey/dark grey in colour. Brownish-greyish sediment is muddy, usually located in larger cavities, and includes
169 a bioclastic component (planktonic and benthic foraminifer shells, small fragments of coralline algae, serpulids,
170 bryozoans, ostracods, molluscs) and appears loose. Greenish coloured sediment is subordinate and distributed in smaller
171 (millimetre- to centimetre- sized) cavities; it seems cemented and consists of mud lacking skeletal fragments, at mesoscale
172 observation (Fig. 2G). This component mainly occurs along the borders of partly filled cavities possibly originally
173 occupied by sponges, as testified by remains of their soft tissue connected with spicules (Fig. 4A and B). The two types
174 of sediment (loose and cemented) seem distributed according to the size of the cavities but they do not show a preferential
175 distribution, from the bottom to the top of the structures, inside the build-up frameworks.

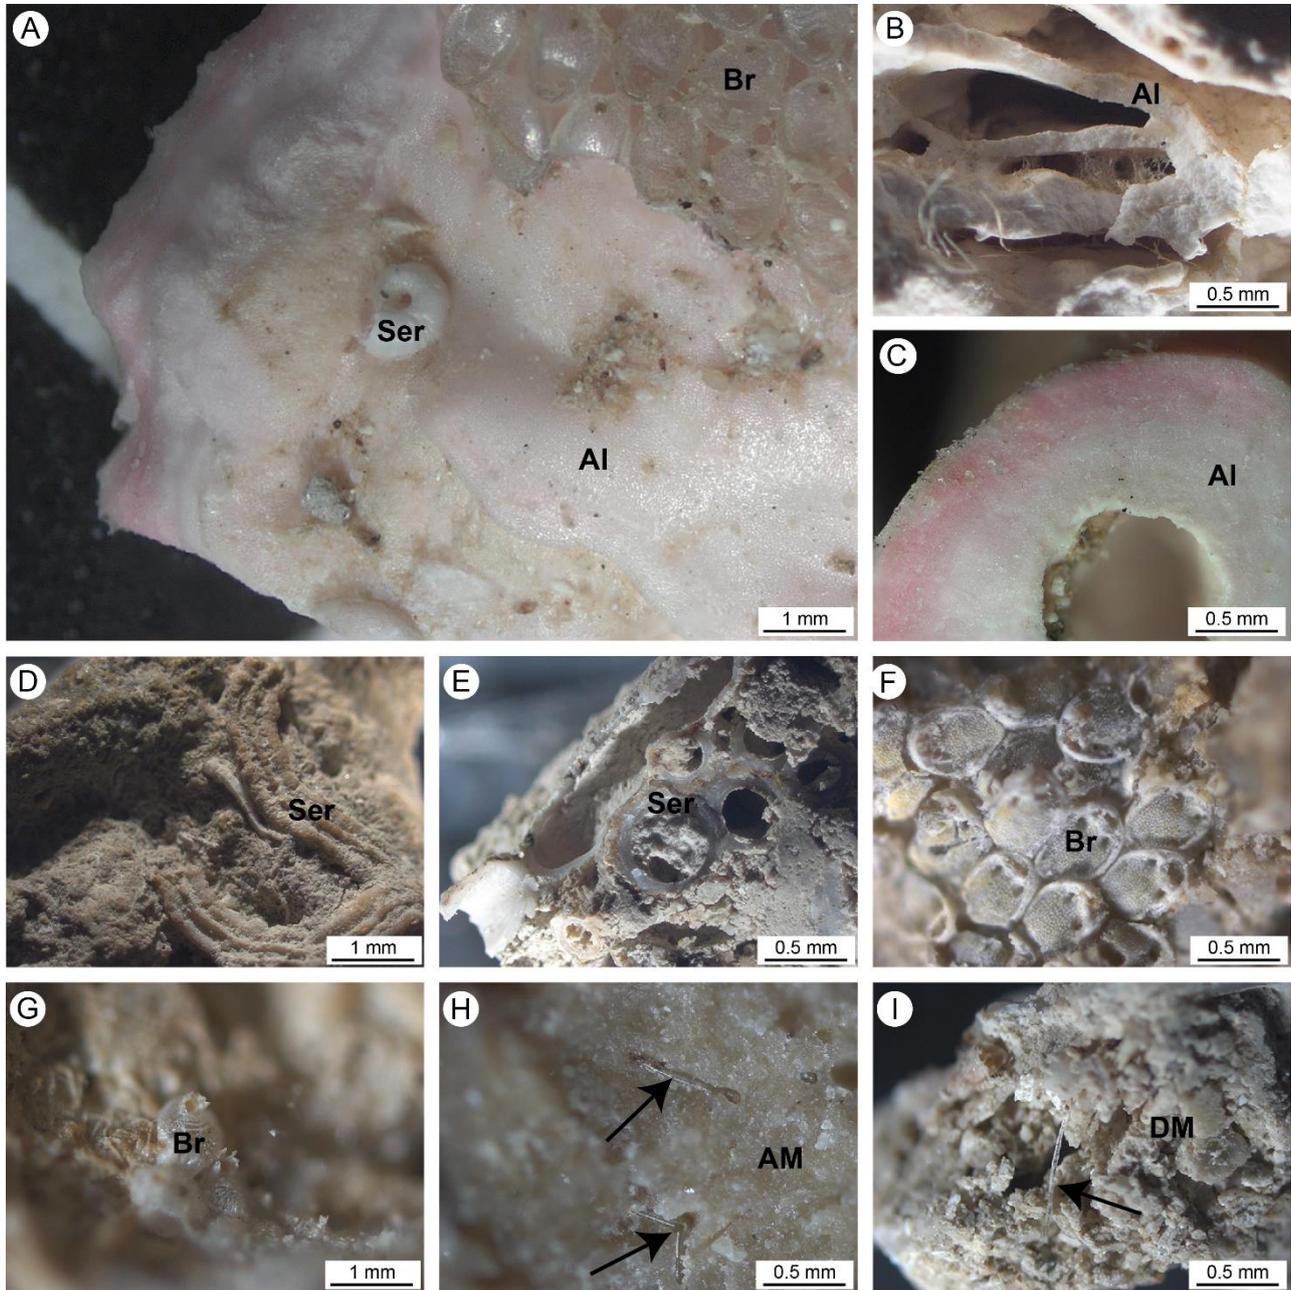

176
177 **Figure 4:** (A-B) Fine micritic sediment associated to remain of sponge tissue (white arrows) in internal cavities of the
178 framework; the yellow arrow points to a sponge colonizing the internal cavity of a serpulid tube. (C and D) Pervasive
179 colonization of sponges in internal cavities and the external surface, respectively.

180 3.2 Analyses of the fragments

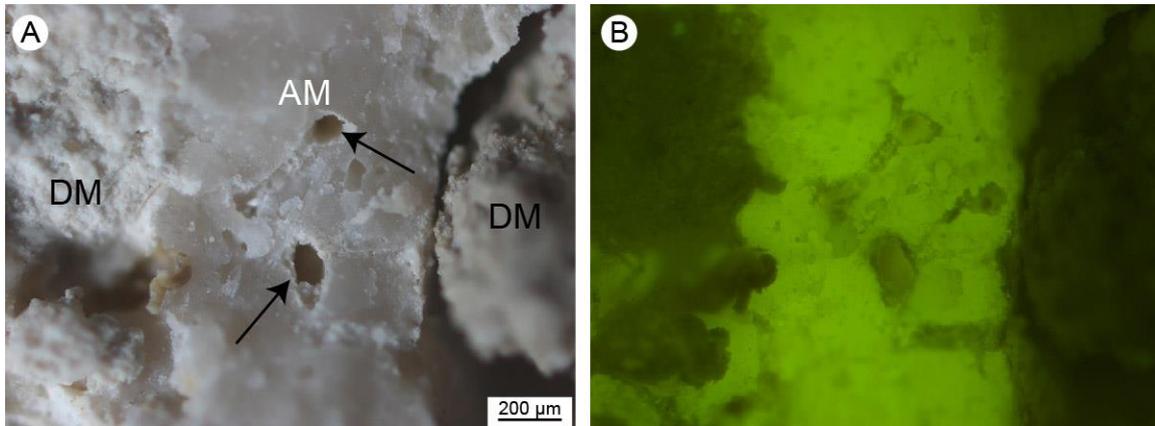

181 The observation of the build-up fragments at the microscale (Fig. 2H and Fig. 5) highlight the superimposition of
182 successive generations of different taxa producing the crusts. The skeletal framework is mainly composed of CCA (Fig.
183 5A-C). Serpulids (Fig. 5A, D and E) and bryozoans (Fig. 5A, F and G) participate subordinately to the formations of the
184 structure. Sponges seem to concur to the general morphologies, regulating the direction of growth of the encrusting
185 organisms, and altering the internal body of the build-ups through bio-erosive processes. The activity of sponges is evident
186 both on external surface and internal microcavities of the fragments testifying the pervasive colonization of these

187 organisms at different scales (Fig. 4). Spicules sometimes are associated with fine carbonate mud (Fig. 4A and B), in
 188 other cases their original presence in empty cavities is testified by organic remains with spicules (Fig. 4C and D) and
 189 specific micro-morphologies of the cavity boundaries which testify the boring activity of these organisms. Molluscs and
 190 other skeletonized invertebrates make a negligible contribution to the build-up growth. Rare solitary corals are also
 191 present.

192
 193 **Figure 5:** (A and B) Main carbonate components of the small fragments collected on the cut surfaces of the build-ups.
 194 (A) Pink crustose coralline algae (Al) encrusted by serpulids (Ser) and bryozoans (Br). (B) Different generations of
 195 crustose coralline algae encrusted one on top of the others. (C) Cross section of a crustose coralline alga. (D) Serpulid
 196 tube encrusting cemented micrite. (E) Section of serpulid tubes intermingled with micritic sediments. (F and G) bryozoan
 197 colonies. (H) Dense and homogeneous autochthonous micrite (AM) engulfing sponge spicules. (I) Heterogeneous and
 198 loose, detrital micrite sediment (DM) engulfing sponge spicules. In (H) and (I) black arrows point to sponge spicules
 199 engulfed in the micrite sediments.

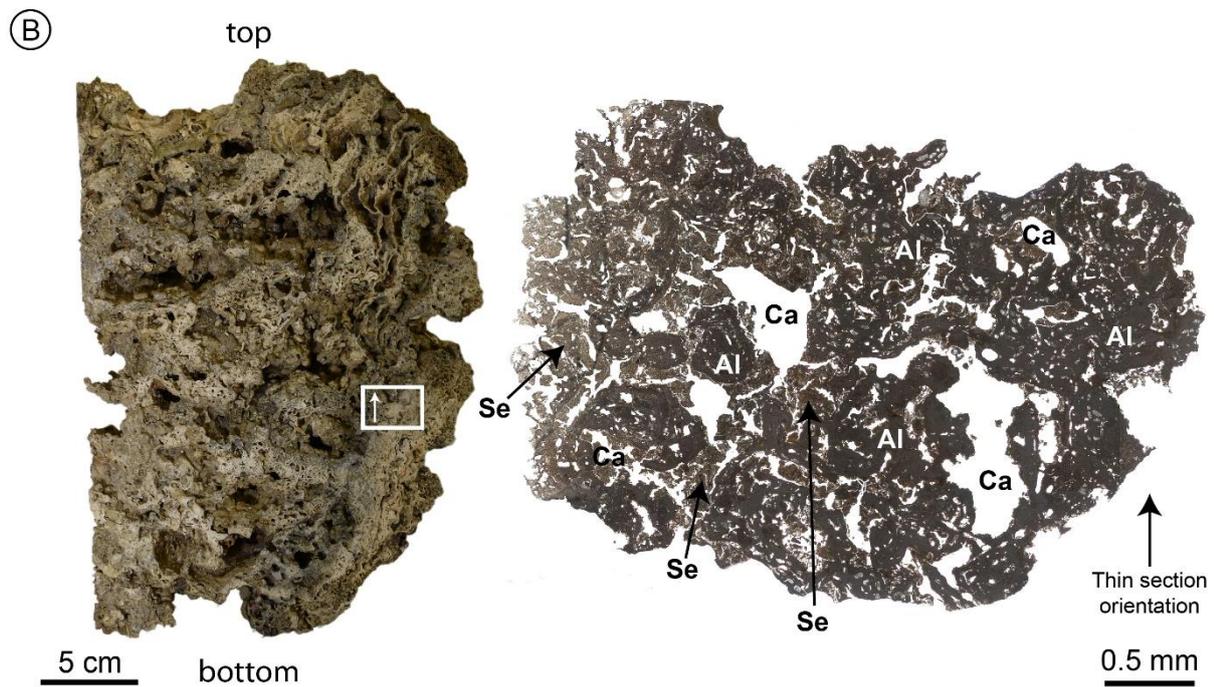

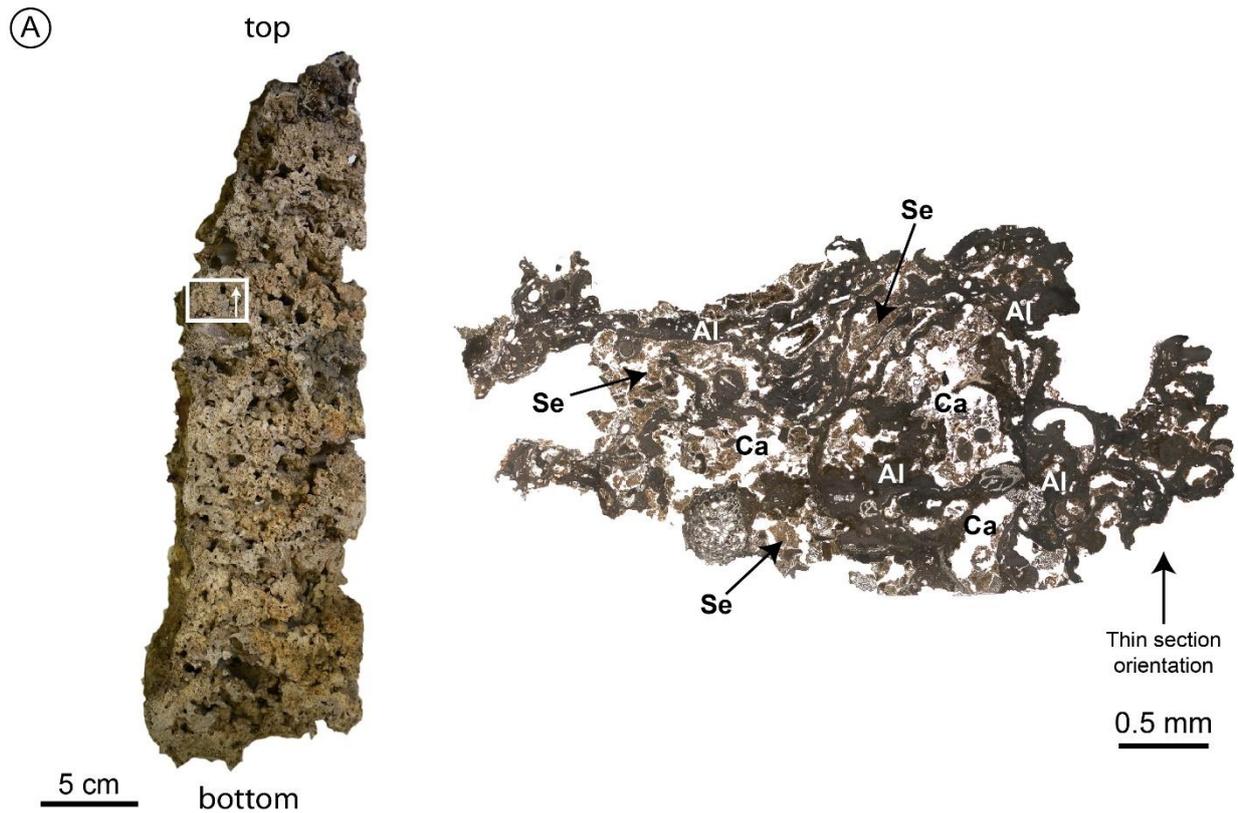

200 Two types of sediments (micrite) have been observed: homogeneous or autochthonous (compact and dense; Fig. 5H) that
201 emits a bright fluorescence when excited with UV-light, and heterogeneous or detrital (less cemented and rich of fine
202 bioclasts; Fig. 5I) that does not emit fluorescence (Fig. 6). Both types of micrites engulf sponge spicules.

203
204 **Figure 6:** Micrite sediments from CBR2_4_21c build-up observed in reflected light (A) and ultraviolet light (B). The
205 bright fluorescence indicates a high content in organic matter of the autochthonous micrite, whereas the absence of
206 fluorescence of the detrital micrite denotes an inorganic origin. Note the microcavities left by sponge spicules (black
207 arrows). AM: autochthonous micrite; DM: detrital micrite.

208 3.3 Microfacies characterization

209 Thin sections observation confirms the main role of skeletonized organisms in forming the carbonate framework of the
210 Coralligenous (Fig. 7). CCA are the main builders through successive generations of specimens encrusted one on top of
211 the others (Fig. 7). Bryozoans and serpulids play a subordinate bio-constructional role. Sponges are abundant and their
212 amorphous remains are widely distributed in cavities and microcavities, often associated to loose sediment, engulfed in
213 cemented micrite. Numerous other bioclasts, produced by organisms that do not participate directly to build the
214 bioconstructions were detected in the cavities together with muddy material. Non-skeletal carbonate material was also
215 detected (see below).

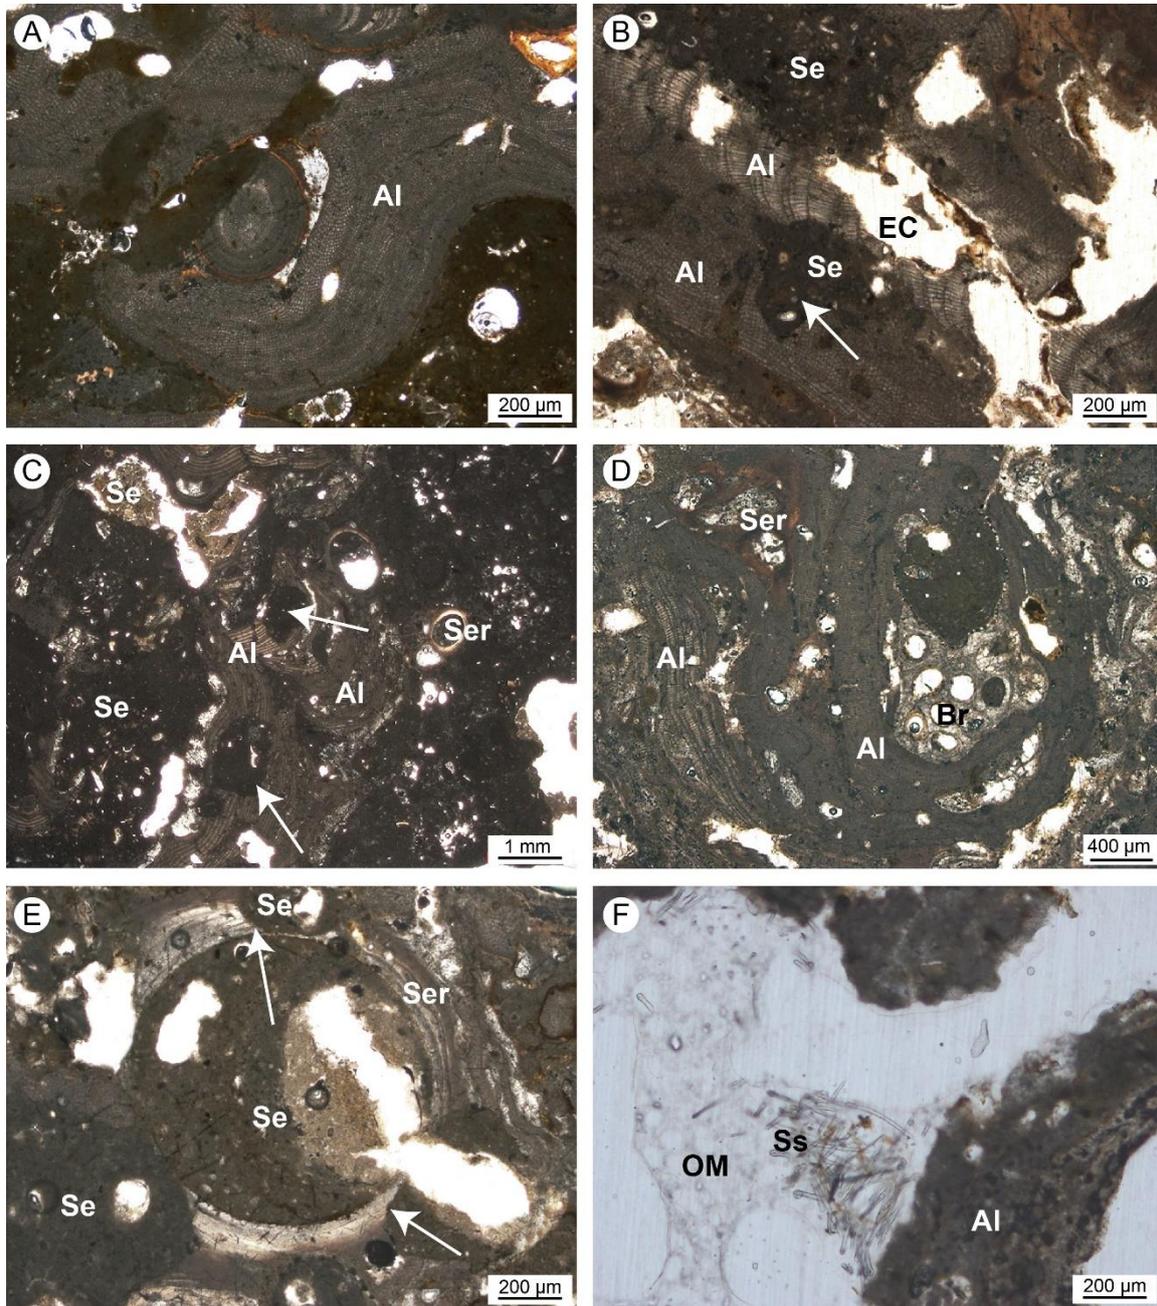

216

217 **Figure 7:** Cutting planes (left) and optical microscope photocomposition of representative thin sections (right) of the
 218 build-ups CBR2_3_7c (A) and CBR2_4_21c (B). Note the primary role of the coralline algae (Al) as major constituent
 219 of both build-ups and the presence of cavities (Ca) empty or filled with micrite sediment (Se). White rectangles and the
 220 arrows within them indicate the location and the orientation of the thin sections.

221 3.3.1 Skeletal components

222 Articulate and crustose coralline red algae are the main skeletal component detected in all thin sections (Fig. 8). The
 223 skeletons of the algae clearly form a continuous framework at the mesoscale (Fig. 7) but at the microscale, laminae are

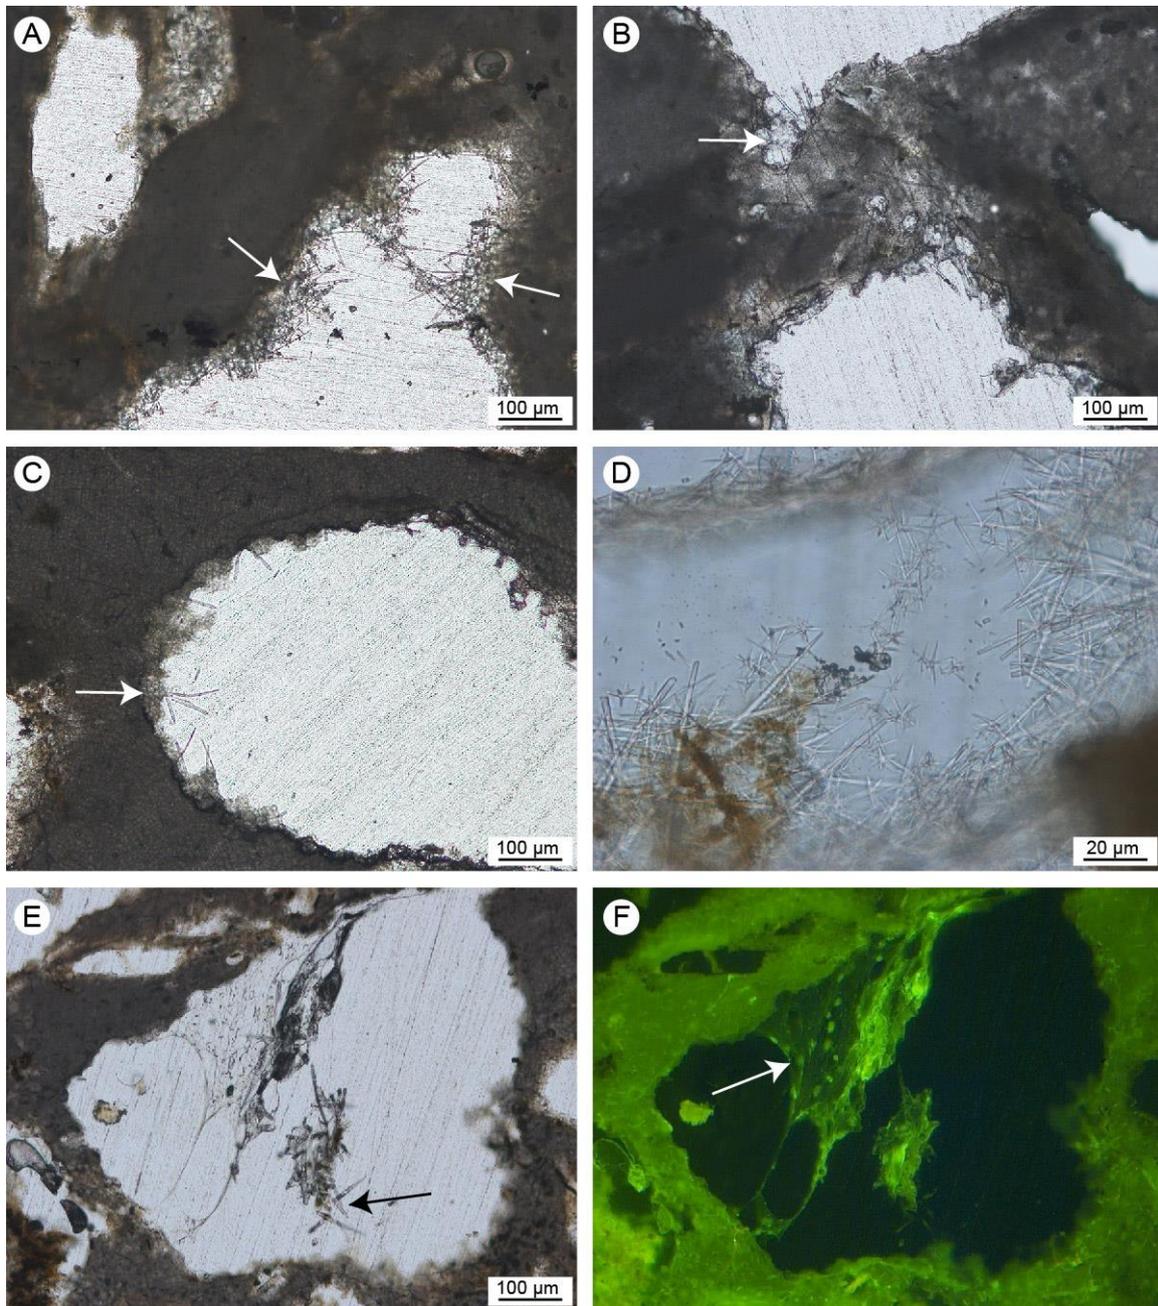

224 rarely continuous, often showing traces of bioerosion (Fig. 8A-C, F). Two main types of bioturbations are distinguishable:
 225 (i) irregular borings and (ii) tube-like micro-borings. Borings, showing sizes from a few microns to a few millimeters are
 226 mainly formed by endolithic sponges that corrode and perforate skeletons. These cavities could be: a) empty due the
 227 decaying of the sponge's organic tissue (Fig. 8B); b) filled with detrital sediment (Fig. 8B); or c) filled with spicules and
 228 remains of organic matter deriving from soft tissue decay of the boring sponge *Cliona* sp. (Fig. 8F).
 229 The skeletons often show also micritization phenomena contributing to the alteration of the original microstructures
 230 together with bioerosion.

231
 232 **Figure 8:** (A-C) Skeletal tissues of algae (Al) showing microcavities due to bioturbations (white arrows); the cavities are
 233 empty (EC) or filled with sediment (Se). (D) Strict interconnection among the main builders of the studied coralligenous
 234 build-ups (Al: algae; Ser: serpulids; Br: ? bryozoans). (E) Bioeroded serpulid skeleton (Ser); note the borings (white
 235 arrows) filled with sediment (Se). (F) Bioerosion cavity in algae (Al) with remains of organic matter (OM) and spicules
 236 (Ss) derived from sponge's decay (*Cliona* sp.). [A-B, E-F: CBR_2_3_7c; C-D: CBR_2_4_21c].

237 The biological activity involved in these bioerosional processes was not investigated but could represent a further step in
238 the reconstruction of the complex biological relationships which develop in these coralligenous ecosystem. The erosive
239 action of sponges is clearly visible where remains of amorphous material and spicules are associated to corroded substrates
240 (Fig. 9).

241 The sponge spicules, mainly belonging to species of the genus *Jaspis*, also fill the algae's conceptacles and often, small
242 spherical corpuscles are recognizable among spicules in UV-epifluorescence.

243
244 **Figure 9:** (A-C) Microcavities inside the skeletal framework of the coralligenous build-ups showing sponge spicules
245 (plurispicular tracts) associated to the corroded substrates (white arrows). (D-F) Details of sponge spicules of *Jaspis* sp.
246 (D) and *Cliona* sp. (E) observed in transmitted light, and UV-epifluorescence (F); the non-fluorescent siliceous spicules
247 are engulfed in remains of organic matter (F) deriving from sponge soft tissue decay. [A-C: CBR_2_4_21c; D-F:
248 CBR_2_3_7c].

249 Serpulids are common in the microfacies of both build-ups. They occur as isolated or grouped tubes with outer diameters
250 ranging from 200 µm to 1 mm. The number of clustered tubes usually increases with decreasing of their sizes. They are

251 empty, or filled with sediment, or sometimes occupied by endolytic sponges (Fig. 4B). Serpulids are often encrusted or
252 encrust bryozoans and/or algae (Fig. 8D). Serpulids show different degree of preservation and their original microstructure
253 is observable in the bigger tubes, while dissolution, recrystallization and/or micritization often alter the smaller ones.
254 Serpulids suffer also bioerosion by endolytic organisms (Fig. 8E).
255 Remains of amorphous material and spicules inside the skeletons of bryozoans may derive from insinuating and/or
256 bioeroding sponges, like observed for other skeletonised taxa.

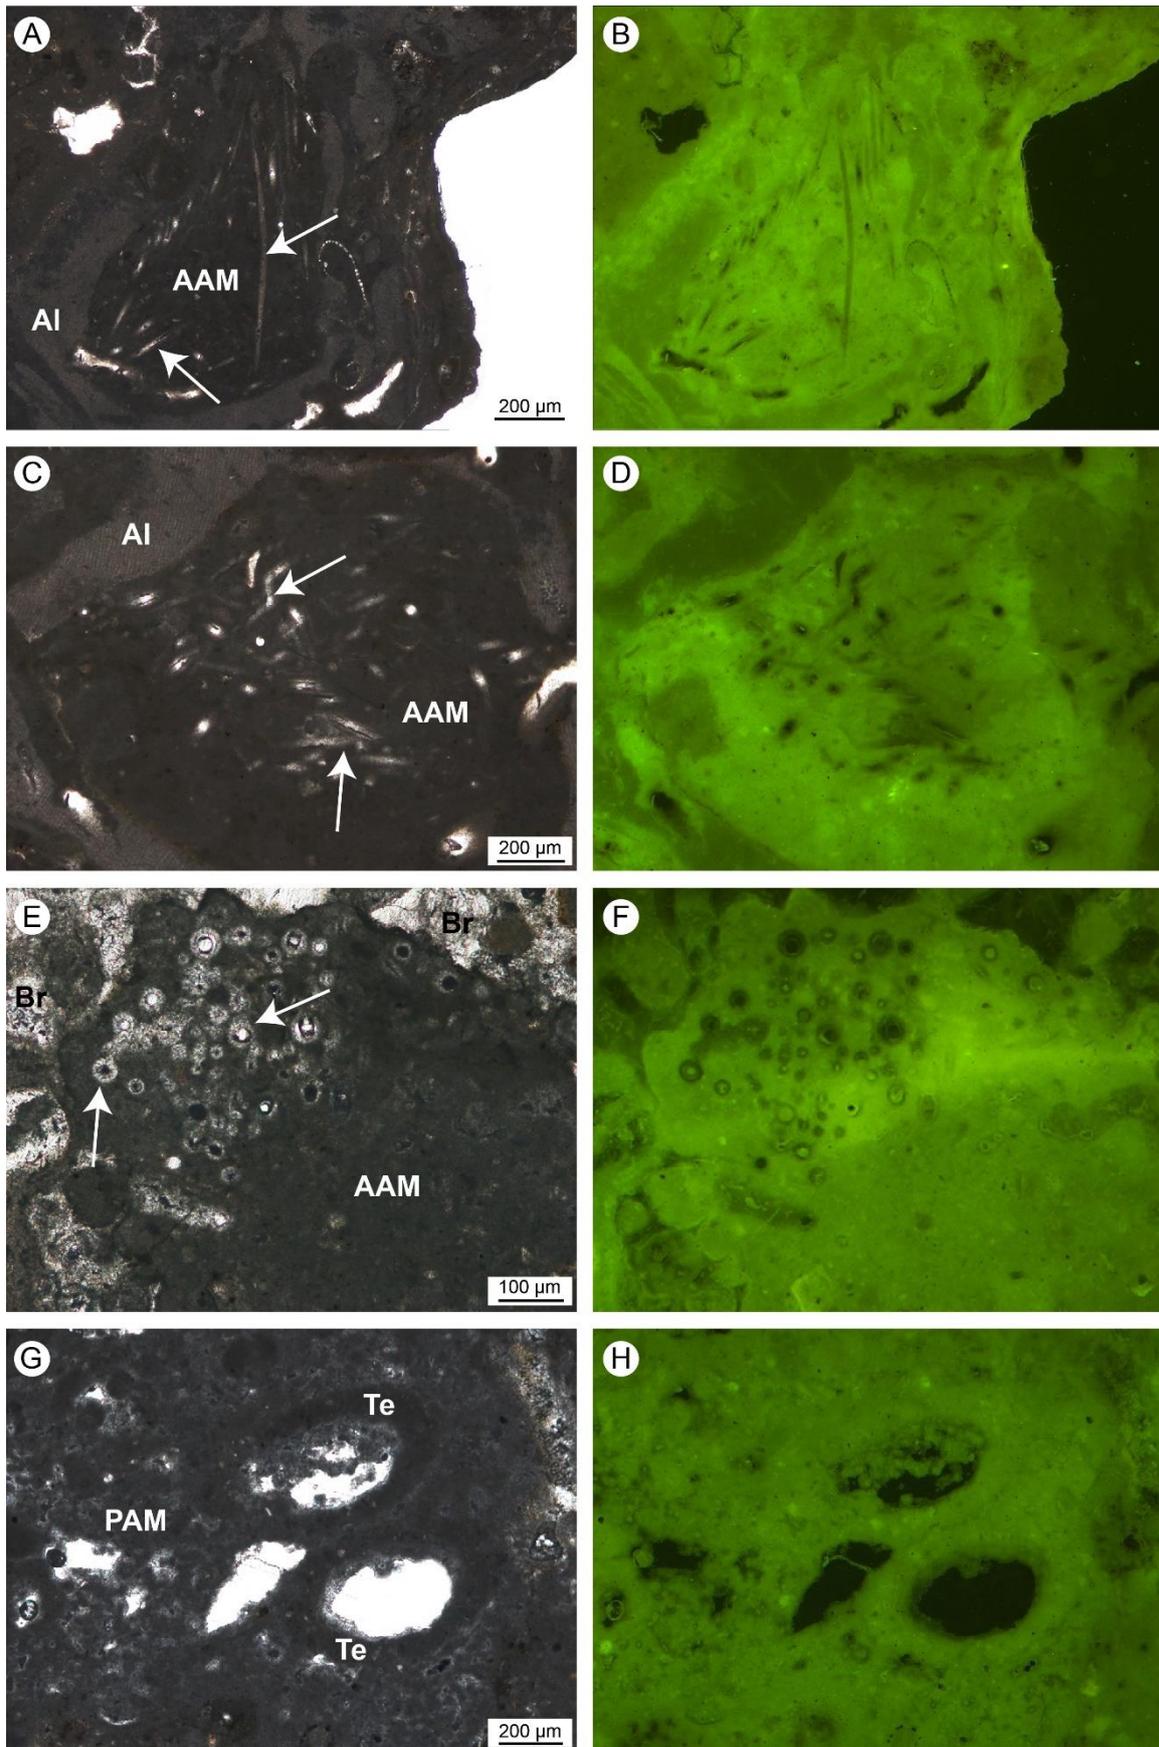

257 **3.3.3 Non-skeletal carbonate components: autochthonous and allochthonous (detrital) micrite**

258 The cavities of the skeletal framework are filled with different micrite types distinguished under light microscope
259 examination and UV-epifluorescence. The texture and organic matter content allowed to distinguish an autochthonous
260 and an allochthonous (detrital) micrite.

261 The autochthonous micrite consists of very fine-grained calcite and shows aphanitic (Fig. 10A-F) or peloidal to clotted
262 peloidal textures (Fig. 10G-H). The autochthonous aphanitic micrite displays a light brown colour and shows a
263 structureless mud-supported texture with rare bioclasts. Autochthonous peloidal micrite displays a darker colour, does
264 not exhibit grain-supported textures and shows interclot areas indicating a not gravitational genesis. Peloidal micrite fills
265 microcavities or coats serpulid tubes or other bioclasts. Peloids aggregate often in clots separated by calcite microspar
266 (euhedral Mg-calcite crystals), forming a clotted texture or, less commonly, a compact texture through the coalescence
267 of several clots. Peloidal and aphanitic microfabric derive from mineralization mediated indirectly by organic processes
268 and represent *in situ* precipitation of the micrite, whose syndepositional cementation contributes to stabilize the skeletal
269 structures of the build-ups.

270 Aphanitic and peloidal micrites show a bright autofluorescence under UV-light indicating a high content of organic matter
271 relicts, most likely related to the bio-induced crystal precipitation. Aphanitic micrite is widely associated with the presence
272 of sponge spicules (Fig. 10A-F), and generally fills bioeroded cavities inside the skeletal framework. On the contrary,
273 peloidal micrite, is not associated to sponge spicules and often occludes serpulid tubes and spaces within adjacent
274 individuals, contributing at cementing the skeletons together. Small terebellid tubes are often associated with this micrite
275 type (Fig. 10G-H).

276 The amount of the autochthonous micrite is variable in the thin sections but always represents a minor component in
277 comparison to the skeletal framework, and shows a different distribution along the bottom-top direction of each build-up,
278 with the major content in the column CBR_2_4_21c.

Figure 10: (A-F) Aphanitic autochthonous micrite (AAM) engulfing sponge spicules (white arrows) observed in transmitted light (left) and UV-epifluorescence (right); the bright epifluorescence of the AAM indicates the presence of organic matter relics closely related to the bioinduced crystals. (G-H) Peloidal autochthonous micrite (PAM) engulfing some agglutinated skeletons of terebellids (Te) observed in transmitted light (left) and UV-epifluorescence (right); even

284 in this case the bright epifluorescence of the PAM indicates the presence of organic matter relics closely related to the
285 bioinduced crystals. [A-B, E-H: CBR_2_4_21c; C-D: CBR_2_3_7c].

286 The detrital micrite shows a light brownish colour and is characterized by a texture with variable density (Fig. 11). Two
287 types of detrital micrite with different textures have been tentatively recognised: organic and inorganic. Organic detrital
288 micrite shows a denser muddy texture and it is enriched in bioclasts, intraclasts and sponge spicules (Fig. 11A, D, E). It
289 shows a very faint to scarce epifluorescence (Fig. 11F). The inorganic detrital micrite is made up of particles with larger
290 sizes (in the silty range) and includes a minor amount of bioclasts. Due to the absence of epifluorescence under UV-light
291 an inorganic nature of these components is assumed. Detrital micrites represent the main non-biomineralized component
292 of both build-ups, and fill primary, inter- and intra-skeletal cavities, and secondary micro-cavities generated by boring
293 organisms.

294
295 **Figure 11:** Detrital micrite textures. (A) Organic detrital micrite (ODM) with a dense muddy texture enriched in bioclasts
296 (white arrows), intraclasts and sponge spicules. (B) Inorganic detrital micrite (IDM) consists of particles with larger sizes
297 incorporating a minor amount of bioclasts (white arrows). (C) Microcavities in bioeroded algae (Al) filled with IDM. (D)

298 ODM engulfing sponge spicules (Ss). (E-F) Relationship between IDM (light brown), ODM (dark brown), algae (Al) and
299 peloidal autochthonous micrite (PAM) observed in transmitted light (left) and UV-epifluorescence (right); faint and scarce
300 fluorescence of the detrital micrite denotes an inorganic nature of this component. [A-B, D-F: CBR_2_4_21c; C:
301 CBR_2_3_7c].

302 **3.3.4 Cements**

303 Cement only sporadically fills cavities representing a subordinate component of the build-ups. Two types of cement have
304 been recognised: primary (syndepositional) and secondary (diagenetic) cement. Syndepositional cement shows
305 isopachous, botryoidal and peloidal microcrystalline fabric. Isopachous cements develop with homogeneous fringes on
306 the surface of intra- and inter-skeletal microcavities. Botryoids consist of dome-shaped hemispheres built by radiating
307 fibrous calcite crystals and crystal fans filling the primary cavities and voids created by bioerosion processes. Peloidal
308 microcrystalline cement is composed of tiny peloids within a microcrystalline calcite matrix; it was mainly detected in
309 small intra-skeletal cavities. Secondary cement is rare and fills residual microcavities with drusy micro-textures.

310 **3.3.5 Point counting analyses**

311 Seven structural and non-structural components have been counted: carbonate framework builders, bioclasts,
312 autochthonous micrite, organic and inorganic detrital micrite, boring sponges and empty cavities. Bioclasts include all
313 skeletal remains of organisms that do not participate to the formation of the skeletal framework but were trapped inside
314 the cavities either first living in association with the build-up or transported by neighbouring habitats. Among these,
315 bivalves, gastropods, foraminifers, ostracods, echinoid plates and spines, and algal fragments have been recognized. The
316 boring sponges counting class includes perforations interpreted as originally occupied by sponges, because infilled of
317 amorphous organic remains rich in spicules. It is worth to note that this component could be underestimated due to the
318 cutting procedures and the preparation of the thin sections which could have washed away the residues of the sponge
319 tissue that originally occupied the cavities. The analysis shows the following average percentages for the CBR_2_3_7c
320 and CBR_2_4_21c build-up respectively: 46.2% and 47.1% carbonate framework builders (algae, serpulids, bryozoans);
321 4.4% and 3.6% other bioclasts (planktonic and benthic foraminifer shells, ostracods, molluscs, echinoid plates and spines
322 and, small fragments of coralline algae); 3.6% and 9.2% autochthonous micrite, 16.4% and 14.3% organic detrital micrite,
323 13.6% and 9.3% inorganic detrital micrite, 14.8% and 15.4% empty cavities and, 1% and 1.1% boring sponges (Tables
324 1-2).

353

Among the non-skeletal carbonate components, the allochthonous (detrital) micrites is definitively more abundant in comparison to the component directly mineralized (autochthonous micrite) in the cavities of the build-ups. Noteworthy, the percentage of autochthonous micrite, whose early cementation contributes to reinforce the coralline algae framework, is higher in the CBR_2_4_21c build-up than in the CBR_2_3_7c build-up. The average percentages of total cavities, *i.e.* the sum of empty cavities and cavities filled with detrital sediment, are similar in the two build-ups.

354 **3.4 Characterization of micromorphology and geochemistry with electron microscopy**

355 SEM observations and EDS microanalyses allowed us to detect the micro/nano-morphologies and the composition of the
356 main skeletal and non-skeletal components. The presence of pristine micro- and nano-morphology and original
357 mineralogy of skeletons (high Mg-calcite or aragonite of algae and serpulids) testify that the carbonate components of the
358 build-ups have not undergone neomorphic processes, like recrystallization, polymorphic transformation or aggrading
359 neomorphism. In some cases, the skeletal components display evidence of dissolution process.

360 Microcavities are filled with sponge spicules and remains of carbonaceous amorphous substances (Fig. 12). Spicules are
361 mainly oxeas and (sub-) tylostyles, which may be associated with species of the *Cliona* genus, but there are also triactines
362 and rare tetractines. Spicules are closely intermingled with organic matter and are often well visible cleats with sterrasters
363 and oxyasters, typical of species of the genus *Erylus* (Fig. 12E and F). Areas close to the corroded boundaries of some
364 microcavities containing spicules (Fig. 12G-H) also include small carbonate chips (Fig. 12I) seemingly detached from
365 the encasing skeleton due to mechanical boring activity of the sponges. The substrate of the bioeroded cavities shows the
366 typical erosion scars (pits) left by the perforating activity of sponges of the Clionidae family (Fig. 12D). Spicules often
367 show circular erosion marks and an enlarged axial canal (Fig. 13A-E) due to silica dissolution caused by high pH values
368 of the porewater inside the crevices of the coralligenous build-up.

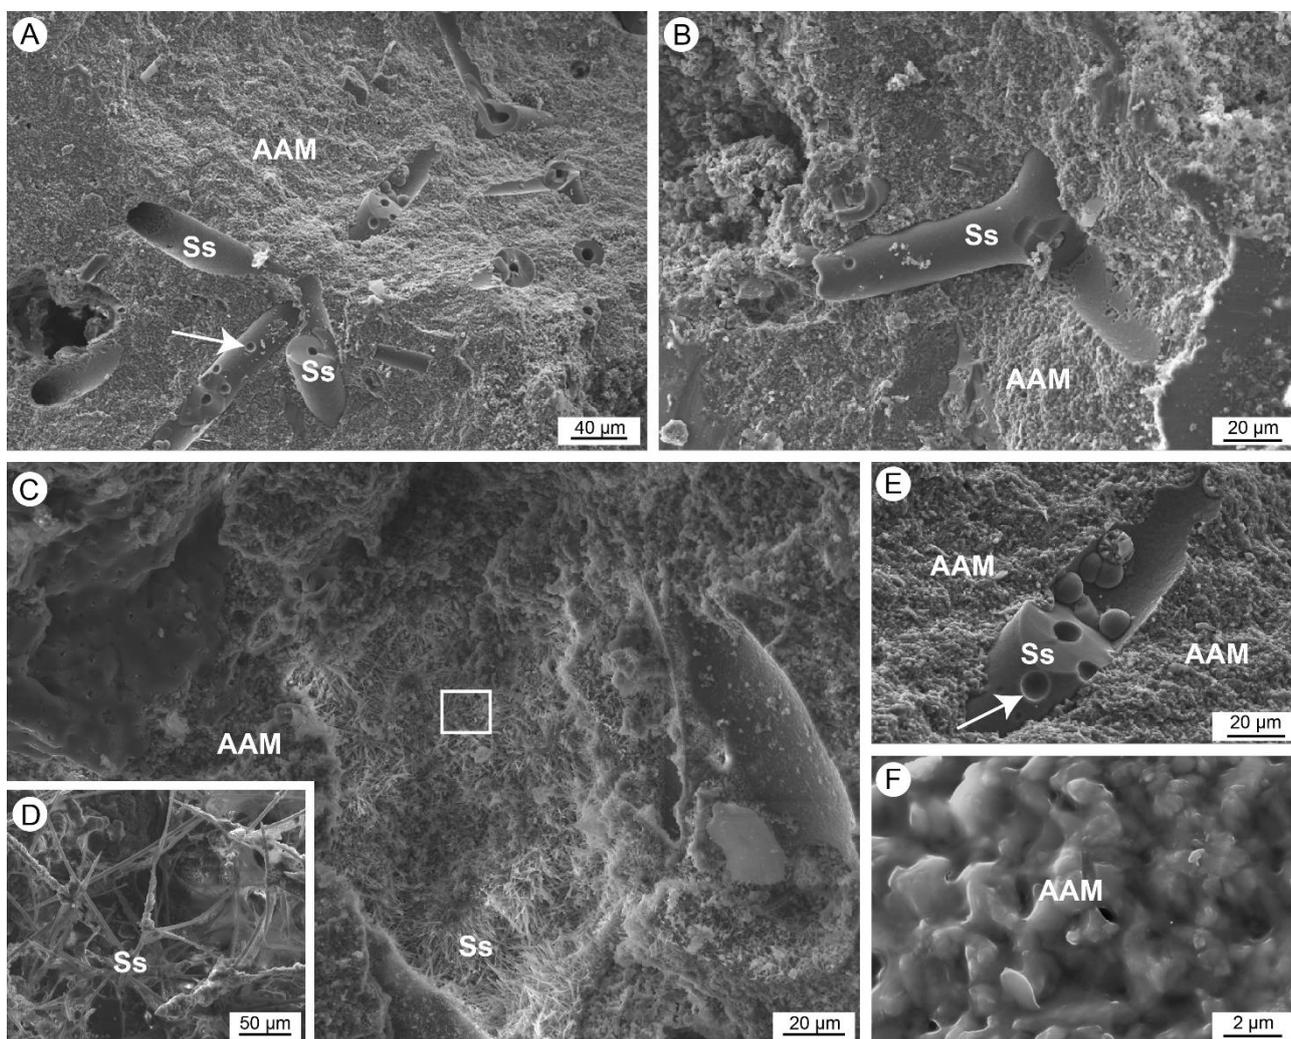

369 **Figure 12:** SEM images of sponge spicules and remains of carbonaceous amorphous substances. (A-C) Coralligenous

 373 Detail of sterraster and oxyaster of *Erylus* sp. (G) *Cliona vermifera* spiraster associated to a bioeroded cavity. (H) Spicules
 374 and amorphous organic matter in an internal microcavity. (I) Detail of spicules and amorphous organic matter englobing
 375 small carbonate chips (white arrows) detached through sponge bioerosion activity. [A, D-F, G-I: CBR_2_3_7c; B-C:
 376 CBR_2_4_21c].

377 A high amount of siliceous and rare calcareous sponge spicules (still under study: Bertolino et al. in prep.) has been
 378 recognised in both autochthonous (Fig. 13) and detrital (Fig. 14) micrite pointing to a considerable diversity.

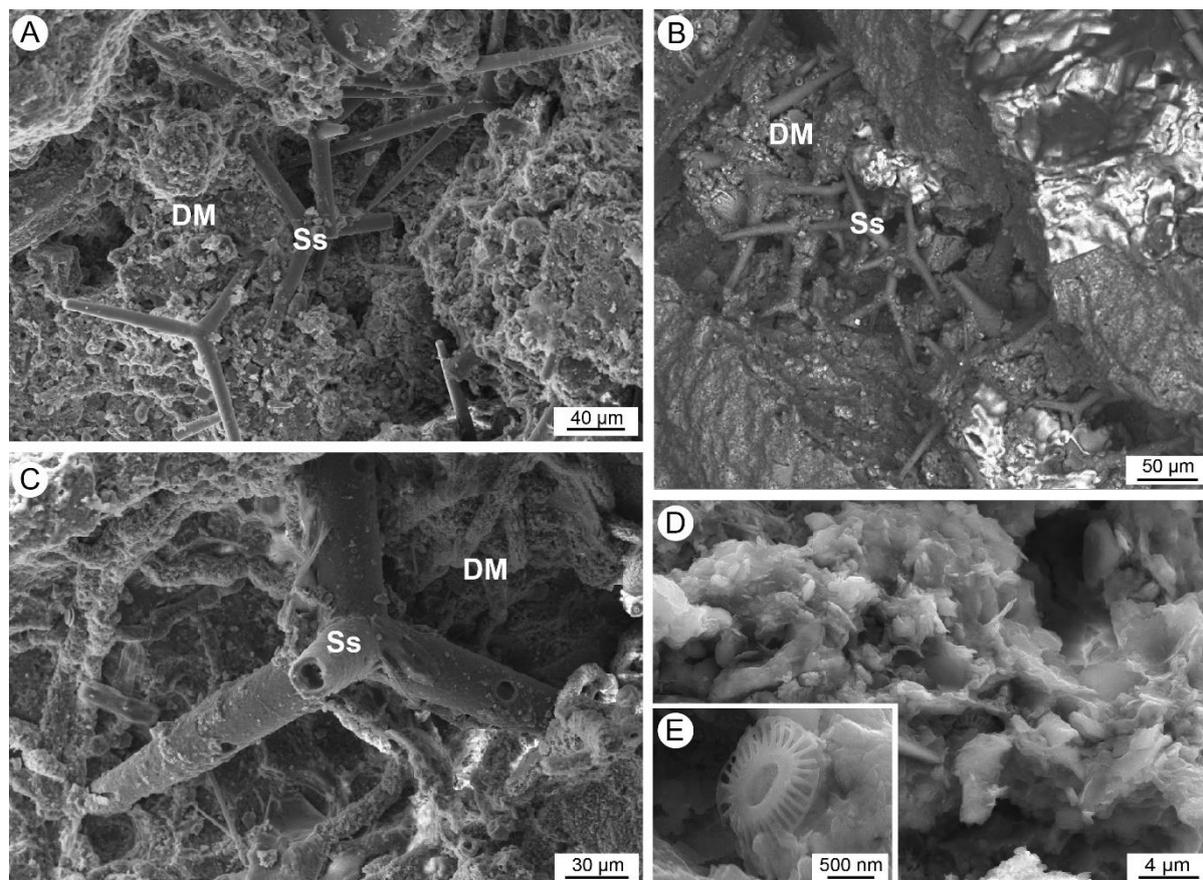

379 Autochthonous micrite shows micro- to nano-meter anhedral to sub-euhedral crystals engulfed in amorphous organic
 380 material (Fig. 13F) and has a high magnesium calcite (Ca ~91 wt%; Mg ~6.5 wt%) composition with minor terrigenous
 381 components (<2 wt%). Micrite engulfing spicules is well cemented (Fig. 13A, B and E). Peloidal micrite passes to
 382 aphanitic textures when cavities become filled. In comparison to the detrital micrite, the autochthonous micrite engulfing
 383 sponge spicules lacks skeleton fragments or allochthonous components like planktonic foraminifers or coccoliths.

384
 385 **Figure 13:** (A-F) SEM images of aphanitic autochthonous micrite (AAM) engulfing sponge spicules (Ss). In (A) and (E)
 386 note the well-defined circular boreholes (white arrows) and enlarged axial canal of the spicules. (D) Magnification of the
 387 spicules in (C). (F) Detail of the aphanitic autochthonous micrite showing the micrometer sub-euhedral crystals engulfed
 388 in amorphous organic material. [A, E-F: CBR_2_3_7c; B-D: CBR_2_4_21c].

389 Detrital micrite shows a heterogeneous composition (Fig. 14), in terms of type and size of the grains, has a magnesium
 390 calcite composition and a high percentage of terrigenous components. It is composed of Ca (~46 wt%), Mg (~3 wt%), Fe
 391 (~6 wt%), K (~3 wt%), a discrete quantity of Si (~26 wt%), Al (~12 wt%) and a lower amount of other elements (S, Na,
 392 Cl <2 wt% each). Detrital micrite constantly incorporates sponge spicules (Fig. 14), but occasionally also small intraclasts

393 and several bioclasts of benthic and planktonic organisms. At the microscale, detrital micrites denote a high amount of
394 nanoplankton plates (e.g., *Emiliana huxleyi*) (Fig. 14E).

395
396 **Figure 14:** (A-C) SEM photos of detrital micrite (DM) engulfing fine intraclasts, bioclasts and sponge spicules (Ss). (D)
397 Details of the detrital micrite and (E) a nanoplankton plate of *Emiliana huxleyi*. [B: CBR_2_4_21c; A, C-E:
398 CBR_2_3_7c].

399 4. Discussion

400 The analysed coralligenous build-ups from the Ionian Sea are mainly constituted of skeletonized organisms with dominant
401 coralline algae and subordinate bryozoans and serpulids. CCA form a porous self-sustaining framework whose
402 stabilization is reinforced by bryozoans and serpulids. The role of foraminifers and corals is negligible. The morphological
403 growth is influenced by sponges. These organisms are highly diversified and play a triple role: locally affect the direction
404 of encrustations of the skeletonised builders, weaken the framework through bioerosion processes and induce
405 precipitation of autochthonous sediments (autochthonous micrite). An important role is played also by the micrite which
406 could be subdivided into two types: autochthonous, directly produced in the build-ups by organic-induced
407 biomineralization processes, and allochthonous (or detrital), derived by the accumulation of loose fine particles in the
408 cavities of the build-ups.

409 4.1 Skeletal builders and framework density

410 The two build-ups are characterized by a high porous skeletal framework, showing primary and secondary cavities, from
411 few millimeters to ten centimeters large. Primary cavities represent the interspaces generated during the superimposition
412 of skeletonized encrusting organisms, whereas secondary cavities could derive from the necrolysis of soft-bodies

413 organisms sandwiched between the skeletonised ones or from the bioerosion produced by endolytic organisms, mainly
414 sponges and subordinately bivalves.

415 Quantitative counting of the microfacies components demonstrates the role of algae, serpulids and bryozoans as builders
416 of the two build-ups (see Table 1 and Table 2). These data agree with the indirect quantification obtained through image
417 analysis and computerized axial tomography by Bracchi et al. (2022) on the same build-ups analysed in this paper. Bracchi
418 et al. (2022) correlated four density classes with the framework cementation degree and distinguished the different
419 components, identifying the CCA as dominant. This because computerized axial tomography does not provide a direct
420 association between skeletal and non-skeletal components and the variation of density. In contrast, and despite referring
421 to only one surface for each build-up, the microfacies characterization at microscale confirmed that the density is not
422 directly correlated to specific components but it is linked to the degree of packing of the skeletons (mainly CCA) and to
423 the degree of cementation of non-skeletal carbonate components. Furthermore, it is worth to note that the presence of
424 autochthonous micrite, which cement syndepositionally, contributes to increase the build-ups density, regardless of the
425 nature of the components to which it is associated.

426 **4.2 Role of the sponges in the coralligenous growth**

427 Coralligenous growth is the results of the interplay between the building activity and the physical and biological
428 demolition (erosion and dissolution) processes (Garrabou and Ballesteros, 2000; Bressan et al., 2001; Cerrano et al., 2001;
429 Ingrosso et al., 2018; Turicchia et al., 2022). Like for bioconstructions in the Mediterranean Sea and worldwide (Rosell
430 and Uriz, 2002; Evcen and Çımar, 2015; Glynn and Manzello, 2015; Achlatis et al., 2017; Turicchia et al., 2022), boring
431 sponges represent the main cause of bioerosion for the coralligenous build-ups of Marzamemi. The colonization, amount
432 and bioerosion processes of sponges is influenced by temperature, nutrients, turbidity, depth, light, and pH (Schönberg,
433 2008; Calcinai et al., 2011; Nava and Carballo, 2013; Marlow et al., 2018). Bioerosion has a direct influence on the
434 coralligenous build-ups due to the erosion of the substrate and the skeletal framework which reduces the mechanical
435 stability of the build-ups (Scott et al., 1988), but at the same time it creates new space and shelter for other organisms
436 (Cerrano et al., 2001; Calcinai et al., 2015).

437 The main boring taxa belong to the family Clionidae, and especially *Cliona celata*, *C. schmidtii* and *C. viridis*. Boring
438 and insinuating, cavity-dwelling endolithic sponges, constitute a considerable proportion of the total biomass, even higher
439 than that of the epibenthic layer, both in coralligenous build-ups (Calcinai et al., 2015) and marine caves (Corriero et al.,
440 2000). The contribution of cryptic fauna should be taken into consideration on Coralligenous studies, considering that the
441 number of sponges occurring outside these build-ups is lower than the number of taxa identified inside them (Calcinai et
442 al., 2015).

443 The high amount of sponges and their expected diversity fits well with results by Bertolino et al. (2013) revealing the
444 occurrence of 53 insinuating and 10 boring species inside the coralligenous build-ups. Among them, not-perforating
445 encrusting or massive species occupy cavities of the bioconstructions previously formed by boring sponges (Bertolino et
446 al., 2013).

447 When sponges die, their spicules remain trapped in the cavities of the coralligenous framework, offering the opportunity
448 to recognize the spongofauna over a very long time (Bertolino et al., 2014; 2017a; 2017b; 2019). Spicules of non-eroding
449 sponges from the build-up surfaces may be mixed with spicules of boring and insinuating species in the cavities of the
450 build-ups (Calcinai et al., 2019). In the studied coralligenous build-ups, the pervasive colonization of sponges is testified
451 by the high amount of spicules occurring on the surface and within cavities. Oxeas and tylostyles sponge spicules were
452 observed mixed or grouped by type. It is unclear if the oxeas and other spicules derive from insinuating sponges or from

453 species (*e.g.* haplosclerids) which encrust the external hard surfaces of the build-ups. Spicules associated with amorphous
454 organic matter (spongin remains) in empty cavities testify the presence of recently dead endolithic sponges, possibly even
455 after the collection of the samples. Among these, boring sponges are recorded by spicules associated to small chips
456 detached from the substrate in cavities showing irregular edges and corroded surfaces. Most of the spicules are mixed
457 with fine detrital sediment and other bioclasts filling intra- and inter-skeletal holes. These spicules may originate from
458 sponges thriving on the build-up surfaces or their internal niches, and together with those preserved in the autochthonous
459 micrite, they represent the record of past Coralligenous sponges. The characterization and dating of these components
460 may reveal the ecological evolution and functional role of the sponge associations during the growth of the build-ups.
461 Sponges seem also to influence the morphological development of the build-ups. They can be often bioimmured by
462 encrusting organisms (mainly crustose algae) thus affecting the local growth direction of the carbonate crusts, that follow
463 the morphologies of the sponges.

464 **4.3 Origin and role of the micrite sediments in the coralligenous framework**

465 The micromorphological observations allowed to recognize and investigate the role of the sediment in the Coralligenous.
466 Of the two main types of sediments detected, *i.e.* autochthonous and allochthonous (detrital) micrite, the former is
467 produced *in situ* through biomineralization processes. Biomineralization involves organisms, processes and products and
468 includes controlled, induced and influenced mineral precipitation (Lowenstam and Weiner, 1989; Riding, 2000, 2011;
469 Benzerara et al., 2011; Phillips et al., 2013; Anbu et al., 2016; Riding and Virgone, 2020). These different pathways of
470 biomineral precipitation depend also on the chemical and physical conditions of the environment (Riding, 2011; Riding
471 and Liang, 2005; Deias et al., 2023). The recognition of biominerals, especially those not biologically controlled (like
472 skeletons) but precipitated via organic mediation in equilibrium with the water medium, can be considered as a remarkable
473 archive, documenting the presence of non-fossilizable associations as well as their relations with environmental
474 conditions. In the Coralligenous, the presence of autochthonous micrite (“automicrite” *sensu* Wolf, 1965) whose
475 precipitation could be linked to microbial metabolic activity (biologically induced mineralization, mediated by living
476 organic substrates, *sensu* Dupraz et al., 2009) or decaying organic matter mediation (biologically influenced, mediated by
477 non-living organic substrates, *sensu* Trichet and Défarge, 1995), documents communities with low preservation potential
478 but heavily affecting the development of the build-ups.

479 The autochthonous micrites detected in the studied coralligenous build-ups show two fabrics: 1) structureless (aphanitic)
480 and 2) peloidal to clotted peloidal. Both types consist of Mg–calcite and show an intense fluorescence when excited with
481 UV-light, suggesting a high content in organic matter. Despite these similarities, the two fabrics may have different
482 origins. The massive presence of spicules engulfed in the aphanitic micrite could indicate a carbonate precipitation in
483 association with decaying organic substrates of sponges as repeatedly suggested in literature (Leinfelder and Keupp, 1995;
484 Reitner and Neuweiler, 1995; Reitner et al., 1995; Trichet and Défarge, 1995; Pickard, 1996; Pratt., 2000; Neuweiler et
485 al., 2000, 2003, 2023; Reolid, 2007, 2010). This organic mineralization (organomineralization, *sensu* Trichet and Défarge,
486 1995) is supposed to form via Ca²⁺-binding ability of humic and fulvic amino acids, derived from organic matter degraded
487 metazoan during early diagenesis (Braga et al., 1995; Neuweiler et al., 1999, 2007; Wood, 2001; Dupraz et al., 2009).
488 This micrite type is usually darker than the allochthonous micrite, due to the organic matter content (Warnke, 1995;
489 Delecat et al., 2001; Delecat and Reitner, 2005). Shen and Neuweiler (2018) suggested an organomineralization (produced
490 by induced or supported processes), rather than microbial mediation for the deposition of the autochthonous micrite in
491 the Ordovician carbonate mounds, formed mainly of calathid–demosponge (north-west China). A similar process was

492 proposed for the autochthonous micrite mineralized in the biotic crust of submarine caves of Lesvos (Guido et al., 2019a,
493 2019b).

494 The peloidal and clotted peloidal micrite have commonly been linked to anaerobic bacteria activity and represent the main
495 component of the microfacies recognised in modern and ancient microbialites (Monty, 1976; Chafetz, 1986; Kennard and
496 James, 1986; Buczynski and Chafetz, 1991; Reitner 1993; Kazmierczak et al., 1996; Dupraz and Strasser, 1999; Folk and
497 Chafetz, 2000; Riding, 2002; Riding and Tomás 2006; Dupraz et al., 2009; Guido et al., 2013, 2016; Riding et al., 2014).
498 The microorganisms and metabolic pathways responsible for the formation of clotted and peloidal micrites still remain
499 unknown in most instances. In the studied build-ups, the scarce peloidal fabric is mainly confined to framework
500 microcavities, particularly the interior of serpulid tubes and spaces between skeletons. In these suboxic/anoxic confined
501 microenvironments anaerobic heterotrophic bacterial communities can flourish, as observed in several submarine caves
502 by Guido et al. (2017a, 2017b, 2019a, 2022). In the Coralligenous, the clotted peloidal micrite is very subordinate in
503 comparison to aphanitic micrite, and generally it is not associated to sponge spicules, but includes terebellid polychaetes
504 often intermingled with the autochthonous peloidal micrite. The presence of terebellids associated to peloidal micrite
505 suggests a close association between these polychaetes and microbial communities. A symbiotic relationship between
506 terebellids and sulphate-reducing bacteria has been described in confined environments of submarine caves (Guido et al.,
507 2014, 2022). These authors proposed that in pendant bioconstructions terebellids use the peloids produced by microbial
508 activity to form their skeletons and the bacteria flourish on the biomass produced by the terebellids and other metazoans.
509 The occurrence of a similar association in the coralligenous build-ups seems to suggest that this symbiosis is not habitat-
510 specific, but develops in different marine settings, from open to confined habitats, where conditions of cryptic micro-
511 environments in the framework of the bioconstructions may promote the development of carbonatogenic microbial
512 communities.

513 An early lithification of autochthonous micrite has been suggested by many authors (*e.g.*, Grotzinger and Knoll, 1999;
514 Reid et al., 2000) as an explanation for the modes of accretion and textures of various types of bioconstructions. The
515 accretion of the Sicilian Coralligenous was clearly produced by the superposition of different generations of skeletonized
516 organisms but early lithification of autochthonous micrite, inside primary and secondary cavities, further contributes to
517 cementation and stabilization of the skeletal framework.

518 The detrital micrite generally derives from degradation and transport of organism's skeletons, transported from
519 neighbouring areas, or from erosion of pre-existing bioclastic rocks (Stockman et al., 1967; Tucker and Wright 1990).
520 The two different types of detrital micrite observed in the studied Coralligenous (*i.e.* organic and inorganic) differ by the
521 occurrence or absence of organic material trapped in the muddy sediment, the different degree of fluorescence under UV-
522 light and the bioclast content. The common loose state of these sediments in the studied build-ups seems to point that
523 their lithification rate is generally lower in comparison to the autochthonous micrite, and may take place some time after
524 the formation of the primary framework. The different amount of organic matter, however, may have a role in the
525 lithification processes. Further knowledge is needed to help the comprehension of the diagenetic dynamic of the detrital
526 micrite helping to clarify the general growth and morphological development of the coralligenous build-ups.

527 **4.4 Coralligenous build-ups vs Biostalactites: comparison between recent bioconstructions of different marine** 528 **settings**

529 Knowledge of the compositional and morphological characterization of the coralligenous build-ups forming along the
530 open marine sectors of the Mediterranean Sea shelf, allows their comparison with bioconstructions forming in confined
531 marine settings, such as blind submarine dark and semi-dark caves. These confined environments have been recently

532 utilized as natural laboratories to study the role of metazoan and microbial communities in forming unusual
533 bioconstructions (Guido et al., 2013; Gischler et al., 2017a). Due to the peculiar conditions of cave environments, notably
534 low water circulation, reduced or null light intensity, oxygen depletion and remarkable oligotrophy, caves are colonized
535 mainly by cryptic organisms like serpulids, bryozoans, sponges and corals (Harmelin, 1985; Fichez, 1990, 1991). These
536 organisms may be involved in the formation of small biogenic crusts or larger bioconstructions named biostalactites that
537 develop under suitable conditions (Onorato et al., 2003; Belmonte et al., 2009, 2020; Guido et al., 2013, 2017b, 2019a,
538 2022; Sanfilippo et al., 2015; Gischler et al., 2017a, 2017b; Onorato and Belmonte, 2017; Kazanidis et al., 2022).
539 Serpulids and bryozoans are the main skeletal builders of the biostalactites that are further stabilized by the early
540 cementation induced by the precipitation of autochthonous peloidal and aphanitic micrites mediated by microbial activity
541 (Guido et al., 2013; Gischler et al., 2017a, 2017b). Despite the difference in size (from some cm up to 1-2 m), biostalactites
542 forming in submarine caves of Sicily, Cyprus and Apulia show a uniform style of growth (Guido et al., 2013, 2017b,
543 2022). In contrast, the biotic crusts forming in the caves from Lesvos island of the Aegean Sea (Fara and Agios Vasilios
544 caves), show a rich sponge association, widely present both on the surface and in the framework microcavities. There,
545 the pervasive presence of sponges in almost all the micro-niches of the bioconstructions, play a limiting role in the
546 development of heterotrophic bacteria (like sulfate reducing bacteria) involved in carbonate precipitation (Guido et al.,
547 2013, 2019a, 2019b, 2022). The competition for space between sponges and carbonatogenic bacteria has been used to
548 explain the morphological differences between large biostalactites and biogenic crusts common in the Mediterranean
549 caves (Guido et al., 2019a, 2019b). In the biotic crusts from Lesvos, sponge spicules are mainly concentrated in detrital
550 micrite that fills primary cavities. Only sporadically, they are associated with autochthonous micrite, suggesting that
551 organomineralization linked to soft sponge tissue decay is a relatively minor process in the in-situ production of micrite
552 (Guido et al., 2019a).

553 A very similar competition could be suggested for the coralligenous build-ups. Despite the different environmental
554 conditions, size and morphologies characterizing the centimetre sized biotic crust of Lesvos caves *versus* the some
555 decimetres to meter-sized coralligenous build-ups of Marzamemi, sponges pervasively cover the surfaces and the internal
556 cavities of both types of bioconstructions. The coralligenous framework is produced by encrusting red algae but the
557 primary inter-skeletal porosity derived from the superposition of different generations of skeletons is enhanced by the
558 bioerosive activity of endolithic organisms. Though cavities could be a site for the settlement of anaerobic bacterial
559 communities (Guido et al., 2013), they are occupied by insinuating and/or perforating endolithic sponges that reduce the
560 availability of micro-niches favourable for the development of sulfate reducing bacteria, hampering the precipitation of
561 autochthonous micrite through their metabolic activity.

562 The decaying of the soft sponge tissue produces a huge amount of spicules that are trapped in cavities together with fine
563 detrital material. Occasionally, the spicules are engulfed in aphanitic micrite rich in organic matter that do not enclose
564 detrital fragments. This material presumably results from induced and/or supported organomineralization of the soft
565 tissue, like observed in the biotic crusts of Lesvos caves (Guido et al., 2019a). The same process has been suggested also
566 for the Ordovician calathid-demosponge carbonate mounds of north-west China (Shen and Neuweiler, 2018).

567 **5. Conclusions**

568 The study of the build-ups from the Ionian Sea (Marzamemi area) offered the opportunity to investigate the relationship
569 between skeletal builders and associated sediments. These components influence the general morphology and internal
570 framework of the Coralligenous and allow the development of a unique ecosystem where peculiar geobiological processes
571 occur, making these build-ups natural laboratories useful for the palaeoecological reconstruction of the fossil record.

572 The studied build-ups are formed mainly of crustose coralline algae, which constitute a self-sustaining skeletal framework
573 further stabilized by bryozoans and serpulids. The superposition of different generations of builders form a high porous
574 structure. The porosity is further enhanced by bio-erosive activity of perforating organisms. These discontinuities in the
575 skeletal framework represent ideal niches for the colonization of cryptic organisms like sponges, bryozoans, serpulids
576 and microbial communities. Among these, sponges are especially common both with insinuating and perforating taxa.
577 After decaying of soft tissue, the spicules of these organisms accumulate in the cavities together with allochthonous
578 micrite and other bioclasts.

579 Muddy to silty sediments represent the main non-skeletal carbonate component. Sediments consist mainly of
580 allochthonous (detrital) components derived from external sources or from (bio)erosive processes of the build-up
581 components. The autochthonous micrite, mineralized directly inside the build-up through organomineralization processes,
582 represents a minor component. It shows mainly structureless textures and it is associated to sponge spicules. The microbial
583 derived micrite, showing peloidal to clotted peloidal texture, is rare and fills small intra- or inter-skeletal microcavities.
584 Actually, sponges colonize the cryptic micro-niches which are ideal microenvironments for the growth of carbonatogenic
585 bacteria, and the small quantities of autochthonous micrite engulfing the spicules probably results from induced- and
586 supported- organomineralization of the soft tissue of sponges, rather than from microbial mediation. Despite the
587 subordinate abundance in comparison to the skeletonized organisms, the occurrence of autochthonous micrite suggests a
588 possible contribution of this component in cementing and strengthening the skeletal framework due to the early
589 cementation of this type of micrite.

590 The formation of microbialites seems to be prevented by the competition between sponges and microbial communities
591 colonizing the same cryptic spaces. The similar competition among these organisms in the biotic crusts of confined
592 submarine caves suggests that this relationship is not habitat specific. It may develop in similar microhabitats of different
593 open to cryptic environments, and could be used for palaeoecological reconstructions and for interpreting the role of
594 metazoans and microbialite in the fossil build-ups.

595 **Data availability.** All raw data can be provided by the corresponding authors upon request.

596 **Author contributions.** Daniela Basso, Antonietta Rosso and Maurizio Muzzupappa designed the project and allowed the
597 collection of the samples. Adriano Guido and Mara Cipriani conducted the study and prepared the first draft. All authors
598 contributed with ideas and in reviewing the manuscript.

599 **Competing interests.** The authors declare that they have no conflict of interest.

600 **Acknowledgements.** The authors wish to express their gratitude to the associate editor Chiara Borrelli and the reviewers,
601 Fritz Neuweiler and another anonymous, for their constructive comments and suggestions. We thank Nunzio Pietralito
602 and SUTTAKKUA diving school (Pachino, SR) and Riccardo Leonardi (University of Catania) for sampling, and
603 Alessandra Savini, Luca Fallati and Andrea Giulia Varzi (University of Milan-Bicocca) for providing underwater images.
604 The authors greatly thank Mariano Davoli and Chiara Benedetta Cannata of the “Microscopy and Microanalysis (CM2)
605 Laboratory Center”, University of Calabria (Infrastructure SILA), for SEM analysis. This is the Catania Palaeoecological
606 Research Group contribution n. 507.

607 **Financial support.** This work was funded by the Italian Ministry of Research and University – Fondo Integrativo Speciale
608 per la Ricerca (FISR). project FISR2019_04543 “CRESCIBLUREEF - Grown in the blue: new technologies for
609 knowledge and conservation of Mediterranean reefs”.
