9

10 **Abstract.** Ocean Alkalinity Enhancement (OAE) is an emerging approach for atmospheric carbon
11 dioxide removal (CDR). The net climatic benefit of OAE depends on how much it can increase CO₂
12 sequestration relative to a baseline state without OAE. This so-called ‘additionality’ can be calculated
13 as:

14

15

$$\text{Additionality} = C_{\text{OAE}} - \Delta C_{\text{baseline}}$$

16

17 So far, feasibility studies on OAE have mainly focussed on enhancing alkalinity in the oceans to
18 stimulate CO₂ sequestration (C_{OAE}) but not primarily how such anthropogenic alkalinity would modify
19 the natural alkalinity cycle and associated baseline CO₂ sequestration (ΔC_{baseline}). Here, I present
20 incubation experiments where materials considered for OAE (sodium hydroxide, steel slag, olivine) are
21 exposed to beach sand to investigate the influence of anthropogenic alkalinity on natural alkalinity
22 sources and sinks. The experiments show that anthropogenic alkalinity can strongly reduce the
23 generation of natural alkalinity, thereby reducing additionality. This is because the anthropogenic
24 alkalinity increases the calcium carbonate saturation state, which reduces the dissolution of calcium
25 carbonate from sand, a natural alkalinity source. I argue that this ‘additionality problem’ of OAE is
26 potentially widespread and applies to many marine systems where OAE implementation is considered
27 – far beyond the beach scenario investigated in this study. However, the problem can potentially be
28 mitigated by dilute dosing of anthropogenic alkalinity into the ocean environment and avoid OAE at
29 hotspots of natural alkalinity cycling such as in marine sediments. Understanding a potential slowdown
30 of the natural alkalinity cycle through the introduction of an anthropogenic alkalinity cycle will be
31 crucial for the assessment of OAE.

32

33 **1. Introduction**

34

35 Keeping global warming between 1.5 to 2°C requires rapid reduction of greenhouse gas emissions and
36 gigatonne-scale atmospheric carbon dioxide removal (CDR), using a portfolio of terrestrial and marine
37 CDR methods (Nemet et al., 2018). Ocean alkalinity enhancement (OAE) is considered as an important

38 CDR method of the marine portfolio (Hartmann et al., 2013). OAE can be achieved through a variety
39 of geochemical and electrochemical processes (Renforth and Henderson, 2017). All of them enhance
40 surface ocean alkalinity to reduce the hydrogen ion (H^+) concentration in seawater (i.e., increase pH).
41 This reduction in $[H^+]$ causes a shift in the carbonate chemistry equilibrium:

42

44

45 from CO_2 on the left towards bicarbonate (HCO_3^-) and carbonate ion (CO_3^{2-}) on the right. The associated
46 reduction of the CO_2 partial pressure in seawater ($p\text{CO}_2$) enables atmospheric CO_2 influx into the oceans
47 (or reduces CO_2 outflux if $p\text{CO}_2 >$ atmospheric $p\text{CO}_2$). This transfer (retention) of atmospheric CO_2
48 into the ocean leads to an increase of the dissolved inorganic carbon (DIC) concentration in seawater,
49 with DIC defined as:

50

$$51 \text{DIC} = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad (2)$$

52

53 Among the widely discussed OAE approaches are coastal enhanced weathering and electrochemical
54 acid removal (Eisaman et al., 2023). Coastal enhanced weathering achieves alkalinity increase via the
55 addition of pulverized alkaline rocks like limestone, olivine, or alkaline industrial products like steel
56 slag to coastal environments (Meysman and Montserrat, 2017; Feng et al., 2017; Harvey, 2008;
57 Schuiling and Krijgsman, 2006; Renforth, 2019).

58 Electrochemical OAE is somewhat different from coastal enhanced weathering since no materials are
59 added to seawater. Instead, water dissociation into H^+ and OH^- is catalyzed in bipolar membranes, and
60 these ions are then separated using electrical energy and ion-selective membranes (de Lannoy et al.,
61 2018). H^+ is captured as hydrochloric acid whilst OH^- is captured as sodium hydroxide (NaOH). The
62 hydrochloric acid needs to be utilised, neutralized in deep ocean sediments, or stored in safe reservoirs
63 outside the ocean (Eisaman et al., 2018; Tyka et al., 2022). NaOH is enriched in the processed seawater,
64 which is released back into the surface to convert CO_2 into HCO_3^- (Eisaman et al., 2018; Tyka et al.,
65 2022).

66 A critical side-effect of OAE is the associated increase in CO_3^{2-} concentrations, which comes through
67 the shift in the marine carbonate equilibrium through H^+ absorption (see above). This increase elevates
68 the saturation state for calcium carbonate (Ω_{CaCO_3}), the metric which determines the solubility of CaCO_3
69 in seawater. Ω_{CaCO_3} is defined as:

70

$$71 \Omega_{\text{CaCO}_3} = \frac{[\text{Ca}^{2+}]_{\text{sw}} \times [\text{CO}_3^{2-}]_{\text{sw}}}{K_{\text{sp}}} \quad (3)$$

72

73 where $[Ca^{2+}]_{sw}$ and $[CO_3^{2-}]_{sw}$ are calcium ion (Ca^{2+}) and CO_3^{2-} concentration in seawater and K_{sp} is the
74 empirically determined solubility product (Mucci, 1983). K_{sp} differs for different crystal forms of
75 $CaCO_3$. It is higher for Aragonite than for Calcite, meaning Aragonite is more soluble (Mucci, 1983).
76 Aragonite (Arg) and Calcite (Cal) precipitation is thermodynamically favoured when Ω_{Arg} and Ω_{Cal} are
77 ≥ 1 (Adkins et al., 2020). $CaCO_3$ precipitation is of high relevance for the assessment of OAE as the
78 drawdown of CO_3^{2-} through precipitation reduces alkalinity, shifts the carbonate chemistry equilibrium
79 (eq. 1) towards CO_2 and thus counters the CDR efficiency of OAE (Moras et al., 2022; Fuhr et al., 2022;
80 Hartmann et al., 2023).

81 Logistical constraints suggest that OAE would at least initially more likely to be conducted in
82 coastal environments (Renforth and Henderson, 2017; Lezaun, 2021; He and Tyka, 2023). Here,
83 alkalinity-enhanced seawater would likely be in contact with marine sediments (Meysman and
84 Montserrat, 2017; Feng et al., 2017; Harvey, 2008). The highly abundant particles in marine sediments
85 can serve as nuclei for $CaCO_3$ precipitation thereby catalysing alkalinity loss when Ω_{CaCO_3} is ≥ 1 (Zhong
86 and Mucci, 1989; Morse et al., 2003; Adkins et al., 2020). This constitutes a problem for OAE because
87 alkalinity-enhanced seawater with its high Ω_{CaCO_3} is then exposed to particles that catalyse precipitation.
88 Indeed, recent studies have demonstrated that this particle-catalysed precipitation can rapidly reduce
89 alkalinity, with the degree and rate of alkalinity reduction depending on the amount of alkalinity added
90 and the particle concentrations (Moras et al., 2022; Fuhr et al., 2022; Hartmann et al., 2023).

91 Particle-catalysed $CaCO_3$ precipitation has received significant consideration as a loss term for OAE
92 efficiency (Renforth and Henderson, 2017; Moras et al., 2022; Fuhr et al., 2022; Hartmann et al., 2013,
93 2023). However, there is another complication affecting OAE efficiency near sediments, which has
94 received no attention and will be in focus of this study. Sediments can not only provide precipitation
95 nuclei but also constitute natural alkalinity sources, for example via dissolution of $CaCO_3$ or other
96 carbonates (Torres et al., 2020; Wallmann et al., 2022; Krumins et al., 2013; Aller, 1982; Middelburg
97 et al., 2020). Sandy beaches can be rich in biogenic carbonates and organic matter thereby creating
98 environments of high respiratory CO_2 . Accordingly, Ω_{CaCO_3} is low close to the sediments or within pore
99 waters and $CaCO_3$ dissolution is favoured (Liu et al., 2021; Perkins et al., 2022; Reckhardt et al., 2015).

100 This form of natural alkalinity formation via $CaCO_3$ dissolution can sequester CO_2 which may have
101 otherwise be released into the atmosphere (Saderne et al., 2021; Krumins et al., 2013; Aller, 1982;
102 Fakhraee et al., 2023; Archer et al., 1998). OAE within these naturally low Ω_{CaCO_3} environments could
103 have two effects. First, it would have the desired effect of consuming H^+ and increasing CO_2
104 sequestration via the generation of anthropogenic alkalinity. Second, the consumption of H^+ would
105 increase Ω_{CaCO_3} , which could reduce the dissolution of $CaCO_3$ and thus reduce natural CO_2 sequestration
106 since less natural alkalinity is produced. Due to this second effect, the first (desired) effect of CO_2
107 sequestration may be significantly reduced. Accordingly, the net gain in CO_2 sequestration would be
108 lower than one would have hoped for.

109 The concept “additionality” describes the net gain in CO₂ sequestration achieved through the
110 implementation of a CDR method relative to a hypothetical baseline (or “business-as-usual”) scenario
111 (Michaelowa et al., 2019). Per definition, “additional” is all CO₂ sequestration achieved through the
112 implementation of a CDR method (here OAE) that goes beyond natural and anthropogenic CO₂
113 sequestration that already occurs in the baseline scenario without the implementation of the CDR
114 method. Additionality is a central concept in climate policy that has been utilized for carbon accounting
115 in the Clean Development Mechanism established under the 1997 Kyoto Protocol (Havukainen et al.,
116 2022). It can be defined in simple terms as:

117

$$118 \text{ Additionality} = C_{\text{OAE}} - \Delta C_{\text{baseline}} \quad (4)$$

119

120 where C_{OAE} is the CO₂ sequestration achieved through OAE, and $\Delta C_{\text{baseline}}$ is the change in the baseline
121 CO₂ sequestration through the implementation of OAE.

122 This study aims to reveal and describe how anthropogenic alkalinity affects natural alkalinity
123 release to better understand the CO₂ sequestration potential of OAE in the context of additionality. I
124 present observational data and three experiments where three types of anthropogenic alkalinity sources
125 (NaOH, steel slag, olivine) are exposed to a natural alkalinity source and sink (beach sand) to investigate
126 their interactions. Afterwards, I examine these interactions (termed “additionality problem”), discuss
127 their relevance, and how it could be managed.

128

129 **2. Methods**

130

131 **2.1. Carbonate chemistry and dissolved silicate transects along Southern Tasmanian** 132 **beaches**

133

134 The project was initialised with near-shore alkalinity, pH, and dissolved silicate (Si(OH)₄) transects on
135 four Tasmanian beaches to determine whether these beaches are detectable alkalinity sinks or sources.
136 The investigated beaches were Clifton South, Clifton North, Goats, and Wedge on the Southarm near
137 Hobart (Tasmania; Fig. 1, Table S1).

138 Samples for alkalinity and Si(OH)₄ were taken by filling 200 mL seawater from 0.2 m depth
139 into a polyethylene (PE) bottle. Samples for pH were collected in a 60 mL polystyrene (PS) jars filled
140 and closed at 0.2 m depth. Both the PE bottles and the PS jars were pre-rinsed with sample. The sample
141 closest to shore was taken in the swash zone (zone where wave bores run up and down the beach) at the
142 spot where a wave bore reached highest within ~5 minutes of observation. A ~0.2 m deep hole was dug
143 (Fig. 1) and water was collected from the groundwater with a 60 mL syringe. The second sample was
144 from the upper part of the swash zone where waves pushed water up the beach. Samples further out
145 were taken from within the wave breaking zone to about 50-100 m beyond the wave breaking zone.

146 Samples were taken by walking into the water to the point it became too deep and a surfboard was used
147 as sampling vehicle.

148 The samples were transported back to the beach where pH was measured within 15 minutes
149 after sampling as described in section 2.4. Alkalinity and $\text{Si}(\text{OH})_4$ samples were filtered after pH
150 measurements with a 0.22 syringe filter (nylon membrane) into a 125 mL PE bottle (alkalinity) or 60
151 mL PS plastic jar ($\text{Si}(\text{OH})_4$). Both containers, the syringe, and the syringe filter were pre-rinsed with
152 sample.

153
154 **Figure 1.** Locations of the beach transects and beach sand sampling in Tasmania. (A) Map of Tasmania
155 with (B) enlarged map of the Southarm region south of Hobart. Needles show locations the beach
156 transects and the pink line along Clifton Beach shows where sand samples (Sand 1-5) were collected
157 for incubation experiments. The camera symbol illustrates the position from where the picture shown
158 in panel (C) was taken. (C) illustrates approximate location of one of the beach transects. (D) A hole
159 that was dug to sample seawater just above the swash zone, i.e., the first sample location along the
160 transects from the beach towards 150-200 m offshore. The maps were reproduced with the permission
161 of the Environment Heritage and Land Division, Department of Natural Resources and Environment
162 Tasmania, © State of Tasmania.

163

164 2.2. Laboratory experiments

165

166 **2.2.1. Experiment 1: Replicated dissolution assays to monitor interaction between**
167 **beach sand and alkaline materials**

168
169 Experiment 1 was designed to investigate the interaction between 4 different beach sands and alkaline
170 materials during the incubation in seawater. The experiment required 60 HDPE bottles, each with a
171 volume of 125 mL. These 60 bottles were thoroughly cleaned with double-deionised water and dried at
172 60°C. Twelve bottles were filled with sand from one of the 4 sampling locations (section 2.3.),
173 respectively (totalling 48 bottles). Another set of 12 bottles were not filled with sand. This yielded 5
174 sets of 12 bottles (Fig. 2). Of each set, 3 bottles remained without further addition, 3 received 51.3 µL
175 of 1 molar NaOH (targeted alkalinity increase was 428 µmol/kg), 3 received 0.0065 g of ground steel
176 slag, and 3 received 1 g of ground olivine (Fig. 2; sand, steel slag, and olivine properties were
177 determined as described in section 2.3.). The 48 bottles that contained sand were filled with 10 g of
178 sand if slag or NaOH was added or 9 g of sand if olivine was added. This was done so that the weights
179 of added sand plus alkalinity feedstock was always ~10 g.

180 Once the solid components were added, each bottle was filled with 120 (+/-4) g of seawater (Salinity
181 =35 ±0.2, alkalinity = 2259.7 µmol/kg) collected in July 2022 in the Derwent Estuary near Tarooma.
182 Salinity and pH of the seawater was determined a few minutes before transfer into the incubation bottles
183 with a Metrohm 914 pH/conductivity meter as described in section 2.4. The transfer of the seawater
184 into the incubation bottles took 30 minutes in total (please note that in the case of NaOH additions,
185 seawater was added to the bottles before 51.3 µL of 1 molar NaOH was added). The incubation bottles
186 were immediately mounted on a plankton wheel (1.06 m diameter, 2 rounds per minute), which was
187 placed in a temperature-controlled room set to 15°C (Fig. S1). The plankton wheel kept the various
188 mixtures of sand, alkalinity source, and seawater moving inside the bottles. The experiment commenced
189 at 16:00 on the 17th of August, 2022.

190 After ~6.8 days (24th of August), bottles were consecutively removed from the plankton wheel in
191 random order between 8:00 and 15:30. pH was measured inside the bottle with a pH electrode, directly
192 after a bottle was taken off the plankton wheel. Afterwards, the alkalinity sample was filtered with a
193 syringe through a 0.2 µm nylon filter into a dry and clean 125 mL HDPE bottle and stored in the dark
194 at 7°C.

195
196 **2.2.2. Experiment 2: Alkalinity formation at Omega gradients**

197
198 Experiment 2 was designed to investigate whether a decline of Ω_{CaCO_3} enhances the formation of natural
199 alkalinity via CaCO_3 dissolution and how anthropogenic alkalinity sources (olivine, slag, NaOH)
200 influence this process. The experiment required 60 HDPE bottles (125 mL) cleaned with acid and
201 double-deionised water (note that acid was used in Experiment 2 to make sure all remnants from
202 Experiment 1 were washed out of the bottles). All 60 incubation bottles were filled with sand from

203 Clifton Beach (section 2.3.). The treatments were then set up as follows: Twelve bottles were filled only
204 with 10 g of sand; Twelve with 10 g of sand and 0.006515 (+/-0.00007) g steel slag; Twelve with 9 g
205 of sand and 1 (+/-0.002) g of olivine; Eight with 10 g of sand at “un-equilibrated” NaOH addition;
206 Sixteen with 10 g of sand at “equilibrated” NaOH addition (Fig. 2).

207 For each treatment, a gradient in seawater CO₂ concentrations was established from bottle 1 (lowest
208 CO₂) to bottle 8-16 (highest CO₂). This was achieved with the following approach: A batch of seawater
209 (Salinity= 35±0.2, alkalinity = 2266.8 µmol/kg) was collected in November 2022 in the Derwent
210 Estuary near Tarooma. About 0.3L of the batch was bubbled with pure CO₂ gas for about 5 minutes to
211 generate highly CO₂-enriched seawater. Another ~7L of the batch was used as source water to fill the
212 incubation bottles. pH and temperature were measured in this batch prior to filling the incubation
213 bottles. The low CO₂ incubation bottles (bottle 1 in the sequence from e.g. 1 to 12, Fig. 2) were then
214 filled first. Afterwards, about 20 mL of the CO₂-enriched seawater was added to the ~7L batch. The
215 batch was shaken thoroughly to mix the seawater with the CO₂-enriched seawater and the pH and
216 temperature were measured again. Once a stable pH/temperature reading was achieved, (bottle 2) was
217 filled. This procedure was repeated until all bottles in a treatment were filled and a CO₂ (and DIC)
218 gradient was established across the incubation bottles. For the equilibrated and un-equilibrated NaOH
219 treatments, I followed the same procedure but separate 0.3L and 7L batches were used for the CO₂
220 enrichment that had previously been amended with NaOH to elevate alkalinity from 2266.8 to 2757.4
221 µmol/kg prior to filling the incubation bottles. All 60 bottles were filled with 120 +/-4 g of seawater
222 and immediately mounted on the plankton wheel (2nd of December, 2022; 17:00) under the same
223 conditions as in Experiment 1 (i.e. 15°C, 2 rounds per minute, Fig. S1).

224 After ~6.8 days (9th of December), bottles were removed from the plankton wheel between 9:00 and
225 16:00. pH and alkalinity were sampled as described in section 2.2.1.

226

227 **2.2.3. Experiment 3: pH dependency of alkalinity formation from slag and olivine**

228

229 Experiment 3 was designed to investigate whether a lower seawater pH would promote alkalinity
230 formation from steel slag and olivine.

231 The experiment required 12 new HDPE bottles (125 mL) cleaned with double-deionised water and
232 dried thereafter. Six of the 12 bottles were filled with 0.00644 (±0.00007) g steel slag and the other six
233 with 1.0003 (±0.002) g of olivine. Three slag and three olivine bottles were filled with seawater from
234 the same seawater source as used in Experiment 2 (Salinity=35±0.2, alkalinity=2263.2 µmol/kg, pH
235 (total scale) = 7.82). pH and temperature were measured prior to filling the bottles with seawater
236 (section 2.4.). Afterwards, the ~2L seawater batch was amended with about 80 mL of CO₂-enriched
237 seawater as explained in section 2.2.2. This enrichment lowered the pH_T (total scale) from 7.82 to 6.85.
238 This low pH_T (high CO₂) seawater was used to fill the other 3 slag and olivine incubation bottles. The
239 12 bottles with 122.8 (±0.15) g of seawater were immediately mounted on the plankton wheel (Fig. S1)

240 after filling (16th of December, 2022; 16:40) under the same conditions as in Experiment 1 and 2 (i.e.
 241 15°C, 2 rounds per minute).
 242 After ~6.8 days (23rd of December), the 12 bottles were randomly removed from the plankton wheel
 243 between 9:00 and 11:00. pH and alkalinity were sampled as described in section 2.2.1.
 244

245
 246 **Figure 2.** Design of Experiments 1, 2, and 3. Bottles represent treatments with incubation of seawater,
 247 sand, and alkalinity sources (colour code represents alkalinity source). In Experiment 2, NaOH was
 248 used as alkalinity source in two explicit scenarios as described in section 2.2.2.
 249

250 2.3. Preparation and characterization of alkaline materials and beach sand

251
 252 In total, 5 sand samples (0.5-1kg) were collected for Experiments 1 and 2 at Clifton Beach, Tasmania
 253 (Fig. 1, Table S2). Sampling permission was granted by the Department of Natural Resources and
 254 Environment (Authority No. ES 22314). Wet sand was sampled on the upper end of the swash zone and
 255 stored in zip bags at 15°C. Samples 1-4 were used for Experiment 1, ~24 hours after sampling while
 256 sample 5 was used for Experiment 2, ~72 hours after sampling.

257 Olivine rocks were sourced from the Mount Shadwell Quarry in Mortlake (Australia, Table S2). Basic
 258 oxygen slag (hereafter just called slag) was sourced from the Liberty Primary Steel – Whyalla
 259 Steelworks (Australia, Table S2). Olivine rocks and slag (Fig. S2) were crushed with a hydraulic crusher
 260 into smaller pieces of about 10 mm and then milled with a ring mill in a chrome milling pot to yield
 261 particle size distributions as shown in Fig. S3.

262 Wet and dry weight of the sand used for laboratory experiments was determined by weight difference
 263 of a wet and a dry sample. The wet sample (~80 g) was put into a clean plastic jar and dried for 24-72
 264 hours at 60°C. The particle size spectra of the 5 dried sand samples as well as slag and olivine mineral
 265 were determined with a Sympatec QICPIC particle imager.

266 For total particulate carbon (TPC) and particulate organic carbon (POC) analyses, dried sand samples
 267 were milled for 12 minutes in a Retsch MM200 ball mill. Between 4-10 mg of each of the pulverized
 268 sand samples were weighed into 10 tin cups for TPC or 10 silver cups for POC (2 TPC and POC
 269 replicates for each sample). The POC samples were moisturized with 50µL of MilliQ water, placed for

270 18 hours in a dessicator that contained 36% HCl to remove all carbonates and then dried. TPC and POC
271 samples were analysed for carbon content using a Thermo Finnigan EA 1112 Series Flash Elemental
272 Analyser. Particulate inorganic carbon (PIC) content of the samples was then calculated as the
273 difference between TPC and POC. Percent content of carbonates was estimated by multiplying % PIC
274 content by the molecular weight of CaCO₃ (100 g/mol) and MgCO₃ (84.3 g/mol) for upper and lower
275 estimates.

276

277 **2.4. Carbonate chemistry, salinity, and Si(OH)₄ measurements**

278

279 pH was determined potentiometrically using a Metrohm 914 pH meter following Standard Operation
280 Procedure 6a described in Dickson et al., (2007) but omitting the test for ideal Nernst behaviour of the
281 electrode (ideal Nernst behaviour was assumed). A new pH electrode (Metrohm Aquatrode Plus) was
282 calibrated on the total pH scale (pH_T) with certified reference material (CRM) TRIS buffer (batch #37),
283 provided by Prof. Andrew Dickson's laboratory. The calibration procedure for the relevant temperature
284 range (~8 – 18°C) followed the exact workflow as described by Ferderer et al., (2022). Precision of the
285 pH measurement was assumed to be ±0.015 based on experience with the probe.

286 Alkalinity was determined in an open cell titration following Dickson et al., (2003). Samples were
287 measured in duplicate (each ~60 g) with a Metrohm 811 titration unit equipped with a Metrohm
288 Aquatrode Plus. Alkalinity was calculated from titration curves using the Calculate function of
289 PyCO₂sys (Humphreys et al., 2020). The difference in alkalinity between duplicate titrations of the
290 sample was on average 1.95 µmol/kg and >75% were within 4 µmol/kg (N=185), which was assumed
291 to be the precision of the measurement (±2 µmol/kg). Accuracy was controlled by correcting alkalinity
292 values with CRM provided by A.G. Dickson's laboratory. Alkalinity was measured within maximally
293 20 days after sampling.

294 Salinity was measured with a Metrohm conductivity probe with a PT1000 temperature sensor connected
295 to a Metrohm 914 conductivity meter. The probe was calibrated with DIC/alkalinity CRM from A.G.
296 Dickson's laboratory for which a salinity of 33.464 has been reported (CRM batch 200). Conductivity
297 was measured in mS/cm² and salinity was subsequently calculated on the practical salinity scale
298 following Lewis and Perkin, (1978), following the workflow described by Moras et al., (2022). A
299 relatively low precision of +/- 0.2 was determined from repeat measurements, although precision was
300 likely lower under field conditions where there was no temperature control.

301 Si concentrations for beach transects were measured 18 hours after sampling following Hansen and
302 Koroleff, (1999). No Si measurements were conducted for Experiments 1-3.

303

304 **2.5. Carbonate chemistry calculations**

305

306 Carbonate chemistry conditions were calculated with the “carb function” in Seacarb (Gattuso et al.,
307 2021), with pH_T , alkalinity, salinity, temperature, phosphate and $Si(OH)_4$ concentrations as input
308 variables, stoichiometric equilibrium constants from (Lueker et al., 2000), and default settings for the
309 other equilibrium constants. Si was not measured due to volume limitations, so I assumed a value of 50
310 $\mu\text{mol/kg}$ at the end of the experiments, when either sand, olivine, or slag were incubated. Likewise,
311 phosphate was not measured and I assumed 2 $\mu\text{mol/kg}$ at the end of the experiments when slag was
312 incubated. These Si and phosphate releases were based upon previous trials. Note, however, that
313 concentrations of Si and phosphate within these ranges have negligible impact on calculated carbonate
314 chemistry parameters (e.g., pCO_2 changes by $\sim 1 \mu\text{atm}$ when Si is assumed to be 0 instead of 50
315 $\mu\text{mol/kg}$).

316 Propagated errors in derived carbonate chemistry parameters (e.g., DIC) were calculated with
317 the “errors” function in Seacarb using measurement precisions described in section 2.4. for pH_T
318 (± 0.015), alkalinity ($\pm 2 \mu\text{mol/kg}$), and salinity (± 0.2), default uncertainties for equilibrium constants
319 and temperature, and when applicable (see above) $\pm 50 \mu\text{mol/kg}$ for $Si(OH)_4$ and $\pm 2 \mu\text{mol/kg}$ for
320 phosphate.

321

322 **2.6. Calculations of the CO_2 uptake ratio (η_{CO_2}) for carbonate and non-carbonate** 323 **alkalinity sources**

324

325 The atmospheric CO_2 uptake ratio for OAE (η_{CO_2}) was defined as the number of moles DIC (ΔDIC)
326 absorbed per number of moles alkalinity added ($\Delta\text{Alkalinity}$) (Tyka et al., 2022).

327

$$328 \eta_{CO_2} = \frac{\Delta\text{DIC}}{\Delta\text{Alkalinity}} \quad (5)$$

329

330 η_{CO_2} was shown to range roughly between 0.75 and 0.9 mol:mol in the surface ocean (Schulz et al.,
331 2023; Tyka et al., 2022). However, this η_{CO_2} range only applies for alkalinity source materials that
332 exclusively increase alkalinity without a concomitant increase in DIC when they are added to seawater
333 ($\text{Alk}_{\text{non-carbonate}}$). Such sources comprise for example NaOH, slag, and olivine. The estimated range does
334 not apply when all or fractions of the added alkalinity comes from carbonates ($\text{Alk}_{\text{carbonate}}$), since $CaCO_3$
335 contributes 2 moles of alkalinity and 1 mole of (non-atmospheric) DIC when they dissolve. In the
336 following three paragraphs I describe how η_{CO_2} was calculated when considering varying contributions
337 of $\text{Alk}_{\text{non-carbonate}}$ and $\text{Alk}_{\text{carbonate}}$ for a hypothetical or observed increase of $\Delta\text{Alkalinity}$. Please note that
338 the sum of $\text{Alk}_{\text{carbonate}}$ and $\text{Alk}_{\text{non-carbonate}}$ always equals $\Delta\text{Alkalinity}$. Please also note that η_{CO_2} was
339 calculated in different ways for a hypothetical case and Experiment 1 (i.e. η_{CO_2} still has the same
340 theoretical meaning as defined in eq. 5 but was estimated in different ways).

341 The dependency of η_{CO_2} on the relative contribution of $\text{Alk}_{\text{carbonate}}$ and $\text{Alk}_{\text{non-carbonate}}$ was calculated as:

342

$$343 \quad \eta_{CO_2} = \frac{DIC_{equilibrated} - \left(\frac{Alk_{carbonate}}{2}\right) - DIC_{initial}}{Alk_{non-carbonate} + Alk_{carbonate} - Alk_{initial}} \quad (6)$$

344

345 where $DIC_{initial}$ and $Alk_{initial}$ are DIC and alkalinity in seawater before alkalinity was increased, assuming
 346 a seawater pCO_2 in equilibration with the atmosphere. $DIC_{equilibrated}$ is the amount of DIC from the
 347 environment (e.g. from the atmosphere) that can be stored in seawater after the increase of $Alk_{carbonate}$
 348 and $Alk_{non-carbonate}$, assuming seawater pCO_2 in equilibrium with the atmosphere. η_{CO_2} was first
 349 calculated for a theoretical case where $Alk_{initial}$ was 2350 $\mu\text{mol/kg}$ and $DIC_{initial}$ was calculated for the
 350 surface ocean (15°C, Salinity = 35, carbonate chemistry constants as in section 2.5), assuming a pCO_2
 351 of 420 μatm . $Alk_{carbonate}$ and $Alk_{non-carbonate}$ were then varied in a range of scenarios (from 0 to 100%
 352 $Alk_{carbonate}$) to increase the sum of them by 1 $\mu\text{mol/kg}$. η_{CO_2} was calculated for each scenario.

353 Next, η_{CO_2} was calculated specifically for Experiment 1 as follows: $\Delta\text{Alkalinity}$ was higher in the NaOH
 354 and slag treatments when no sand was present compared to incubations with sand (section 3.2).
 355 $\Delta\text{Alkalinity}$ was very likely $Alk_{non-carbonate}$ in all incubations while the reduced $\Delta\text{Alkalinity}$ in the
 356 incubations with sand was likely due to secondary precipitation of carbonates (section 4.2.1). Based on
 357 these conclusions, η_{CO_2} was estimated for Experiment 1 as:

358

$$359 \quad \eta_{CO_2} = \frac{(\Delta\text{Alkalinity}_{no-sand} - \Delta\text{Alkalinity}_{sand}) \times 0.5 + \Delta\text{Alkalinity}_{sand} \times 0.86}{\Delta\text{Alkalinity}_{no-sand}} \quad (7)$$

360

361 where $\Delta\text{Alkalinity}_{no-sand}$ and $\Delta\text{Alkalinity}_{sand}$ are the changes in alkalinity measured in incubations
 362 without sand and with sand, respectively; 0.5 is the η_{CO_2} when $Alk_{non-carbonate}$ is lost via the precipitation
 363 of carbonates where 2 moles of alkalinity and 1 mol of DIC are sequestered; 0.86 is the η_{CO_2} when all
 364 $\Delta\text{Alkalinity}$ is $Alk_{non-carbonate}$ under the conditions set up in the experiments (i.e. 15°C, salinity=35; see
 365 above). Please note that $\Delta\text{Alkalinity}$ was higher in the olivine incubations when sand was present, which
 366 is opposite to the NaOH and slag incubations for reasons discussed in section 4.2.1. Therefore, η_{CO_2}
 367 was calculated assuming all $\Delta\text{Alkalinity}$ was $Alk_{non-carbonate}$ for the olivine incubations (i.e. $\eta_{CO_2} = 0.86$).
 368 For the incubations without an added alkalinity source all $\Delta\text{Alkalinity}$ was assumed to be $Alk_{carbonate}$ so
 369 that η_{CO_2} was 0.36. This assumption is justified with a 2:1 mol:mol $\Delta\text{Alkalinity}:\Delta\text{DIC}$ release ratio as
 370 observed in Experiment 2 (see next paragraph).

371 η_{CO_2} was also specifically calculated for Experiment 2. This required knowledge of how much of the
 372 measured $\Delta\text{Alkalinity}$ was contributed by $Alk_{carbonate}$ and $Alk_{non-carbonate}$. In the treatments where only
 373 sand was incubated, alkalinity and DIC increased roughly in a 2:1 molar ratio over the course of the
 374 experiment (i.e. $\Delta\text{Alkalinity}:\Delta\text{DIC} = 2:1$ mol:mol). Thus, it can be assumed that most of the measured
 375 alkalinity increase is $Alk_{carbonate}$. In contrast, when sand was incubated with alkaline materials, alkalinity
 376 and DIC generally increased with a molar ratio that was $>2:1$ because alkaline materials release

377 alkalinity without a concomitant increase of DIC. Based on these constraints, we can roughly
378 approximate the contribution of $Alk_{\text{carbonate}}$ and $Alk_{\text{non-carbonate}}$ to the measured alkalinity increase
379 ($\Delta\text{Alkalinity}$) as:

380

$$381 \quad \%Alk_{\text{carbonate}} = 1 / \left(\left(\frac{\Delta\text{Alkalinity}}{\Delta\text{DIC}} \right) / 2 \right) \times 100 \quad (8)$$

382

383 Where $\%Alk_{\text{carbonate}}$ is the percentage contribution of $Alk_{\text{carbonate}}$ to $\Delta\text{Alkalinity}$. Based on eq. (8), a
384 $\Delta\text{Alkalinity}:\Delta\text{DIC}$ of for example 8:1 mol:mol would suggest that 25% of the $\Delta\text{Alkalinity}$ is $Alk_{\text{carbonate}}$
385 and the other 75% $Alk_{\text{non-carbonate}}$. $Alk_{\text{carbonate}}$ and $Alk_{\text{non-carbonate}}$ were calculated with eq. 8 for all
386 incubations in Experiment 2 and this information was then used to calculate η_{CO_2} with eq. (6). Finally,
387 the amount of DIC that can be stored in seawater due to an increase of $Alk_{\text{carbonate}}$ and $Alk_{\text{non-carbonate}}$
388 (DIC_{OAE}) was calculated as:

389

$$390 \quad \text{DIC}_{\text{OAE}} = \eta_{\text{CO}_2} * \Delta\text{Alkalinity} \quad (9)$$

391

392 for experiment 2.

393

394 **2.7. Statistical analysis**

395

396 Experiment 1 and 3 were analysed with a two-way analysis of variance (ANOVA) where either “sand”
397 and “alkalinity source material” (Experiment 1) or “carbonate chemistry” and “alkalinity source
398 material” (Experiment 3) were defined as independent variables. The dependent variables were the
399 changes in carbonate chemistry (e.g. $\Delta\text{Alkalinity}$) over the course of the incubations. Homogeneity of
400 variance was assessed by visually inspecting if plotted model residuals vs. fitted values were scattering
401 similarly around 0. Normality of the residuals was assessed by inspecting qqplots where theoretical
402 quantiles plotted against standardized residuals should ideally resemble a straight line. Such a straight-
403 line appearance (i.e. ideal normality) was not always given, so some datasets were rank-transformed.
404 However, transformation did not improve normality substantially so that non-transformed data was
405 used for all analyses. Statistical differences between individual treatments were assessed with a Tukey
406 post-hoc test. Significant differences were assumed when $p < 0.05$.

407 Experiment 2 was analysed by plotting $\Delta\text{Alkalinity}$ for each alkalinity source material and sand against
408 the increase in DIC that was established via additions of CO_2 -saturated seawater (section 2.2.2). The
409 data was fitted with the polynomial equation ax^2+bx+c , where x is the amount of DIC added to each
410 treatment and a , b , c are fit parameters. To estimate additionality of $\Delta\text{Alkalinity}$ and DIC_{OAE} , the curve
411 fitted to the sand-only data was compared to the curves fitted to the treatments.

412

413 **3. Results**

414

415 **3.1. Beach transects**

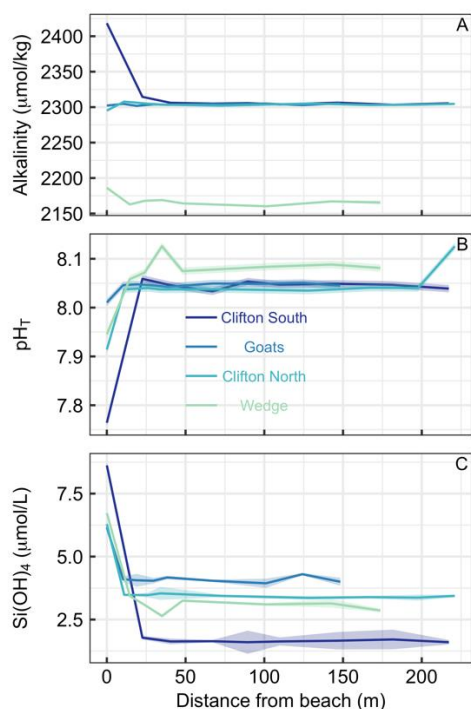

416

417 Beach transects consisted of 8-9 sampling points from just above the swash zone to 150-220 m offshore
418 at four locations (Table S1, Fig. 1). Alkalinity showed distinct patterns across the locations. At Clifton
419 South and Wedge, alkalinity was higher in the swash zone than in the open water. This was particularly
420 pronounced at Clifton South with a value of 2418 $\mu\text{mol/kg}$ relative to open water values of about 2300
421 $\mu\text{mol/kg}$ (Fig. 3A). At Goats Beach, no such alkalinity gradient was observed across the transect, while
422 alkalinity was lower in the swash zone at Clifton North (Fig. 3A). Wedge differed to the other locations
423 in that alkalinity was generally lower (~ 2160 compared to ~ 2300 $\mu\text{mol/kg}$ in open water).

424 pH_T was lowest in samples just above the swash zone at all four locations (Fig. 3B). The difference
425 relative to open water was most pronounced at Clifton South with pH_T of 7.76 just above the swash
426 zone compared to approximately 8.05 in the open water, while least pronounced at Goats. Gradients at
427 Clifton North and Wedge were in between these two extremes. pH_T at Wedge was on average higher in
428 the open water than at the other locations, i.e. 8.08 compared to 8.05 (Fig. 3B).

429 Si(OH)_4 concentrations were highest in samples from just above the swash zone at all four locations
430 (Fig. 3C). The most pronounced gradient was observed at Clifton South, with Si(OH)_4 of 8.6 $\mu\text{mol/L}$
431 just above the swash zone and ~ 1.6 $\mu\text{mol/L}$ in open water. The least pronounced gradient was observed
432 at Goats, and intermediate gradients at Clifton North and Wedge (Fig. 3C).

433 Overall, the data shows consistency across the three parameters measured in that Clifton South showed
434 most pronounced trends, Goats the least pronounced trends, and Clifton North and Wedge being in
435 between (Fig. 3).

436

437 **Figure 3.** Transects of (A) alkalinity, (B) pH_T , and (C) Si(OH)_4 at four different beach locations in
 438 southern Tasmania (see Table S1 and Fig. 1 for locations). The first sampling was at the upper end of
 439 the swash zone and then 7-8 more samples were taken until 150-200 m offshore. Lines and shaded areas
 440 show averages and uncertainties, respectively.

441

442 3.2. Experiment 1

443

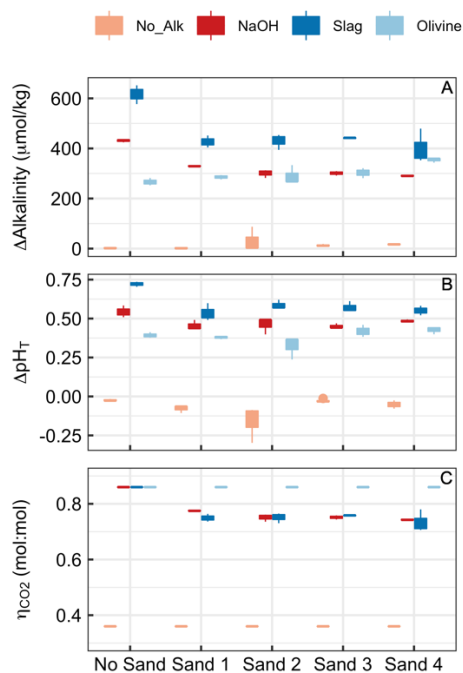

444 Alkalinity increased over the course of the 6.8 days in all treatments where alkaline materials were
 445 added (Fig. 4). Changes in alkalinity ($\Delta\text{Alkalinity}$) were between ~ 610 - $400 \mu\text{mol/kg}$ for the slag, ~ 420 -
 446 $290 \mu\text{mol/kg}$ for the NaOH, and 280 - $370 \mu\text{mol/kg}$ for the olivine treatment. In contrast, $\Delta\text{Alkalinity}$
 447 changed very little (i.e., $\Delta\text{Alkalinity} \leq 6 \mu\text{mol/kg}$) when no alkaline materials were added. (Please note
 448 that an important outlier was observed in Sand 2 where $\Delta\text{Alkalinity}$ was $87.3 \mu\text{mol/kg}$ which will be
 449 discussed in section 4.2.2.). The two-way ANOVA revealed significant effects of (1) the type of sand,
 450 (2) the type of alkalinity source, and (3) the interaction of these two on $\Delta\text{Alkalinity}$ ($p < 0.05$). For the
 451 slag and the NaOH treatment, $\Delta\text{Alkalinity}$ was significantly higher when these were incubated without
 452 sand but only small differences were observed across the four sand samples. In contrast, $\Delta\text{Alkalinity}$
 453 was slightly lower in the olivine treatment when no sand was present during incubations although the
 454 difference was only significant relative to olivine incubated in Sand 4 (Fig. 4A).

455 Changes in pH_T (ΔpH_T) reflected the patterns described for $\Delta\text{Alkalinity}$ (Fig. 4B). ΔpH_T was highest in
 456 the slag and the NaOH treatment when no sand was added, while this difference between the presence
 457 and absence of sand was not observed for olivine. ΔpH_T was slightly negative in treatments where no

458 alkalinity source was added to the incubated sand samples. The two-way ANOVA revealed significant
459 effects of sand, alkalinity source and their interaction on ΔpH_T ($p < 0.05$).

460 η_{CO_2} was prescribed to be 0.36 when sand without an anthropogenic alkalinity source was incubated
461 and 0.86 for olivine incubations (see section 2.6.). Calculated η_{CO_2} for NaOH and slag treatments were
462 slightly lower due to relatively lower $\Delta\text{Alkalinity}$ in the presence of sand than without the presence of
463 sand (Fig 4C). Statistics are not provided for η_{CO_2} data because assumptions of the ANOVA model
464 were heavily violated.

465

466

467 **Figure 4.** Results of Experiment 1. Changes of (A) alkalinity and (B) pH_T from the beginning to the
468 end of the 6.8 days experiment. (C) η_{CO_2} at the end of the experiment. Boxplots are based on three
469 replicates per treatment. Colours refer to the added alkalinity source (No_Alk means no alkalinity
470 source was added). The alignment on the x-Axis indicates if (or which) sand sample was present in the
471 incubation bottles (“No Sand” means no Sand was added).

472

473 3.3. Experiment 2

474

475 The additions of CO_2 -enriched seawater established a gradient of increasing DIC and accordingly a
476 decline in pH_T and Ω_{Arg} (Table S3). The rationale for this setup was that beach sediments can contain
477 high amounts of respiratory CO_2 so that anthropogenic alkalinity added to beaches has a high likelihood
478 to be exposed to such high CO_2 conditions (Liu et al., 2021; Perkins et al., 2022; Reckhardt et al., 2015).
479 Fig. 5 shows $\Delta\text{Alkalinity}$ along the DIC gradient for different alkalinity source materials (NaOH, slag,
480 olivine) and compares this to $\Delta\text{Alkalinity}$ along the same DIC gradient where only sand from a beach

481 was present. The “sand only” data is identical in all four plots (orange lines in Fig. 5). It shows that
482 Δ Alkalinity is close to zero in the sand-only incubations when no DIC is added but increases
483 exponentially with increasing DIC additions up to 537 $\mu\text{mol/kg}$.

484 OAE via NaOH additions was set up in two different scenarios (Fig. 5A, B). In the first scenario, the
485 carbonate system was equilibrated with atmospheric CO_2 after the NaOH deployment and before
486 exposed to the sand (Fig. 5A). Such a scenario could occur when NaOH is added to the ocean, but
487 subsequent air-sea CO_2 influx fully equilibrated the NaOH-induced seawater CO_2 deficit before any
488 interactions with sediments occur. Likewise, equilibration of CO_2 -deficient seawater could be
489 established within the electrochemical OAE facility and thus before the alkalinity-enhanced seawater
490 is discharged back into the ocean. The equilibrated setup leads to a gradient in Ω_{Arg} from 2.1 to 0.2 at
491 the beginning of the 6.8 days incubations (highest Ω_{Arg} at the lowest DIC addition). In the second
492 scenario, the carbonate system was not equilibrated, thereby assuming that a NaOH-enriched patch of
493 seawater would be exposed to sand sediments before it had taken up atmospheric CO_2 (Fig. 5B). Here,
494 initial Ω_{Arg} ranges from 7.1 to 2.3 along the DIC gradient. In the equilibrated scenario, Δ Alkalinity was
495 482 $\mu\text{mol/kg}$ when no DIC was added and increased exponentially to 973 $\mu\text{mol/kg}$ at the highest DIC
496 addition (Fig. 5A). In the unequilibrated scenario, Δ Alkalinity was 344 $\mu\text{mol/kg}$ when no DIC was
497 added and increased to 474 $\mu\text{mol/kg}$ at the highest DIC addition. However, in contrast to the
498 equilibrated treatment, the Δ Alkalinity increase in the unequilibrated treatment weakened along the DIC
499 gradient and Δ Alkalinity was lower than in the sand-only treatment when the DIC addition was >400
500 $\mu\text{mol/kg}$ (Fig. 5B).

501 In the slag treatment, Δ Alkalinity was 521 $\mu\text{mol/kg}$ when no DIC was added. Δ Alkalinity increased
502 exponentially along the DIC gradient to 814 $\mu\text{mol/kg}$. The increase of Δ Alkalinity was less pronounced
503 than in the sand-only treatment. Overall, the slag data showed more scatter relative to the other alkalinity
504 source materials and sand-only treatments (Fig. 5C).

505 In the olivine treatment, Δ Alkalinity was 258 $\mu\text{mol/kg}$ when no DIC was added. Δ Alkalinity increased
506 exponentially with increasing DIC additions to 453 $\mu\text{mol/kg}$ although much less pronounced than in
507 the sand-only treatment. Δ Alkalinity was lower in the olivine than in the sand-only treatment when DIC
508 additions were >350 $\mu\text{mol/kg}$ (Fig. 5C).

509

510

511 **Figure 5.** Results of Experiment 2. All panels show the change in alkalinity from the beginning to the
 512 end of the 6.8 days experiment along a gradient of DIC added to the incubation bottles (DIC values
 513 shown here refer to the values calculated from alkalinity and pH at the start of the experiment). The
 514 orange data displayed on all panels show Δ Alkalinity for incubations where only sand was incubated.
 515 The other data on each panel show Δ Alkalinity when sand was incubated with an external alkalinity
 516 source or addition scenario. Corresponding Ω_{Arg} and pH_T values for all scenarios are provided in Table
 517 S3. (A) Sand and NaOH equilibrated with atmospheric CO_2 upon addition; (B) Sand and NaOH which
 518 was not equilibrated with atmospheric CO_2 upon addition; (C) Sand and slag; (D) Sand and olivine.

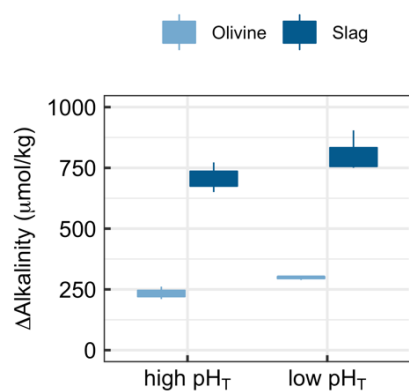

519

520 3.4. Experiment 3

521

522 Experiment 3 tested if there is a carbonate chemistry dependency of alkalinity release by olivine and
 523 slag (Fig. 6). The two-way ANOVA revealed a significant influence of pH_T on the release of alkalinity
 524 from olivine and slag (Fig. 6, please note that pH_T was used for analysing the data but other carbonate
 525 chemistry parameters could also be the driver of the response). Slag released $707 \pm 61 \mu\text{mol/kg}$ alkalinity
 526 when incubated within a pH_T from initially 7.82 to 8.67 at the end of the 6.8 days incubation. Within
 527 the lower pH_T range from 6.86-8.39, slag released $805 \pm 86 \mu\text{mol/kg}$. Olivine released $234 \pm 36 \mu\text{mol/kg}$

528 when incubated within a pH_T from initially 7.82 to 8.20 at the end of the 6.8 days incubation. Within
529 the lower low pH_T range from 6.86-7.63, olivine released $298 \pm 8 \mu\text{mol/kg}$ (Fig. 5).
530

531
532 **Figure 6.** Results of Experiment 3. Changes in alkalinity from the beginning to the end of the 6.8 days
533 experiment when olivine or slag were incubated (without sand) under high (initially 7.82) or low pH_T
534 (initially 6.85). $\Delta\text{Alkalinity}$ was significantly higher under low pH_T ($p < 0.05$).

535 536 4. Discussion

537 538 4.1. Carbonate-derived alkalinity is less efficient for CDR than non-carbonate-derived 539 alkalinity

540
541 Section 2.6. introduced equations which show that alkalinity originating from carbonates ($\text{Alk}_{\text{carbonate}}$)
542 has considerably less capacity to absorb CO_2 than alkalinity originating from non-carbonate sources
543 such as olivine, slag, or NaOH ($\text{Alk}_{\text{non-carbonate}}$). The large influence of this chemical constraint on OAE
544 is exemplified in Fig. 7. Here, the uptake potential for atmospheric CO_2 per mol alkalinity added to the
545 ocean (η_{CO_2}) is shown as a function of the carbonate contribution to the alkalinity source. When all
546 $\Delta\text{Alkalinity}$ delivered via OAE originates from non-carbonate sources (e.g., NaOH, slag, olivine), then
547 η_{CO_2} equals 0.86. η_{CO_2} declines linearly with an increasing contribution $\text{Alk}_{\text{carbonate}}$ to $\Delta\text{Alkalinity}$ to the
548 lowest theoretical value for η_{CO_2} of 0.36, which is reached when OAE provides all alkalinity as
549 $\text{Alk}_{\text{carbonate}}$ (Fig. 7).

550 The dependency of η_{CO_2} on the alkalinity source material (Fig. 7) has important implications for OAE
551 methods that aim to utilise CaCO_3 as alkalinity source (Renforth et al., 2022; Wallmann et al., 2022;
552 Harvey, 2008; Rau and Caldeira, 1999). The molar efficiency for atmospheric CO_2 sequestration of
553 OAE is $>50\%$ lower when using carbonates (e.g. CaCO_3). Or put differently, OAE approaches utilising
554 CaCO_3 as alkalinity source would have to increase alkalinity by more than twice as much to generate
555 similar CDR compared to methods that use non-carbonates (e.g. NaOH, slag, or olivine). Importantly,
556 while this disadvantage of carbonate sources of alkalinity appears to be substantial, it is not the only

557 important factor determining the potential of such OAE approaches. It is possible that the use of
558 carbonates still holds higher potential, for example because limestone is relatively abundant (Caserini
559 et al., 2022), can dissolve quickly (Renforth et al., 2022), or because it contains fewer components
560 potentially affecting marine organisms (Bach et al., 2019). Nevertheless, the dependency of η_{CO_2} on the
561 alkalinity source (Fig. 7) needs to be considered when assessing the efficiency of different OAE
562 methods, as will become apparent in section 4.2.
563

564
565 **Figure 7.** Changes in η_{CO_2} with the fraction alkalinity originating from carbonates (e.g. CaCO_3
566 dissolution). The x-axis ranges from 0 (all $\Delta\text{Alkalinity}$ originates from non-carbonate sources such as
567 NaOH , slag, or olivine) to 1 (all $\Delta\text{Alkalinity}$ originates from carbonate sources such as CaCO_3 or
568 MgCO_3).

569 4.2. The additionality problem of OAE

570
571
572 The experiments considered here investigate coastal applications of OAE, for example when ground
573 materials or NaOH are exposed to beaches or sandy sediments. In the experiments, the treatments where
574 only sand was incubated constitute the baseline system while incubations of sand and an alkalinity
575 source constitute the OAE deployments. Both the baseline system and the OAE deployment were run
576 in parallel under identical conditions. To assess the additionality of OAE, CO_2 sequestration achieved
577 through an OAE deployment must be compared to the baseline state where no such deployment
578 occurred (see eq. 4). As such, additionality can be affected through processes that affect the OAE
579 deployment directly (section 4.2.1.), or when the OAE deployment alters the baseline state of the system
580 (section 4.2.2.).

581 4.2.1. Change of additionality through interaction of alkalinity sources with sand

582
583
584 The $\Delta\text{Alkalinities}$ determined in Experiment 1 were lower in NaOH and slag incubations with sand than
585 in incubations without sand. The reduction in the presence of sand was likely due secondary
586 precipitation of carbonates, which is promoted when Ω_{CaCO_3} is elevated and/or there are particles (here

587 sand), which provide nucleation sites for CaCO_3 precipitation (Moras et al., 2022; Fuhr et al., 2022;
588 Zhong and Mucci, 1989).

589 In contrast to the NaOH and slag incubations, the olivine incubations generated more $\Delta\text{Alkalinity}$ when
590 sand was present, even though the enhancement was small and only in one case statistically significant
591 (i.e., No Sand vs Sand 4; Fig. 4A). This contrasting observation can be explained as follows. First,
592 $\Delta\text{Alkalinity}$ was generally lower in the olivine incubations than in the NaOH and slag incubations when
593 no sand was present ($266 \pm 14.8 \mu\text{mol/kg}$ for olivine vs. $>420 \mu\text{mol/kg}$ for NaOH and slag). Moras et
594 al., (2022) have shown that the onset of secondary precipitation depends on $\Delta\text{Alkalinity}$ and they
595 observed no secondary precipitation over a 40-day experimental incubation when $\Delta\text{Alkalinity}$ was ~ 250
596 $\mu\text{mol/kg}$ ($\Omega_{\text{Arg}} \sim 4$). This suggests that the $266 \pm 14.8 \mu\text{mol/kg}$ $\Delta\text{Alkalinity}$ generated by olivine did not
597 elevate Ω_{Arg} to high enough levels to induce noticeable secondary precipitation within 6.8 days.
598 However, the absence of such secondary precipitation cannot explain why $\Delta\text{Alkalinity}$ increased in the
599 presence of sand. It is possible that the sand itself released alkalinity via carbonate dissolution as a very
600 small increase in $\Delta\text{Alkalinity}$ was also observed in some sand-only incubations (e.g. $17.4 \pm 2.6 \mu\text{mol/kg}$
601 in Sand 4; Fig. 4A). However, Ω_{Arg} was higher in the olivine incubations as in the sand-only treatment
602 so that a release of carbonate alkalinity seems unlikely. It is also unlikely that the pH differences
603 between olivine-only and olivine+sand incubations drove this trend. While Experiment 3 underscores
604 that lower pH promotes the release of alkalinity from olivine (Fig. 6), pH_T was higher in the
605 olivine+sand treatment where significantly more alkalinity was released (see Sand 4 in Fig. 5A). What
606 appears as a plausible explanation is that the sand caused physical destruction of coatings that develop
607 on the olivine particles during dissolution and are known to reduce dissolution rates (Oelkers et al.,
608 2018). Indeed, the dissolution-enhancing role physical abrasion has been hypothesised to increase OAE
609 efficiency when using olivine (Schuiling and de Boer, 2010), as has recently been confirmed by
610 (Flipkens et al., 2023).

611 η_{CO_2} is reduced when the presence of sand catalyses secondary precipitation (Fig. 5C). Consequently,
612 the amount of DIC that can be sequestered via OAE declines. Among other factors, the degree of
613 alkalinity loss due to secondary precipitation depends on the duration carbonate supersaturated water is
614 exposed to the sand. The experiments presented here lasted for 6.8 days and it is likely that secondary
615 precipitation would have proceeded (and η_{CO_2} further declined) if the experiments had lasted for longer.
616 Indeed, Moras et al., (2022) observed that secondary precipitation catalysed by particles only slowed
617 down once Ω_{Arg} reached ~ 2 . In the experiments presented here, Ω_{Arg} was generally >5 at the end of the
618 study. A back-of-the-envelope carbonate chemistry calculation with seacarb suggests that a decline until
619 Ω_{Arg} reaches 2 via carbonate precipitation (i.e. alkalinity and DIC decline in a 2:1 molar ratio) would
620 have reduced alkalinity by $\sim 560 \mu\text{mol/kg}$ for the NaOH and $840 \mu\text{mol/kg}$ for the slag incubations,
621 respectively. In both cases the alkalinity after the OAE perturbation would be lower than before but

622 atmospheric CO₂ uptake would still occur ($\eta_{\text{CO}_2} = 0.39$ for NaOH and 0.37 for slag) because the pCO₂
623 is still slightly lower than before the perturbation (Moras et al., 2022).

624

625 **4.2.2. Reduction of additionality through modification of baseline alkalinity** 626 **formation**

627

628 One interesting observation was made during a sand-only incubation of Experiment 1 (i.e. “No_ Alk in
629 Fig. 4). For Sand 2, $\Delta\text{Alkalinity}$ was about 85 $\mu\text{mol/kg}$ higher in one replicate bottle than in the other
630 two. This difference was due to a small arthropod (likely a sand flea) that was unintentionally added to
631 the incubation bottle where the high $\Delta\text{Alkalinity}$ was observed. The arthropod was still alive at the end
632 of the 6.8 incubation period. During those 6.8 days, the organism respired, thereby reducing Ω_{Arg} , and
633 causing alkalinity release from the sand via CaCO₃ dissolution. This observation pointed out that the
634 baseline system can already release substantial amounts of alkalinity even before OAE is implemented
635 given sufficient respiration. Indeed, the in-situ observations at Clifton South suggest that alkalinity
636 release occurs in the baseline system used here (section 3.1). Furthermore, there is widespread evidence
637 from the literature that beaches release alkalinity via CaCO₃ dissolution (Liu et al., 2021; Perkins et al.,
638 2022; Reckhardt et al., 2015). These insights collectively inspired Experiment 2, where a DIC gradient
639 (high to low Ω_{Arg}) was set up to test if natural alkalinity release via CaCO₃ dissolution would be
640 influenced by anthropogenic alkalinity release via OAE.

641 Experiment 2 demonstrated that the release of natural alkalinity can be disturbed by the addition of
642 anthropogenic alkalinity sources (Fig. 8). Fig. 8A illustrates the additionality of alkalinity release,
643 calculated by subtracting $\Delta\text{Alkalinity}$ from sand-only incubations (represented by the orange lines in
644 Fig. 5 panels A-D) from $\Delta\text{Alkalinity}$ in sand+alkalinity incubations (represented by the red and blue
645 lines). Fig. 8A reveals that the additionality of $\Delta\text{Alkalinity}$ declines with increasing amounts of added
646 DIC. The reason for this trend is that the alkalinity sources added to the incubation bottles buffered the
647 DIC-induced pH decline. This buffering elevated Ω_{Arg} during the incubations, resulting in a reduced
648 release of natural alkalinity through CaCO₃ dissolution. Or in simpler terms, by adding a new buffer
649 system via OAE (NaOH, slag, or olivine), a natural buffer system (CaCO₃ dissolution) is partially
650 replaced. In cases where olivine or non-equilibrated NaOH was tested, the additionality of $\Delta\text{Alkalinity}$
651 became even negative when DIC additions were >350 and >400 $\mu\text{mol/kg}$, respectively (Fig. 8A).

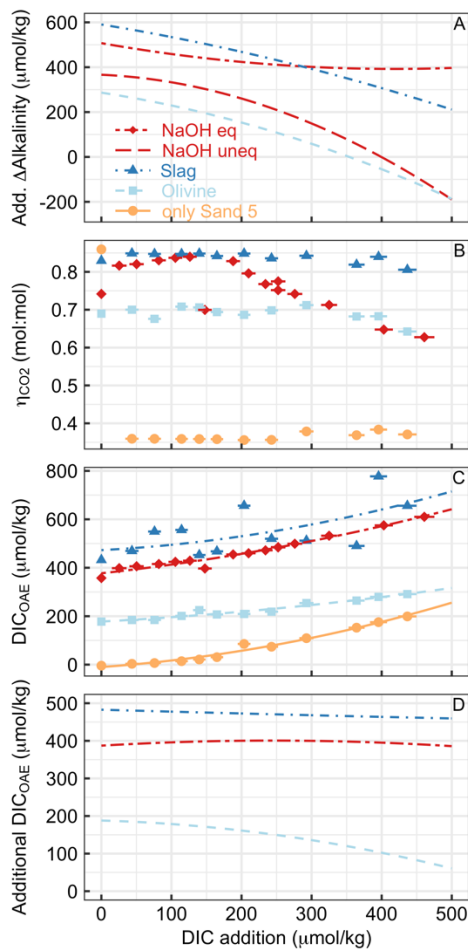

652 Alkalinity release is generally seen as a good indicator for the amount of CO₂ that can be removed per
653 mole alkalinity enhancement (η_{CO_2}). However, as discussed in section 4.1., η_{CO_2} also critically depends
654 on whether the released alkalinity is $\text{Alk}_{\text{carbonate}}$ or $\text{Alk}_{\text{non-carbonate}}$. In Experiment 2, η_{CO_2} varies greatly
655 depending on the alkalinity source and the amount of DIC added to the incubation (Fig. 8B). η_{CO_2} is
656 low for sand-only incubations because basically all $\Delta\text{Alkalinity}$ is $\text{Alk}_{\text{carbonate}}$, whereas it is substantially
657 higher in treatments with an anthropogenic $\text{Alk}_{\text{non-carbonate}}$ source. For olivine, η_{CO_2} was around 0.7 up

658 until the highest DIC additions where η_{CO_2} declines slightly. This is lower than for slag, where η_{CO_2}
659 remains close to the theoretical maximum of 0.86. The difference between slag and olivine could be
660 due to faster dissolution of slag, which elevates Ω_{Arg} before substantial CaCO_3 dissolution had occurred.
661 In contrast, olivine dissolves more slowly (Fuhr et al., 2022; Montserrat et al., 2017; Hangx and Spiers,
662 2009), so that some CaCO_3 dissolution may have occurred before olivine dissolution elevated Ω_{Arg}
663 enough to limit further CaCO_3 dissolution. (Please note, however, that this explanation does not explain
664 why η_{CO_2} is also lower than in slag incubations at low DIC additions, where Ω_{Arg} was high enough to
665 limit CaCO_3 dissolution from the start). The reason for the decreasing η_{CO_2} in the equilibrated NaOH
666 scenario (Fig. 8B) is an increasing contribution of $\text{Alk}_{\text{carbonate}}$ to $\Delta\text{Alkalinity}$. It is important to note that
667 for the same added DIC, Ω_{Arg} is much lower in the equilibrated NaOH scenario than in unequilibrated
668 NaOH scenario (e.g. 0.28 vs. 2.9 at $\sim 400 \mu\text{mol/kg}$ added DIC for the equilibrated and unequilibrated
669 NaOH scenarios, respectively). This lower Ω_{Arg} is because the equilibrated scenario simulates that
670 atmospheric CO_2 has already been absorbed by the alkalinity-enhanced seawater. Accordingly,
671 alkalinity-enhanced seawater that has been equilibrated with atmospheric CO_2 interacts with beach
672 sediments at a lower Ω_{Arg} than if the alkalinity-enhanced seawater was unequilibrated. As such, the
673 equilibrated OAE scenario causes less reduction of natural alkalinity release from sediments via CaCO_3
674 dissolution.

675 Measurements and estimates of $\Delta\text{Alkalinity}$ and η_{CO_2} enabled calculation of how much DIC could be
676 maximally stored by the generated alkalinity (i.e., DIC_{OAE} as calculated in eq. 9 is shown in Fig. 8C).
677 DIC_{OAE} increases with higher DIC additions due to the release of alkalinity via CaCO_3 dissolution.
678 However, the increase is less pronounced as observed for $\Delta\text{Alkalinity}$ (Fig. 8A) because $\text{Alk}_{\text{carbonate}}$ from
679 CaCO_3 dissolution is less efficient in sequestering environmental CO_2 than $\text{Alk}_{\text{non-carbonate}}$ from NaOH,
680 slag, or olivine (section 4.1).

681 To calculate the additionality of DIC_{OAE} , I subtracted DIC_{OAE} of the sand-only incubations (baseline)
682 of DIC_{OAE} of the OAE scenarios (Fig. 8D). The additionality of DIC_{OAE} is arguably the most important
683 parameter to assess whether an OAE deployment has led to the net sequestration of CO_2 . In the case of
684 the equilibrated NaOH and slag scenarios, the additionality of DIC_{OAE} was constant over the applied
685 gradient, suggesting that the release of $\text{Alk}_{\text{carbonate}}$ via CaCO_3 dissolution led to similar DIC_{OAE} potential
686 in the sand-only scenario and these two OAE scenarios. In contrast, the additionality of DIC_{OAE} declined
687 in the olivine scenario because there was relatively more $\text{Alk}_{\text{carbonate}}$ release in the sand only scenario
688 than in the olivine scenario (Fig. 8D). Importantly, however, the additionality of DIC_{OAE} remains
689 positive up until the highest DIC addition, which is in stark contrast to the additionality of $\Delta\text{Alkalinity}$
690 (compare Fig 8A and D). This means that the addition of olivine maintained a positive CO_2
691 sequestration potential even though less alkalinity was generated in the olivine treatment than in the
692 sand-only treatment (Fig. 8C). The reason for this counterintuitive observation is simply that the $\text{Alk}_{\text{non-}}$

693 carbonate released by olivine has more potential to sequester CO₂ than the Alk_{carbonate} released via CaCO₃
 694 dissolution.
 695

696
 697 **Figure 8.** Various measures of OAE efficiency under increasing additions of DIC in Experiment 2 (DIC
 698 could for example be CO₂ from the respiration of organic material in sediments). (A) The additionality
 699 of ΔAlkalinity. (B) η_{CO2} at the end of the experiment. Please note that the extreme outlier at lowest DIC
 700 addition in the sand-only treatment was likely due to measurement uncertainty. (C) DIC_{OAE}, i.e., how
 701 much seawater CO₂ could have potentially been absorbed with the amount of ΔAlkalinity provided by
 702 the various alkalinity sources. (D) The additionality of DIC_{OAE}. Please note that panels (B-D) only show
 703 data for the equilibrated NaOH scenario. I omitted the unequilibrated scenario for logical reasons, i.e.,
 704 because the core assumption in this scenario (no CO₂ equilibration with the atmosphere after OAE) is
 705 at odds with the necessary assumption of CO₂ equilibration to calculate η_{CO2} (section 2.6).

706
 707 **4.3. Relevance of the additionality problem**

708
 709 Modifications of additionality can occur when OAE triggers subsequent alkalinity loss through biotic
 710 and abiotic carbonate precipitation (section 4.2.1.). This feedback has been widely discussed and is

711 already a predominant topic in OAE research (Hartmann et al., 2013; Bach et al., 2019; Moras et al.,
712 2022; Fuhr et al., 2022; Hartmann et al., 2023). Not yet discussed is the modification of additionality
713 that may occur when anthropogenic alkalinity sources (via OAE) modify the release of natural alkalinity
714 (section 4.2.2.). Thus, I will focus on the relevance of this second pathway of additionality modification
715 in the following paragraphs.

716 The experiments conducted here tested how anthropogenic alkalinity sources can interact with beach
717 sand in a setting that assumes constant mixing, inspired by conditions observed in a high energy wave
718 impact zone. This setting was chosen based on the widely discussed OAE implementation strategy of
719 adding olivine powder to beaches. The results suggest that the “additionality problem” needs to be
720 considered for this specific OAE approach. However, the wave impact zone comprises a tiny fraction
721 of the coastal ocean and the question is to what extent the additionality problem also applies to the vast
722 shelf, bank, embayment and reef areas where OAE could also be implemented (Feng et al., 2017;
723 Meysman and Montserrat, 2017; Mongin et al., 2021).

724 The coastal ocean is a net sink of ~ 36 Tmol/year alkalinity via CaCO_3 burial (Middelburg et al., 2020),
725 but considerable amounts of alkalinity are also generated in the various coastal sediments via CaCO_3
726 dissolution (one estimate suggests ~13 Tmol/year; (Krumins et al., 2013)). The dissolution depends on
727 the solubility of CaCO_3 present in the sediments and pore water Ω_{CaCO_3} (Middelburg et al., 2020).
728 Conditions for dissolution are generally favourable in coastal ocean sediments because soluble forms
729 of CaCO_3 occur more frequently and relatively high supply of organic matter lowers Ω_{CaCO_3} (Krumins
730 et al., 2013; Lunstrum and Berelson, 2022; Morse et al., 1985). Thus, the introduction of an
731 anthropogenic buffer via OAE (which increases Ω_{CaCO_3}) is likely to cause a reduction of alkalinity
732 release from the seafloor.

733 Indeed, more soluble forms of CaCO_3 were shown to protect less soluble forms of CaCO_3 from
734 dissolution at the seafloor (Sulpis et al., 2022). Furthermore, an experiment exposed a coral reef to
735 moderate levels of increased alkalinity ($\Delta\text{Alkalinity} = \sim 50 \mu\text{mol/kg}$) and found a net increase of reef
736 calcification, with some evidence suggesting that the measured effect was due to reduced reef
737 dissolution (Albright et al., 2016). Anthropogenic alkalinity sources (e.g. NaOH, slag, olivine)
738 introduced via OAE can be considered to have a similar effect and reduce natural alkalinity release via
739 CaCO_3 dissolution. It is worth noting that the negative effect of anthropogenic alkalinity on natural
740 alkalinity release may also occur in the open surface ocean. Here, part of the alkalinity bound in
741 particulate form via biotic calcification re-dissolves, for example in corrosive microenvironments such
742 as zooplankton or marine snow (Subhas et al., 2022; Milliman et al., 1999; Sulpis et al., 2021). If
743 anthropogenic alkalinity introduced via OAE reduces this natural dissolution of CaCO_3 in the surface
744 ocean, then less alkalinity would remain in the surface ocean and the additionality of OAE would be
745 reduced (Bach et al., 2019). Thus, the “additionality problem” of OAE could be widespread and not
746 restricted to the specific environment studied experimentally in this paper.

747 Another interesting aspect to consider is the time and scale-dependency of the additionality
748 problem. A detectable slow-down of natural alkalinity formation may occur in the environment where
749 anthropogenic alkalinity was added (as observed in the experiments presented here). Such an “acute”
750 additionality problem may be comparatively easy to associate with the responsible OAE deployment
751 and there may be straight-forward ways to mitigate it. (see section 4.4 and Box 1). However, the
752 problem could turn from “acute” to “chronic” over much longer timescales should OAE be up-scaled
753 to climate-relevance and cause a significant increase of Ω throughout the ocean. In the chronic scenario,
754 anthropogenic alkalinity may partially replace the “natural” alkalinity release enforced by fossil fuel
755 CO₂ neutralization via carbonate dissolution (Archer et al., 1998). A chronic additionality problem
756 would unlikely be attributable to individual OAE deployments and suggested mitigation measures
757 described in section 4.4. and Box 1 would not work. Indeed, similar chronic problems for CDR imposed
758 by Earth system feedbacks have already been described, for example the possible weakening of natural
759 terrestrial and marine CO₂ sinks due to CDR implementation (Keller et al., 2018). However, assessing
760 whether the hypothesis of a chronic additionality problem is valid remains to be seen and will require
761 more targeted follow-up research.

762

763 **4.4. Possible ways to manage the additionality problem**

764

765 This section discusses potential pathways to manage an acute additionality problem. The discussion is
766 accompanied with Box 1, which translates thoughts raised here into suggestions how practitioners (e.g.
767 OAE start-ups) could deal with acute additionality problems.

768 To manage the additionality problem, it is important to monitor the natural alkalinity release in a
769 designated OAE deployment site before OAE is implemented. Natural alkalinity release occurs in all
770 coastal habitats (Krumins et al., 2013; Aller, 1982; Perkins et al., 2022; Liu et al., 2021) and recent
771 evidence suggests that even small CaCO₃ content in sediments is sufficient to yield high alkalinity
772 release rates (Lunstrum and Berelson, 2022). As such, dissolution is not restricted to CaCO₃ rich
773 sediments and avoiding these may therefore not mitigate the additionality problem. More crucial than
774 the CaCO₃ content appears to be the supply of organic matter to the seafloor, which provides respiratory
775 CO₂ needed for CaCO₃ dissolution and associated alkalinity release (but note that organic matter supply
776 also drives organic or other inorganic alkalinity release (Krumins et al., 2013; Aller, 1982; Lunstrum
777 and Berelson, 2022; Perkins et al., 2022; Liu et al., 2021)). Therefore, it may be useful to avoid OAE
778 near sediments exposed to high organic matter load to reduce the interference of anthropogenic
779 alkalinity with natural alkalinity release.

780 Another mitigation pathway for the additionality problem is dilution. When anthropogenic alkalinity is
781 diluted quickly then there is less chance for the new buffer system to generate oversaturated Ω in
782 seawater, sediment pore waters, or other microenvironments. Indeed, the data from the beach transects
783 show that alkalinity (and Si(OH)₄) deviations in the upper end of the swash zone were quickly lost upon

784 moving offshore (Fig. 3). The experiments presented here do not allow for such dilution as they are
785 performed in enclosed volumes. They can therefore be considered a more extreme case, which do not
786 correctly represent the vastness of the ocean and its volume. Indeed, previous experiments investigating
787 the risk of alkalinity loss after OAE due to secondary precipitation found that dilution effectively
788 mitigates the secondary precipitation problem (Moras et al., 2022). It is very likely that dilution is
789 similarly effective to mitigate the additionality problem.

790 Finally, the data presented here clearly show that the additionality problem scales with the degree of
791 CaCO_3 oversaturation introduced through the anthropogenic alkalinity source. This is most obvious
792 when comparing the equilibrated with the unequilibrated NaOH OAE scenario. The increase of Ω_{CaCO_3}
793 is much more pronounced in the unequilibrated scenario because atmospheric CO_2 has not yet entered
794 the seawater and brought down Ω_{CaCO_3} to levels it was before the OAE perturbation. As such, the
795 additionality problem will be much more pronounced when an alkalinity source interacts with naturally
796 alkalinity releasing sediments before the OAE-perturbed seawater has been equilibrated with
797 atmospheric CO_2 . Nevertheless, a close look at Fig. 4A (equilibrated NaOH) shows that even the
798 relatively small increase of Ω_{CaCO_3} that coincides with OAE fully equilibrated with atmospheric CO_2 ,
799 can reduce natural alkalinity release. Thus, atmospheric CO_2 equilibration following OAE mitigates the
800 additionality problem but cannot fully avoid it.

801

802 **Box 1. Suggestions for OAE practitioners.**

803

804 Research much beyond the present study is needed to better constrain the magnitude of the additionality
805 problem and evaluate its relevance for OAE. However, real-world OAE assessments and ambitions for
806 implementation are already underway so that some initial guidance on the additionality problem may
807 be important already now, even if based on limited evidence. This Box translates thoughts discussed in
808 section 4 into suggestions directed to those working on the implementation of OAE. Importantly,
809 practitioners should remain critical about these suggestions (they may change with further knowledge
810 gain) and apply at own risk.

811

- 812 - With the currently limited understanding of the additionality problem, it may be
813 best to avoid it as much as possible.
- 814 - Choose a field site with high dilution. Interaction of anthropogenic alkalinity with the natural
815 alkalinity cycle are less likely to occur when alkalinity-enhanced seawater is quickly mixed
816 with unperturbed seawater. As such, volumes with restricted exchange (e.g. bays, lagoons,
817 fjords) may be more problematic.
- 818 - Enable fast equilibration of the alkalinity-enhanced seawater with atmospheric CO_2 . The influx
819 of atmospheric CO_2 returns Ω_{CaCO_3} of alkalinity-enhanced seawater to values closer to
820 unperturbed seawater and thus has less potential to affect CaCO_3 dissolution or precipitation.

- 821 - When possible, restrict contact of anthropogenic alkalinity with sediments to reduce
822 interactions at hotspots of natural alkalinity cycling. This suggestion is not feasible for OAE
823 implementation via coastal enhanced weathering where alkaline minerals are added to
824 sediments (Eisaman et al., 2023). For this OAE strategy, it is suggested to prefer sediments
825 depleted in organic matter where less “fuel” is available for respiration and associated carbonate
826 dissolution (i.e., natural alkalinity release).
- 827 - Frameworks to monitor, report, and verify the success of OAE should include sediment
828 interactions and account for the additionality problem.

829

830 **5. Conclusion and outlook**

831

832 The additionality problem described herein could influence the effectiveness of OAE. It suggests that
833 interference of anthropogenic alkalinity with the natural alkalinity cycle must be assessed as a factor
834 that can modify the OAE efficiency. The arguments provided in the discussion suggest that the
835 additionality problem is potentially widespread, even though the dataset presented here only considers
836 OAE near or on wave-exposed beaches. Future research should aim to confirm or dismiss these
837 arguments and to better understand the extent of the problem.

838 The additionality problem adds a layer of complexity to monitoring, reporting, and verification of CO₂
839 removal with OAE. Strictly speaking, it is not sufficient to monitor the generation (e.g., via NaOH,
840 slag, or olivine dissolution) and potential loss (e.g., via biotic and abiotic precipitation) of anthropogenic
841 alkalinity after its generation. It also needs to be assessed to what extent anthropogenic alkalinity alters
842 the baseline removal or delivery of natural alkalinity. It will be crucial to understand whether the
843 anthropogenic acceleration of the alkalinity cycle in the oceans via OAE could slow down the natural
844 alkalinity cycle.
