17 **Abstract.** Nitrogen (N) and warming effects on ecosystem carbon (C) budgets and  
18 stabilization are critical to understand as C sequestration is considered as a mechanism  
19 to offset anthropogenic CO<sub>2</sub> emissions, which is important for accurately predicting  
20 ecosystem C sequestration and/or potential C loss, remaining controversial though.  
21 ~~Understanding the changes in soil organic carbon (SOC) storage and chemical~~  
22 ~~stabilization dynamics is important for accurately predicting ecosystem C sequestration~~

23 ~~and/or potential C loss,~~ but the relevant information, especially for the intervention of  
24 environmental controls on grassland soil is limited in Tibetan plateau (TP) regions.

25 Here we used a 9-year two-way factorial experiment involving warming with open top  
26 chambers (+1.80 °C in the daytime and +0.77 °C in the nighttime at the soil surface)  
27 and multilevel nitrogen (N) enrichment treatments (0, 5, 10, and 15 g m<sup>-2</sup> year<sup>-1</sup>) in the  
28 ~~TP Tibetan plateau~~ to investigate the changes in SOC pool size and chemical structure.

29 9-year warming treatment significantly decreased SOC stock in the Tibetan grassland.

30 We observed decreasing SOC concentrations which may be related to changes in the C  
31 degrading enzymes. Surprisingly, the SOC molecular structure remained unchanged in  
32 all N enrichment and warmed plots, suggesting that both treatments had affected all  
33 forms of SOC, from simple and complex polymeric in a similar way. Our results suggest  
34 that long-term warming stimulates soil C loss but no preference in SOC loss with  
35 different chemical structure.

## 39 1. Introduction

40 Soil organic matter is the largest organic carbon reservoir of near-surface terrestrial  
41 ecosystem (Dlamini et al. 2016). Even subtle acceleration in SOC decomposition will  
42 result in large CO<sub>2</sub> emissions (Davidson and Janssens 2006). So, knowledge of the  
43 factors affecting SOC storage and decomposition is essential for understanding the  
44 dynamically changing global C cycle. The influence of global warming on  
45 decomposition of soil carbon has been well documented (Poeplau et al. 2017, Guan et  
46 al. 2018, Ding et al. 2019b), but there remains considerable uncertainty in the potential  
47 response of soil C dynamics to the rapid global increase in reactive nitrogen (N, coming  
48 largely from agricultural fertilizers and fossil fuel combustion) as well as the combined  
49 effects with warming (Liang and Balser 2012, Devaraju et al. 2015, Li et al. 2017). For  
50 example, soil N availability would strongly affect microbial physiology and C-  
51 degrading enzymes (EnC), which can subsequently alter soil C feedbacks to warming  
52 (Mack et al. 2004; Contosta & Cooper 2015). EnC has been shown to play an important  
53 role in SOM nutrient cycling and catabolism (Chen et al. 2018a), and information on  
54 such activity can be used to investigate substrate nutrient demand and response to  
55 environmental changes (Allison et al. 2010; Wang et al. 2015). The knowledge gap  
56 demonstrated a need to focus research on biological and physicochemical controls of  
57 SOC stabilization and destabilization processes as a basis for understanding causal  
58 relationships and key processes that determine pool sizes and turnover rates of  
59 functional SOC pools (von Lützow and Kögel-Knabner 2009).

60 Soil warming experiments in the field have shown that warming generates a  
61 considerable short-term soil C loss (Lu et al. 2013, Romero-Olivares et al. 2017). This  
62 loss declines over time (e.g. > 2 years) (Romero-Olivares et al. 2017), although there is  
63 evidence that it can continue for longer (e.g. > 20 years) (Melillo et al. 2017). Also,  
64 indirect effects of warming on nutrient cycling (Pendall et al. 2004) or plant inputs  
65 (Bradford et al. 2016) may have cascading effects on SOC quality and quantity (Lu et  
66 al. 2013) and consequently on microbial decomposition of SOC, including recent plant-  
67 derived material (Hicks Pries et al. 2017) or older SOC (Vaughn and Torn 2019).  
68 Because ecosystems in alpine meadow are normally N limited (Hobbie et al. 2002),  
69 increased N released from decomposing SOC could stimulate plant productivity,  
70 thereby increasing ecosystem C storage (Moscatelli et al. 2008). However, field  
71 evidence suggests that soil microbial activity and biomass may also be N limited in  
72 some C-rich ecosystems (Mack et al. 2004, Rinnan et al. 2007). Therefore, increased N  
73 released from decomposition of SOC could further fuel microbial activity and decrease  
74 soil C storage. Besides, according to the priming effect hypothesis, the increase in N  
75 availability and labile C substrates promotes microbial C utilization, thereby increasing  
76 the degradation of less decomposable SOC and leading to a negative effect on soil C  
77 accumulation over the long term (Riggs and Hobbie 2016). However, it has been proven  
78 difficult to quantify bulk SOC stocks changes and organic matter composition directly  
79 (Sistla et al. 2013, Van Gestel et al. 2018). As alternatives, molecular-level techniques  
80 can detect how temperature affects plant and soil organic matter, microbial growth and

81 their community composition under climate warming (Feng et al. 2008, Xue et al. 2016,  
82 Pold et al. 2017).

83 Since the molecular structure of organic material has long been thought to determine  
84 long-term decomposition rates in soil humic substances, solid-state CPMAS <sup>13</sup>C NMR  
85 spectroscopy and diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy  
86 has been successfully applied in studies on changes of SOC chemical structure during  
87 organic matter decomposition without any physical or chemical destruction (Schmidt  
88 et al. 2011). ~~However, because of the large number of variables affecting a spectrum, it~~  
89 ~~is extremely difficult to obtain a complete and fine molecular structure from a single~~  
90 ~~spectrum without additional knowledge obtained by other spectroscopic techniques~~  
91 ~~(Ferrari et al. 2011). So, we employed another complementary molecular level analysis~~  
92 ~~called diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy, which is a~~  
93 ~~useful method for the characterization of organic matter (Olk et al. 2000) and humic~~  
94 ~~substances (Mao et al. 2008, Francioso et al. 2009), to explore potential shifts in SOC~~  
95 ~~composition in response to warming and N enrichment.~~ The structure of SOC could be  
96 very complex but by combining both techniques (~~DRIFT and~~ solid-state <sup>13</sup>C NMR and  
97 DRIFT) complementary information could be obtained on aromatic and aliphatic  
98 components (Ferrari et al. 2011).

99 Despite the importance of the response of SOC stocks to warming and N enrichment  
100 in the intact ecosystem, results about the chemical stabilization mechanisms (i.e.  
101 molecular structure of SOC) in alpine meadows remained controversial. ~~Despite the~~  
102 ~~importance of the response of SOC stocks to warming and N enrichment in the intact~~

103 ~~ecosystem, this has not been assessed empirically in alpine meadows.~~ This knowledge  
104 gap is significant because the Tibetan Plateau (TP) stores a large C pool, with 36.6 Pg  
105 C stored in the top 3 m of the soil, accounting for 23.5% of China's total organic soil-  
106 stored C and 2.5% of the global pool of soil C, which is of great importance in  
107 regulating future global climate change and C emission (Genxu et al. 2002, Ding et al.  
108 2019a). At the same time, the ~~TP Tibetan Plateau~~ has experienced climate warming at  
109 a rate that is two times faster than that in other regions worldwide and is predicted to  
110 lead to great soil C losses via microbial respiration in the future (Biskaborn et al. 2019).  
111 In addition, during recent decades, the ~~TP Tibetan Plateau~~ has been subject to high  
112 levels of N enrichment driven by agricultural activities (up to  $\sim 8.0 \text{ g m}^{-2} \text{ y}^{-1}$ ) (Gao et al.  
113 2007, Bo et al. 2012, Zhang and Fu 2020) and atmospheric N deposition ( $1 \text{ g N m}^{-2} \text{ y}^{-1}$ )  
114 (Lü and Tian 2007, Yu et al. 2019) with an annual rate of increase in deposition ( $0.053$   
115  $\text{ g N m}^{-2} \text{ y}^{-1}$ ) (Liu et al. 2013, Wang et al. 2019b), and this kind of enrichment has been  
116 shown to induce soil C loss and affect SOC stabilization in this typical N-constrained  
117 ecosystem (Xiao et al. 2021).

118 Since temperature is one of the main drivers of the vegetation growth and  
119 decomposition of organic matter, on-going climate change may alter biophysical  
120 processes with consequences for ecosystem functioning, especially in highly sensitive  
121 cold regions such as the alpine meadow on the ~~TP Tibetan plateau~~ (Piao et al. 2006,  
122 Yang et al. 2008). However, how and to what extent ~~physical-chemical~~ stabilization of  
123 SOC shifts may occur, and consequently SOC storage and C-climate feedback would  
124 respond to warming and N enrichment in an alpine meadow ecosystem, remains largely

125 unknown. Here, we used soils from a 9-year experiment with a two-way factorial design  
126 involving soil warming (daytime: 1.80°C; nighttime: 0.77°C) and control plots and N  
127 enrichments (0, 5, 10, and 15 g m<sup>-2</sup> y<sup>-1</sup>; marked as N0, N1, N2, and N3, respectively)  
128 (Liu et al. 2016) on the ~~TP Tibetan Plateau~~ to examine the changes in the stock and  
129 molecular structure of SOC.

130 We hypothesized that 9-years N enrichment and warming would affect SOC stock and  
131 the chemical structure of the SOC. N enrichment below a certain threshold may favor  
132 C sequestration in the alpine grassland ecosystem but warming may result in the C loss.  
133 And added N would stimulate hydrolytic enzyme activity while warming would repress  
134 enzyme activity. Finally, we hypothesized that variation in enzyme response to N and  
135 temperature would emerge as an important explanation for variability in the effect of  
136 added N and warming on SOC stock.

137

138

## 139 2. Materials and methods

### 140 2.1 Site description

141 Plot sampling was conducted in a grassland ecosystem located on the eastern edge  
142 of the Tibetan Plateau, Maqu County, Gansu Province, China (101°53' E, 35°58' N,  
143 3500 m above sea level, Figure 1 (NOAA 2015)), in August 2019. The grassland  
144 ecosystem of the TP covers an area of about 1.53 million km<sup>2</sup>, accounting for nearly  
145 60% of the total area of the TP (Liu et al., 2016). Alpine meadow is the main vegetation  
146 type in this area, the plant community is dominated by perennial herbaceous species  
147 of *Poaceae*, *Ranunculaceae*, and *Asteraceae*. The area of alpine meadow accounts for  
148 more than 44% of the area of alpine grasslands, and its SOC storage accounts for 56%  
149 of the SOC storage of alpine grasslands on the whole ~~TP~~ (Yang et al. 2008). The soil  
150 in the alpine meadow is classified as Mat-Cryic Cambisol (Hou et al. 2019). This region  
151 has a typical plateau continental climate. The mean annual precipitation is 620 mm, and  
152 most falls in the growing season (summer). The mean annual temperature is 1.2°C, with  
153 the lowest monthly mean temperature occurring in January (-10.7°C) and the highest  
154 monthly mean temperature occurring in July (11.7°C). During the past several decades,  
155 the mean annual temperatures in the region have risen at a rate of 0.58°C per decade  
156 (Liu et al. 2016). ~~The plant community is dominated by perennial herbaceous species~~  
157 ~~of *Poaceae*, *Ranunculaceae*, and *Asteraceae*.~~

### 158 2.2 Experimental design and soil sampling

159 A field-based warming experiment was established in June 2011 with a split-plot  
160 block design, in which both temperature (open-top chamber, +1.80°C in the daytime

161 and +0.77°C in the nighttime at the soil surface) and nitrogen (0, 5, 10, and 15 g m<sup>-2</sup> y<sup>-</sup>  
162 <sup>1</sup>, corresponding to N0, N1, N2, and N3, respectively) were manipulated, with six  
163 replicates per treatment (Liu et al., 2016). The 48 plots (8 treatments (N0, N1, N2, N3,  
164 WN0, WN1, WN2, WN3) with 6 replicates each treatment) with roughly the same  
165 species diversity and community structure were 5 × 5 m and were separated by 1 m  
166 from adjacent edges. Additional details can be found in our previous studies (Sun et al.,  
167 2023). Surface layer (0-10 cm) soils were collected from these 48 plots using a 4-cm-  
168 diameter auger in August 2019. Then, the fresh soil samples were transported to the  
169 laboratory on ice.

### 170 2.3 Soil analysis

171 Soil microbial biomass carbon (MBC) was measured according to the chloroform  
172 fumigation extraction method using a TOC analyzer (Multi N/C 3100, Analytik Jena  
173 GmbH, Germany) (Vance et al. 1987). The soil pH was determined in a 1:5 soil: water  
174 suspension with a pH meter (PHS-3D, Rex, Shanghai, China). Bulk density samples  
175 were dried at 105 °C for 48 h and calculated by dividing the oven-dried soil mass by  
176 the steel cylinder volume (100 cm<sup>3</sup>) because coarse fragments (stones or large roots)  
177 were not obtained in ring samples. For soil organic carbon (SOC) analysis, air-dried  
178 soil was ground and HCl-fumigated (Komada et al. 2008), and then the SOC  
179 concentration was determined with an elemental analyzer (FlashSmart, Thermo Fisher  
180 Scientific, USA). The SOC stocks (0-10 cm) were ~~are~~ calculated by multiplying the  
181 SOC concentration by the bulk density (Walter et al. 2016). At these 48~~each~~ sites, all

182 plants in three plots (50 × 50 cm) were harvested and dried to determine the  
183 aboveground biomass (AGB).

184 We measured the activity of four extracellular enzymes in the soil at an in situ pH  
185 (Nie et al. 2013). The absorbance of the C degradation enzymes β-D-cellubiosidase  
186 (CB), α-glucosidase (AG), β-glucosidase (BG) and β-xylosidase (XYL) were measured  
187 using a Tecan infinite M200 microplate fluorometer (Grodig, Austria) with 365 nm  
188 excitation and 460 nm emission filters. The activities were expressed in units of nmol  
189 h<sup>-1</sup> g<sup>-1</sup> dry soil. We combined CB, AG, BG and XYL into a C-degrading enzyme variable  
190 (EnC).

#### 191 2.4.5-SOC molecular structure examination using NMR spectroscopy

192 The soil samples used for NMR spectroscopy analysis were pretreated using HF (2%)  
193 to eliminate paramagnetic materials, e.g. ferric ion and manganese ion, that may affect  
194 the NMR signals (Skjemstad et al. 1994, Schmidt et al. 1997, Mathers et al. 2002). The  
195 solid-state NMR spectra (<sup>13</sup>C-CP-MAS) were recorded on a Bruker AVANCE III  
196 600 MHz instrument (Bruker Instrument Inc., Billerica, MA, USA). The acquisition  
197 conditions were set at frequency of 75.5 MHz, with 20 kHz spectra width, 5 kHz  
198 spinning speed, 2 ms contact time, and 2.5 s recycle time. The regions of 0–210 ppm  
199 spectra were plotted.

200 We examined seven chemical shift regions to represent the main C functional groups  
201 (Golchin et al. 1997, Sun et al. 2019). We report proportions of each chemical shift area  
202 and calculated 4 ratios indicative for the characteristics of soil organic matter. The alkyl  
203 C, the most persistent fraction of SOC, comes from original plant biopolymers (such as

204 cutin, suberin and waxes) or from metabolic products of soil microorganisms (Ussiri  
205 and Johnson 2003). As these materials decompose, the relative abundance of O-alkyl C  
206 in the litter materials decreases, and there is a progressive increase in alkyl C  
207 (Bonanomi et al. 2013). Therefore, the ratio of alkyl C to O-alkyl C ( $A/O-A = C_{0-45}/C_{60-90}$ )  
208 is an index represents the extent of SOC decomposition, the higher this ratio, the  
209 higher the decomposition degree of SOC (Wang et al. 2015). Aromaticity ( $C_{110-165}/C_{0-165}$ ),  
210 was used to indicate the complexity of molecular structure (Dai et al. 2001). The  
211 ratio of aliphatic C/aromatic C (Alip/Arom),  $C_{0-110}/C_{110-165}$ , also indicates the molecular  
212 structure of soil C, with higher Alip/Arom means less aromatic nuclear structure in  
213 humus. The hydrophobic C/hydrophilic C (HB/Hi) ratio,  $(C_{0-45} + C_{110-165})/(C_{45-110} + C_{165-210})$ ,  
214 was used to reflect the stability of soil aggregation (Spaccini et al. 2006,  
215 Wang et al. 2010). The higher values of HB/Hi ratio indicated that SOC was more  
216 hydrophobic (Cao et al., 2016), which, in turn, implied that SOC was more stable  
217 (Spaccini et al., 2006, Wu et al., 2014).

218

## 219 **2.54 Bulk soil organic matter composition using DRIFT spectroscopy**

220 However, bBecause of the large number of variables affecting a spectrum, it is  
221 extremely difficult to obtain a complete and fine molecular structure from a single  
222 spectrum without additional knowledge obtained by other spectroscopic techniques  
223 (Ferrari et al. 2011). So, we employed another complementary molecular-level analysis  
224 called diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy, which is a  
225 useful method for the characterization of organic matter (Olk et al. 2000) and humic

226 substances (Mao et al. 2008, Francioso et al. 2009), to explore potential shifts in SOC  
227 composition in response to warming and N enrichment. To characterize warming/N-  
228 induced changes in SOC composition, 6 mg of ground soil sample was examined by  
229 diffuse reflectance infrared Fourier transform spectroscopy (DRIFT). Mid-infrared  
230 spectra were recorded using a Bruker TENSOR 27 spectrometer (Billerica,  
231 Massachusetts, USA) from 4000 to 400  $\text{cm}^{-1}$  (average of 16 scans per sample at 4  $\text{cm}^{-1}$   
232 resolution). Infrared absorption bands were represented by functional groups.  
233 Infrared absorption bands were represented by functional groups as follows: aliphatic  
234 C–H (2900  $\text{cm}^{-1}$ ), aromatic esters, carbonyl/carboxyl C=O (1735–1720  $\text{cm}^{-1}$ ),  
235 aromatic C=C (1660–1600  $\text{cm}^{-1}$ , 1430–1380  $\text{cm}^{-1}$ ), lignin-like residues (1515–1500  
236  $\text{cm}^{-1}$ ), phenolic/cellulose (1260–1210  $\text{cm}^{-1}$ ), and aromatic C–H (880, 805, 745  $\text{cm}^{-1}$ )  
237 carbon (Niemeyer et al. 1992; Leifeld, 2006; Chatterjee et al. 2012). A summary of the  
238 absorption bands associated with different compound classes can be found in Figure S2.  
239 Additional details can be found in our previous studies (Ofiti et al. 2021).

#### 240 ~~2.5 SOC molecular structure examination using NMR spectroscopy~~

241 ~~The soil samples used for NMR spectroscopy analysis were pretreated using HF (2%)~~  
242 ~~to eliminate paramagnetic materials, e.g. ferric ion and manganese ion, that may affect~~  
243 ~~the NMR signals (Skjemstad et al. 1994, Schmidt et al. 1997, Mathers et al. 2002). The~~  
244 ~~solid state NMR spectra ( $^{13}\text{C}$  CP-MAS) were recorded on a Bruker AVANCE III~~  
245 ~~600 MHz instrument (Bruker Instrument Inc., Billerica, MA, USA). The acquisition~~  
246 ~~conditions were set at frequency of 75.5 MHz, with 20 kHz spectra width, 5 kHz~~

247 ~~spinning speed, 2 ms contact time, and 2.5 s recycle time. The regions of 0–210 ppm~~  
248 ~~spectra were plotted.~~

249 ~~We examined seven chemical shift regions to represent the main C functional groups~~  
250 ~~(Golchin et al. 1997, Sun et al. 2019). We report proportions of each chemical shift area~~  
251 ~~and calculated 4 ratios indicative for the characteristics of soil organic matter. The alkyl~~  
252 ~~C, the most persistent fraction of SOC, comes from original plant biopolymers (such as~~  
253 ~~cutin, suberin and waxes) or from metabolic products of soil microorganisms (Ussiri~~  
254 ~~and Johnson 2003). As these materials decompose, the relative abundance of O-alkyl C~~  
255 ~~in the litter materials decreases, and there is a progressive increase in alkyl C~~  
256 ~~(Bonanomi et al. 2013). Therefore, the ratio of alkyl C to O-alkyl C ( $A/O = C_{0-45}/C_{60-$~~   
257 ~~90) is an index represents the extent of SOC decomposition, the higher this ratio, the~~  
258 ~~higher the decomposition degree of SOC (Wang et al. 2015). Aromaticity ( $C_{110-165}/C_{0-$~~   
259 ~~165), was used to indicate the complexity of molecular structure (Dai et al. 2001). The~~  
260 ~~ratio of aliphatic C/aromatic C (Alip/Arom),  $C_{0-110}/C_{110-165}$ , also indicates the molecular~~  
261 ~~structure of soil C, with higher Alip/Arom means less aromatic nuclear structure in~~  
262 ~~humus. The hydrophobic C/hydrophilic C (HB/HH) ratio,  $(C_{0-45} + C_{110-165})/(C_{45-$~~   
263 ~~110 + C\_{165-210}), was used to reflect the stability of soil aggregation (Spaceini et al. 2006,~~  
264 ~~Wang et al. 2010).~~

## 265 **2.6 Regulating factors of SOC indicated by structural equation model**

266 ~~To access the direct and indirect effects of external factors on SOC stock, structural~~  
267 ~~equation modeling (SEM) was performed using the R package ‘plspm’ and~~  
268 ~~‘piecewiseSEM’ (Li et al. 2020). For this purpose, firstly, all data were tested for~~

269 ~~normality using the Kolmogorov–Smirnov test, and the non-normal variables were log-~~  
270 ~~transformed. Secondly, we established a prior model based on prior knowledge of~~  
271 ~~effects and relationships among the driving factors. Finally, we selected the best model~~  
272 ~~based on overall goodness of fits, including the chi-square ( $\chi^2$ ) statistic, degrees of~~  
273 ~~freedom (df), whole model *P* value, goodness of fit index, and the root mean square~~  
274 ~~error of approximation (Schermelleh-Engel et al. 2003).~~

## 275 **2.67 Statistical analysis**

276 All data are presented as the mean values of six field replicates. Any significant  
277 differences in soil physicochemical properties among the different N enrichment levels  
278 and warming treatments were identified by using two-way ANOVA followed by  
279 Tukey’s HSD post hoc test, with differences considered to be statistically significant at  
280  $P < 0.05$ . The statistical analysis was conducted using SPSS 13.0 and R version 3.5.1  
281 (R Foundation for Statistical Computing, Vienna, Austria, 2013). To access the direct  
282 and indirect effects of external factors on SOC stock, structural equation modeling  
283 (SEM) was performed using the R package ‘plspm’ and ‘piecewiseSEM’ (Li et al. 2020).  
284 For this purpose, firstly, all data were tested for normality using the Kolmogorov–  
285 Smirnov test, and the non-normal variables were log-transformed. Secondly, we  
286 established a prior model based on prior knowledge of effects and relationships among  
287 the driving factors. Finally, we selected the best model based on overall goodness of  
288 fits, including the chi-square ( $\chi^2$ ) statistic, degrees of freedom (df), whole-model *P*  
289 value, goodness of fit index, and the root-mean-square error of approximation  
290 (Schermelleh-Engel et al. 2003).

292

### 293 3. Results

#### 294 3.1 Bulk soil properties

295 N enrichment and warming have significant interaction on pH, AGB, EnC, C/N and  
296 SOC stock (P < 0.05, Figure 2). ~~Soil bulk density, SOC concentration, SOC stock, AGB,~~  
297 ~~and EnC and SOC stock~~ increased significantly under N enrichment but ~~the increment~~  
298 decreased with rising N addition concentration (P < 0.05, Figure 2b, 2c, 2f). ~~decreased~~  
299 ~~with N enrichment level as well as warming treatment (P < 0.05, Figure 2, Table S1,~~  
300 ~~Figure S1).~~ Warming exacerbates soil acidification and decreased the AGB, EnC, MBC  
301 and the SOC stock significantly. ~~Effects of N enrichment and warming treatment on soil~~  
302 ~~properties were shown in the Figure 2 and Table S1. Warming aggravated N-induced~~  
303 ~~soil acidification and microbial biomass C loss (P < 0.05, Figure 2a, 2e, 2f). ~~Soil bulk~~~~  
304 ~~density, SOC concentration, SOC stock, AGB and EnC increased significantly under N~~  
305 ~~enrichment but decreased with N enrichment level as well as warming treatment (P <~~  
306 ~~0.05, Figure 2, Table S1, Figure S1).~~ Both N enrichment and warming significantly  
307 decreased C/N ratio (P < 0.05, Figure 2d). Except for MBC, the NW interactions  
308 significantly altered soil physicochemical properties (Figure 2, Table S1).

#### 309 3.2 SOC speciation as seen by DRIFT and NMR spectroscopy

310 Changes in SOC molecular composition became apparent in diffuse reflectance  
311 infrared Fourier transform (DRIFT) and nuclear magnetic resonance (NMR) spectra  
312 (Figure 3, 4 and Figure S2, S3). In all N enrichment and warming treatments, there was  
313 a statistically non-significant change in the SOC composition and molecular structure  
314 observed by both DRIFT and NMR spectra. The relative abundance of

315 carbonyl/carboxyl C=O, ~~and~~ C=C aromatics compounds as well as lignin-like residues  
316 decreased slightly after N enrichment, not significantly though. The relative abundance  
317 of the phenolic/cellulose remained stable in all individual and interaction treatments  
318 ~~decreased (non-significant) after N enrichment, however, kept steady in warming plots~~  
319 (Figure 3 and S2).

320 The results of  $^{13}\text{C}$  NMR spectroscopy indicated the relative abundance of different C  
321 components (Table 1, Figure 4 and S3), showing that the proportion of the seven C  
322 functional groups did not change in soils under N enrichment and warming treatments.  
323 The relative proportions of the seven C functional groups were ~~similar~~ stable in the 8  
324 treatments in the following abundance order: O-alkyl C (mean 33%), followed by alkyl  
325 C (mean 22%), aromatic C (mean 12%), N-alkyl C (11%), carbonyl C and di-O-alkyl  
326 C (mean 8%), and finally phenolic C (mean 3%) (Table 1, Figure S3). The four indexes  
327 which can represent the extent of SOC decomposition observed by NMR spectra also  
328 showed no significant difference under all the N-enrichment and warming treatments  
329 (Figure 4), suggesting that SOC showed a similar degradation state at all N level  
330 enrichments and warming treatments as well as the interaction effects.

### 331 **3.3 Factors driving the SOC stocks**

332 We then developed a structural equation model (SEM) to assess the direct and  
333 indirect effects of soil variables on the SOC stocks (Figure 5). The SEM results revealed  
334 strong connections among global change, biotic, and edaphic factors (Figure 5),  
335 demonstrating a need to consider their interactions when predicting SOC stock and its  
336 response to individual and interactive effects of N enrichment and warming ~~N~~

337 ~~enrichment and warming~~. Overall, the SEM explained 44%, ~~and~~ 55% and 21% of the  
338 variance in SOC stock driven by N enrichment ~~and~~ warming treatment and the  
339 interaction effects, respectively. In both N and warming patterns, C-degrading enzymes  
340 showed an important indirect factor in regulating SOC stock. N enrichment had a  
341 positive effect on SOC stock by enhancing enzyme activities. In contrast, warming had  
342 a negative effect on SOC stock by inhibiting microbial enzymes. Besides, warming had  
343 a strong negative direct effect on SOC stock (Figure 5b). However, no significant direct  
344 or indirect pathways for the interaction effects of N and warming on SOC stock were  
345 observed (Figure 5C).

346

## 347 4. Discussion

### 348 4.1. Effects of warming and N enrichment on soil C pool size \_

349 It is suggested that small N inputs can decrease CO<sub>2</sub> emissions by changing the  
350 interaction between plants and soil microbes in N-limited ecosystems, for example, by  
351 increasing plant productivity and root biomass and then organic C inputs to the soil by  
352 promoting N availability and thus retard litter and SOC decomposition (Franklin et al.  
353 2003, Mo et al. 2008, Zhou et al. 2014). However, in an alpine grassland, Jiang et al.  
354 [2012](#) found that both plant growth and microbial activity were generally N-limited, but  
355 the ability of plants to capture soil inorganic N was much stronger than that of soil  
356 microorganisms. When N was added, increased N availability resulted in increased  
357 plant growth, microbial activity and plant biomass (Micks et al. 2004). Therefore, the  
358 decomposition of litter and SOM is enhanced by increasing the quantity of litter input  
359 or by elevating microbial activity, and consequently, soil functions would shift from C  
360 sequestration to C loss. The increased N has consequently reduced the soil pH by 0.26  
361 globally in only one decade, which may significantly influence the microbial  
362 community composition and activity and then SOC sequestration capacity (Geisseler  
363 and Scow 2014, Tian and Niu 2015, Raza et al. 2021). This speculation is consistent  
364 with our results that N input below ~~the critical level~~ [a threshold level \(for example, 10 g](#)  
365 [m<sup>-2</sup> in this study\)](#) may be beneficial for C sequestration in alpine meadows of the TP  
366 and can partly explain the patterns of SOC pool size under various N enrichment levels  
367 in this study. [Specifically, the SOC stock increased following N enrichment, but as the](#)  
368 [N addition concentration increased, this growth progressively diminished, eventually](#)

369 even disappearing. Our results revealed that alpine grassland ecosystems on the TP may  
370 become a potential C source under future scenarios of increasing N enrichment.

371  
372 In our study presented here, the 9 years of warming resulted in a very significant  
373 SOC loss of 14 to— 28 % (Figure 2 and S1). The ~~TP Tibetan plateau~~ stored large  
374 amounts of SOC because of the permafrost soil, where limited C decomposition has led  
375 to the accumulation of large SOC stocks (Hengl et al. 2014, Schuur et al. 2015).  
376 Previous studies showed that the vulnerability of soils with large C stocks derives from  
377 the high temperature sensitivity of C decomposition and biogeochemical restrictions on  
378 the processes driving soil C inputs (Davidson and Janssens 2006; García-Palacios et al.  
379 2021). Contrast with that, in soils with low initial C stocks, small losses coming from  
380 accelerated decomposition induced by rising temperature may be offset by concurrent  
381 increases in plant growth and soil C stabilization (Day et al. 2008, Macias-Fauria et al.  
382 2012, Crowther et al. 2015). However, in areas with larger SOC stocks, accelerated  
383 decomposition exceeds the potential C accumulation of plant growth, contributing to a  
384 significant C loss to the atmosphere (Luo et al. 2019).

#### 385 **4.2. Effects of N enrichment and warming on SOC chemical compositions**

386 SOC chemical composition not only is controlled by the chemistry of the plant  
387 materials input to the soil, but also by the microbial processing and degradation of SOC  
388 (Baldock et al. 1992). Although N addition can stimulate plant growth and increase  
389 litter fall, it can also accelerate or slow down microbial processing of plant residues,  
390 thus altering the chemical composition of SOC (Wang et al. 2019a). Surprisingly we

391 observed that the SOC molecular structure remained unchanged in all N enrichment  
392 and warmed plots (Figure 3, 4).

393 As the predominant chemical component of SOC across all treatments in our study,  
394 O-alkyl C is mainly composed of carbohydrates, peptides and other labile organic  
395 components derived from the fresh material, which could be preferentially degraded  
396 compared with more resistant components such as alkyl C (Simpson and Simpson, 2012,  
397 He et al. 2018). So, we hypothesized that this result could indicate that N and warming  
398 may have the same impact on the input of fresh plants on the TP Tibetan plateau. Unlike  
399 O-alkyl C, lipids represent the main source of alkyl C (aliphatic chains), which is  
400 derived from original plant biopolymers. Lignin and tannin represent the main source  
401 of aromatic C, together with phenolic C, mainly originating from lignin and amino acids  
402 of peptides (Baldock et al 1992). All these components are more resistant to microbial  
403 decomposition than labile O-alkyl C (Simpson and Simpson, 2012). Our results  
404 suggested that the proportions of the stable SOC chemical structures remained the same  
405 between the different N enrichment concentrations and warming treatments, indicating  
406 the synchronous degradation of SOC. The alkyl/O-alkyl ratio and aromaticity, normally  
407 regarded as the indicator of the relative stage of SOC degradation and has been widely  
408 used as an indicator to reflect the complexity of SOC chemical structure (Baldock et al.  
409 1992), exhibited no significant difference among N enrichment or warming  
410 treatments~~no change after 9-year N enrichment and warming~~, suggesting that all N  
411 levels and warming treatments exerted similar effects on the degradation of SOC and  
412 aromatic and complex molecular structure (Zhang et al. 2013).

413 Infrared spectroscopy of SOC showed a statistically non-significant change in the  
414 treated plots and the control plots, which were consistent with a previous study that  
415 showed the 4.5 years of +4 °C whole-soil warming did not change the relative  
416 abundance of carbonyl/carboxyl C=O, and C=C aromatics compounds in the surface  
417 soils (above 20 cm) from a forest (Ofiti et al. 2021). Collectively, the above results  
418 suggested that molecular structure of surface SOC may not be as sensitive to long-term  
419 warming as we thought before (Atanassova and Doerr 2011, Chen et al. 2018a). Surface  
420 SOC is dominated by recent (less transformed) plant-litter inputs, which is less  
421 degraded and transformed than subsoil SOC (Ofiti et al. 2021). The lack of change in  
422 plant- and microorganism-derived organic matter in the surface soil may be due to slight  
423 drying and warming near the surface (Soong et al. 2021) which could have inhibited or  
424 resulted in relatively less surface inputs. We noticed that warming significantly reduced  
425 ~~aboveground biomass~~AGB under N1 and N2 enrichments in this study (Figure 2).  
426 Compared with labile SOC, stable SOC can be more vulnerable to priming once  
427 microbes are provided with exogenous C substrates. This high vulnerability of stable  
428 SOC to priming warrants more attention in future studies on SOC cycling and global  
429 change (Zhang et al. 2022). Overall, ~~stable functional SOC molecular structure~~  
430 ~~indicated that soil warming and N enrichment had similarly affected easily~~  
431 ~~decomposable and stabilized SOC of this C-rich grassland soil despite the C loss.~~the  
432 stabilized functional SOC molecular structure suggests that soil warming and N  
433 enrichment had similarly affected the labile and stabilized SOC of this C-rich grassland  
434 soil at the level of chemical stability of organic C molecules, along with the C loss.

### 435 **4.3 Regulating factors of SOC stock**

436 Our interpretation that prolonged warming could reduce SOC storage is further  
437 supported by the simultaneous reduction of different C pool sizes characterized with  
438 various chemical structural complexity with long-term warming. Many previous studies  
439 have shown that microorganisms preferentially use the labile C pool for community  
440 utilization and turnover after short-term warming (Melillo et al. 2002, Kirschbaum  
441 2004). However, after the initial microbial assimilation of readily accessible SOC with  
442 warming, soil microorganisms can acclimate to C starvation through utilization of  
443 chemical less available C with continued warming (Chen et al. 2020). This  
444 transformation in microbial preference of C substrates can be facilitated by changes in  
445 C-degrading enzyme activities (Crowther and Bradford 2013).

446 O

447 Our results indicated that C-degrading enzymes could play a key role in regulating  
448 soil C storage ([Figure 5a, 5b](#)), which is in line with previous explanations for continued  
449 soil C loss with long-term warming, such as shifts in microbial community and  
450 physiology (Melillo et al. 2017, Metcalfe 2017), changes in microbial carbon use  
451 efficiency (Tucker et al. 2013), and increased microbial accessibility to litter and SOC  
452 (Doetterl et al. 2015, Bailey et al. 2019), which are all closely related to changes in  
453 microbial C-degrading enzyme activities. For example, warming decreased the  
454 abundance of lignin-derived compounds but increased ligninase activity in a mixed  
455 temperate forest (Feng et al. 2008). Although only cellulase activity was measured in  
456 our study, a previous meta-analysis study has shown significantly increasing ligninase

457 activity after warming, enhancing the evidence of microbial response to recalcitrant C  
458 pools and the evidence of simultaneous loss of different C fractions after long-term  
459 warming (Chen et al. 2018b). Microbial utilization of recalcitrant C pools could  
460 substantially accelerate overall soil C loss. This is –because depolymerization of these  
461 recalcitrant macromolecules increases microbial accessibility to litter and SOC that was  
462 previously protected by recalcitrant C pools before (Schmidt et al. 2011, Lehmann and  
463 Kleber 2015, Paustian et al. 2016).

464 While N fertilization exerts both direct and indirect impacts on SOC, its influence on  
465 carbonates is direct, leading to continuous losses. This not only serves as a source of  
466 atmospheric CO<sub>2</sub> (Kim et al., 2020; Raza et al., 2020; Zamanian et al., 2018) but also  
467 degrades soil structure and affects physical, chemical, and biological properties (Meng  
468 and Li, 2019). Under acidic conditions, this process induces fundamental changes in  
469 microbial community composition and enzyme activity critical for SOC stability  
470 (Rowley et al., 2020). In ecosystems characterized by N limitation, such as permafrost  
471 and peatland regions, N enrichment enhances N availability, accelerating the  
472 decomposition of labile organic C, especially in these otherwise C-rich ecosystems.  
473 This, in turn, results in decreased soil C availability (Craine et al., 2007; Janssens et al.,  
474 2010; Song et al., 2017). A previous study at our research site revealed a significant  
475 reduction in the soil labile C pool within the particulate organic C fraction with  
476 increasing N enrichment, signifying a decline in soil C availability (Chen et al., 2019).  
477 Our findings demonstrate that N enrichment significantly stimulates extracellular  
478 enzyme (EnC) activities and enhances microbial demand for C (Figure 2), aligning with

479 prior research indicating that added N stimulates the activity of soil cellulose-degrading  
480 enzymes (e.g., cellobiosidase (CB) and  $\beta$ -glucosidase (BG)) (Carreiro et al., 2000;  
481 Saiya-Cork et al., 2002; Chen et al., 2017). This stimulation may be attributed to the  
482 increase in C-acquiring enzymes resulting from heightened microbial demand for C,  
483 especially in N-limited ecosystems (Keeler et al., 2009). Previous studies suggest that  
484 N enrichment could induce C limitation by reducing plant allocation to fine root  
485 production, leading to lower C input into the soil (Treseder, 2008). Thus, we propose  
486 that factors beyond the thermal environment, such as N enrichment, can modulate soil  
487 enzymes and alter substrate availability. Moreover, these processes can mediate the  
488 strength of the soil C-climate feedback. Although N enrichment may increase soil C  
489 sinks, this increase may be counteracted by warming. In summary, our results suggest  
490 that warming and N enrichment have antagonistic interaction effects on SOC stock,  
491 with differential effects on the contribution of alpine meadows to the soil C pool, which  
492 may explain the result that the NW interaction did not show significant direct or indirect  
493 effects on SOC storage in the SEM results. All these results underscore the importance  
494 of considering soil C availability and enzymatic activity responses, which collectively  
495 determine the response of the C balance to multiple environmental changes, for a more  
496 comprehensive understanding of C storage dynamics.

497

498

499 **5. Conclusion**

500 Based on a 9-year warming (+1.80 °C in the daytime and +0.77 °C in the nighttime  
501 at the soil surface) and different level N enrichment experiment (0, 5, 10, and 15 g m<sup>-2</sup>  
502 year<sup>-1</sup>), we examined the responses of SOC stocks and their molecular components in  
503 a Tibetan alpine meadow ecosystem. In summary, our results show little effects of soil  
504 warming and N enrichment on the chemical composition of bulk soil despite ongoing  
505 C loss in the warmed plots of the study site (Figure 2). The SOC molecular structure  
506 suggested that the easily decomposable and stabilized SOC are synchronously similarly  
507 affected after 9-year warming and N treatments despite the large changes in SOC stocks.  
508 Given the long residence time of some SOC (Schmidt et al., 2011), the similar loss of  
509 all measurable chemical forms of SOC under global change treatments could have  
510 important climate consequences. ~~Permafrost soils contain half of global SOC stocks~~  
511 ~~(Ding et al. 2016, Hugelius et al. 2020)~~. While we found little effects of soil warming  
512 on SOC chemistry and molecular structure of bulk soil, consistent and long lasting  
513 changes could appear with prolonged soil warming and decreasing SOC stocks in the  
514 following years. In this process, the importance of enzyme activity must be emphasized,  
515 which has been found to be an important indirect factor in regulating changes in SOC  
516 stocks.

517

518 **Data availability**

519 The data that support the findings of this study and those not presented within the article  
520 and its Supplementary Information file are available from [https://doi.org/](https://doi.org/10.5281/zenodo.8289311)

948 **Figure and table legends**

949 **Figure 1.** Elevation mapLocation of the studied sites (a, the pentagram refers to the  
950 sampling point), photo of the alpine meadow (b) and the diagram of the warming  
951 treatment (open-top chamber) (c).

952 **Figure 2.** N and warming-induced changes in the soil properties (mean  $\pm$  SE, n = 6).  
953 Control (white bar) and warmed plots (black bar) at four different levels of simulated  
954 N deposition. N0, N1, N2, and N3 indicate N-enrichments of 0, 5, 10, and 15 g N m<sup>-2</sup>  
955 year<sup>-1</sup>, respectively. Parameters are: Soil pH (a); AGB, aboveground biomass (b); EnC,  
956 C-degrading enzymes (c); C/N, ratio of soil C concentration to N concentration (d);  
957 MBC, microbial biomass carbon (e); SOC, soil organic carbon stock (f).

958  
959 **Figure 33.** N and warming-induced changes in the relative abundance of different  
960 functional groups identifiable by diffuse reflectance infrared Fourier transform (DRIFT)  
961 spectroscopy in warmed and control plots (mean  $\pm$  SE, n = 6). The spectral regions were  
962 assigned to aromatic carbonyl/carboxyl C=O groups, aromatic C=C groups, lignin-like  
963 residues, and cellulose/phenolic. ~~No significant differences were found.~~

964 **Figure 44.** Four different SOC chemical structural complexity indexes (mean  $\pm$  SE, n  
965 = 6) from solid-state <sup>13</sup>C CPMASNMR spectra of soil samples from different treatments.  
966 A/O-A=Alkyl C/O-alkyl C; HB/HI = hydrophobic C/hydrophilic C; Alip/Arom =  
967 aliphatic C/aromatic C. ~~No significant differences were found.~~

968 **Figure 55.** The factors regulating the SOC stock under (a) N enrichment, ~~and~~ (b)  
969 warming treatment and (c) interactive effects of N and warming. In the structural

970 equation model (SEM) analysis, black arrows represent significant positive pathways,  
971 gray arrows represent significant negative pathways, and gray dashed arrows indicate  
972 nonsignificant pathways. Values next to the arrows represent standardized effect sizes  
973 with statistical significance ( $*P < 0.05$ ;  $**P < 0.01$ ;  $***P < 0.001$ ). The thickness of  
974 the arrow represents the standardized effect sizes. C-degrading enzyme indicate sum of  
975  $\beta$ -D-cellubiosidase (CB),  $\alpha$ -glucosidase (AG),  $\beta$ -glucosidase (BG) and  $\beta$ -xylosidase  
976 (XYL). Goodness-of-fit statistics for the model are shown as follows: (a),  $\chi^2 = 4.53$ ,  $P$   
977  $= 0.53$ , GFI = 0.99, RMSEA  $< 0.001$ ; (b),  $\chi^2 = 4.47$ ,  $P = 0.486$ , GFI = 0.99, RMSEA  $<$   
978  $0.001$ .

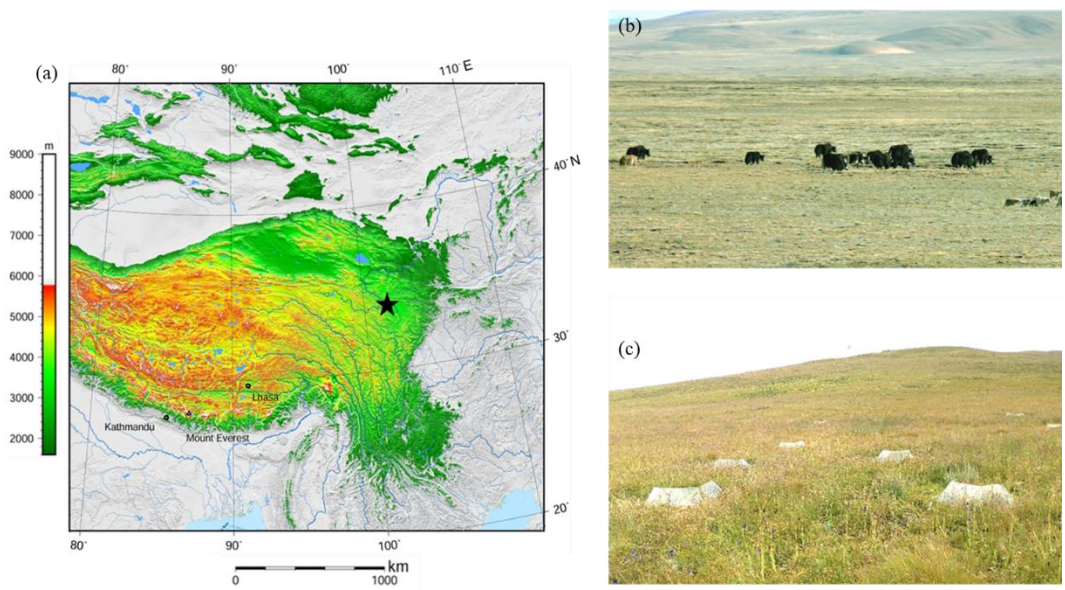

979 **Table 1.** Relative intensities (mean  $\pm$  SE, n = 6) of different carbon chemical shifts from  
980 solid-state  $^{13}\text{C}$  CPMAS NMR spectra of soil samples from N and warming treatments.

981 ~~No significant differences were found.~~
