21 **Abstract**

22 Increasing the marine CO₂ absorption capacity by adding alkaline minerals into the world's oceans is a promising
23 marine carbon dioxide removal (mCDR) approach to increase the ocean's CO₂ storage potential and mitigate
24 ocean acidification. Still, the biological impacts of dispersion of alkaline minerals needs to be evaluated prior to
25 its field deployment, especially the impacts of the initial discharge causing local and temporary extreme
26 alkalinity/pH changes. In this study, the toxicity effect on marine microalgae of two commonly used alkaline
27 minerals, calcium hydroxide (Ca(OH)₂) and magnesium hydroxide (Mg(OH)₂), by adding the same equivalent
28 molar concentration of hydroxyl ions. Cultures of marine green microalgae *Tetraselmis suecica* were exposed
29 to Ca(OH)₂ or Mg(OH)₂, in concentrations mimicking the initial high concentrations following a dispersion
30 scenario from a ship. A short-term exposure with high alkaline mineral concentration called "dispersion phase"
31 was followed by a dilution step and a "regrowth" phase over six days. There was no detectable effect of Mg(OH)₂
32 treatment on algae growth either after the dispersion phase or during the regrowth phase, compared to control
33 treatments. The Ca(OH)₂ treatment resulted in very few living algal cells after the dispersion phase, but a similar
34 growth rate was observed during the regrowth phase as was for the Mg(OH)₂ and control treatments. Standardized
35 whole effluent toxicity (WET) tests were carried out with a range of Mg(OH)₂ concentrations using a sensitive
36 marine diatom, *Skeletonema costatum*, which confirmed the relative low toxicity effect of Mg(OH)₂. Similar
37 biological effects were observed on natural microalgae assemblages from a local seawater source when applying
38 the same Mg(OH)₂ concentration range and exposure time used in the WET tests. The results suggest that
39 Mg(OH)₂ is relatively safe compared to Ca(OH)₂ with respect to marine microalgae.

40

41 **1 Introduction**

42 It is widely recognized that reducing the carbon dioxide emissions is not sufficient to accomplish the goals of the
43 Paris agreement of 2015, limiting global warming and ocean acidification (Pathak et al., 2022). Accordingly, there

44 is an urgent need for additional carbon dioxide removing approaches. Many different marine dioxide carbon
45 removal (mCDR) approaches are currently under evaluation (GESAMP, 2019), including artificial
46 upwelling/downwelling, nutrient fertilization, deep sea storage, electrochemical ocean carbon dioxide removal,
47 macroalgal/microalgal cultivation, marine ecosystem restoration, and ocean alkalinity enhancement (OAE). In
48 general, the principle of some of these approaches is based on acceleration of the natural process of absorption
49 and long-term storage of the excess atmospheric carbon dioxide by the ocean (Siegel et al., 2021, NASEM, 2021).
50 Among them, OAE has been put forward as one of the most promising approaches, because the acidification
51 remediation process itself triggers the reduction of the atmospheric carbon dioxide level (Renforth and Henderson,
52 2017). Hence, when the aqueous carbon dioxide deficit, generated by the addition of alkaline mineral, returns to
53 the initial equilibrium with atmospheric carbon dioxide, the final pH still remains slightly higher than the initial
54 pH, while calcite (most stable polymorph of calcium carbonate CaCO_3) level and aragonite (crystal structure of
55 calcium carbonate) saturation state are elevated. The aragonite saturation state is commonly used to track ocean
56 acidification (Qing-Jiang et al., 2015). The most studied alkaline minerals for OAE approaches are limestone
57 (CaCO_3), olivine ($\text{Mg,Fe}_2\text{SiO}_4$), sodium hydroxide (NaOH) and calcium hydroxide (Ca(OH)_2) (DOSI, 2022).
58 While the latter mineral has been evaluated for large scale application on the Mediterranean Sea (Butenschön et
59 al., 2021), a large-scale study involving field deployment of olivine in coastal waters off New York, USA is
60 currently being performed (Tollefson, 2023). Magnesium hydroxide has also recently been studied (Yang et al.,
61 2023; Hartmann et al., 2022). Its relatively low water solubility allows it to be added in a larger amount without
62 reaching harmful pH levels (Tollefson, 2023) and will potentially increase the durability of the alkalization
63 effect. Following this, in addition to raw material source scalability (Caserini et al., 2022), alkalization efficiency
64 and solubility are important criteria of OAEs (Hartmann et al., 2022; Ilyina et al., 2013). Moreover, the effects on
65 the aquatic environment need to be considered, including the biological impact of the initial discharge of high
66 alkaline mineral concentrations upon dispersion causing local and temporary extreme alkalinity/pH changes.
67 Accordingly, Bach et al., (2019) and Burns and Corbett (2020) pointed out that before approval of the alkaline
68 mineral dispersion at global scale, a risk assessment of the toxicity effect of the alkaline minerals on marine
69 organisms must be performed. Thus, it is crucial to consider not only the toxicity effect, if any, of the final low
70 alkaline mineral concentration after expected final dilution into ocean, but also the potential initial toxicity effect
71 of the initial hot spot discharge of the alkaline mineral on local organisms. These discharges upon dispersion
72 might be local and temporary, but it is important to consider that they would be applied at a global scale. These
73 local and temporary effects will potentially include increased cation levels (Mg^{2+} and Ca^{2+}), increased bicarbonate
74 and carbonate ions, pH increase or decrease of dissolved carbon dioxide. Perturbations that potentially form
75 impact hotspots, affecting phytoplankton species composition and growth, resulting in impacts higher up in the
76 food chain (Bach et al., 2019). Biological impacts will strongly depend on the spatial and temporal scale of
77 alkaline mineral dispersion, and studies must therefore use realistic alkaline mineral dispersion scenarios.

78 In this study, the biological impact of initial and temporary discharge of Mg(OH)_2 concentrations expected from
79 dispersion from a moving ship was compared to Ca(OH)_2 on marine microalga. This was done by exposing
80 cultured *Tetraselmis suecica* to the above alkaline minerals. The toxicity of Mg(OH)_2 was then further investigated
81 by using a sensitive microalgal species, in a recognized and standardized whole effluent toxicity (WET) test with
82 cultured diatom *Skeletonoma costatum*. Additional experiments were performed for further toxicity assessment
83 of Mg(OH)_2 on a natural microalgal assemblage from local seawater.

84

85 **2 Methods**

86 The study was performed in three steps. In the first step, the toxicity effect was studied by exposing marine alga
87 to alkaline minerals in successive concentrations mimicking dispersion from a moving ship. These experiments
88 were carried out with *Tetraselmis suecica*, a standard test organism in toxicity studies (Ebenezer et al., 2017; Li
89 et al., 2017; Seoane et al., 2014; Vagi et al., 2005). In the second step, toxicity effects of the alkaline minerals
90 were verified by a standardized WET ecotoxicology assay with *Skeletonoma costatum*, a more sensitive marine
91 algal species (Petersen et al., 2014, Wee et al., 2016), by using the recognized 72 hours growth inhibition test
92 (ISO 10253:2016). In the third step, the toxicity effect was studied by exposing a natural assemblage of marine
93 algal species from the Oslofjord, Drøbak, Norway to similar $Mg(OH)_2$ concentrations used in the WET tests. All
94 experiments were carried out in non-airtight containers to allow ambient CO_2 to re-equilibrate with seawater used
95 for the experiments.

96

97 **2.1 Exposure of *Tetraselmis suecica* to simulated dispersion of alkaline minerals from a moving ship**

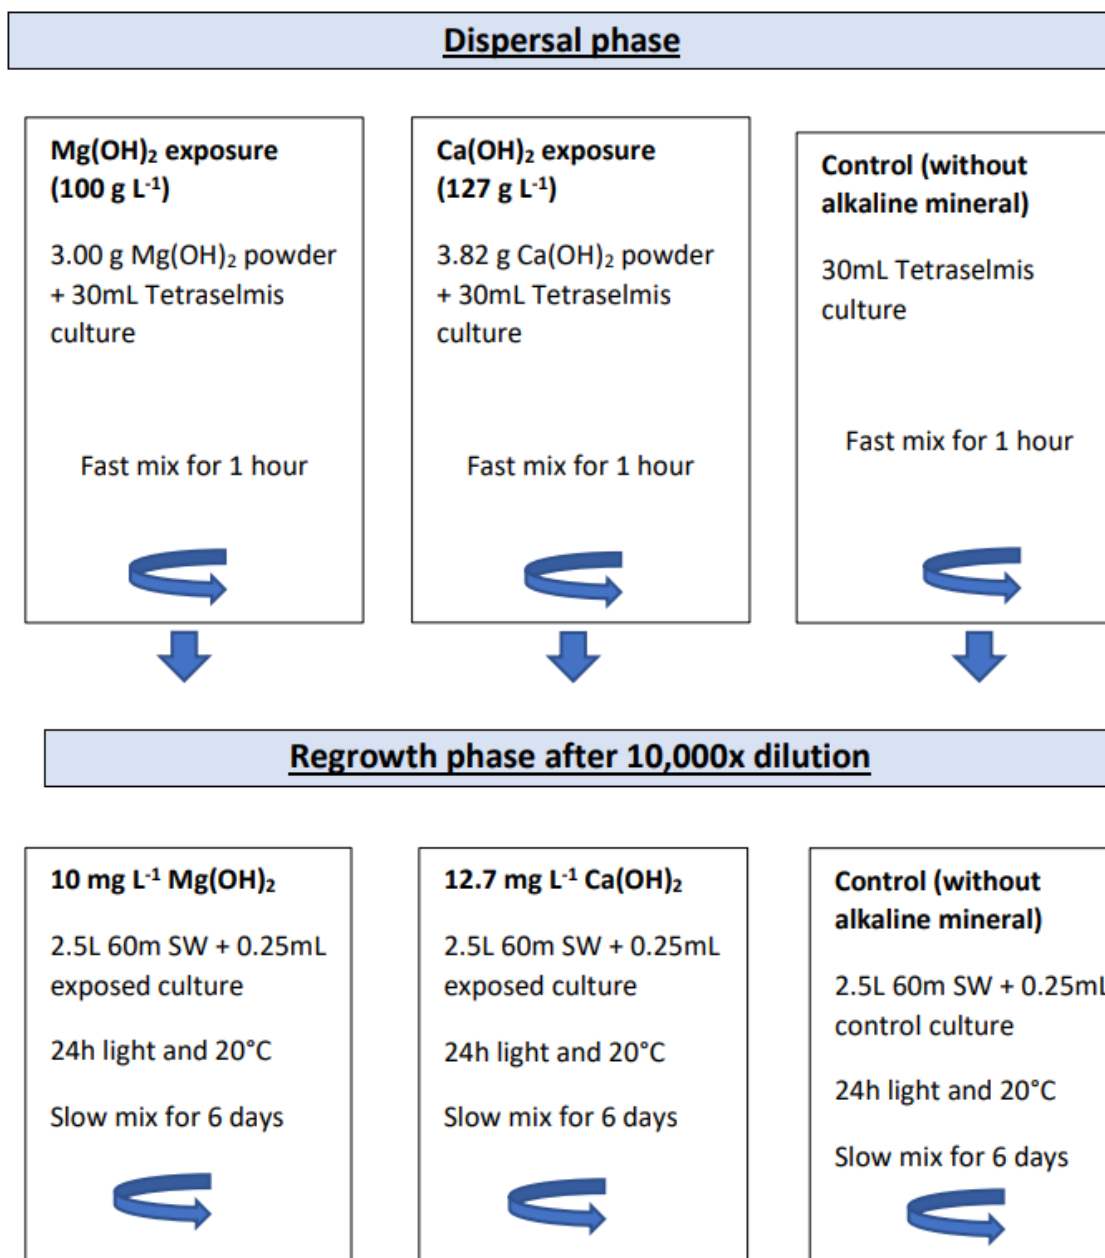

98 The expected distribution of a slurry of $Mg(OH)_2$ during its dispersion from the ship's discharge point on the
99 surface of the oceans was determined utilizing computational fluid dynamic (CFD) models (FORCE Technology
100 Inc., Denmark) and the Bottom RedOx Model (BROM) (Yakushev et al., 2017). In those models, both the forced
101 and natural mixing effects of the $Mg(OH)_2$ by the ship's propeller and physical oceanic processes (as waves,
102 convection, currents, etc.), respectively, in the ship's wake were simulated with different scenarios, including
103 propeller motion, velocity of tangential ocean currents, $Mg(OH)_2$ slurry discharge rate/dissolution rate/settling
104 rate, ship size and ship speed. Dilution was observed with an immediate minimum dilution rate of 1/1000 within
105 2 minutes after injection, followed by an additional minimum dilution rate of 1/7000 during the next 5 hours
106 and a final minimum dilution rate of 1/154000 during the following next 5 hours. Moreover, the tonnage capacity
107 and operating costs of a ship were also considered together with a final $Mg(OH)_2$ concentration target of $< 1 \text{ mg}$
108 L^{-1} . Taken together, this suggested that the dispersion rate of 500 kg s^{-1} would be the most realistic applicable
109 scenario. From this dispersion rate, it was concluded that marine organisms would be exposed to $< 100 \text{ g L}^{-1}$
110 approximately for less than one hour followed by a dilution to $< 10 \text{ mg L}^{-1}$ over a period of 10 hours. A simplified
111 formula for dilution factor based on volume discharge rate, vessel speed, water line depth, and time after
112 disposal was adopted in 1975 by the former International Maritime Consultative Organization (now the
113 International Maritime Organization). Subsequent studies found that the formula underestimated dilution factor
114 (e.g., Byrne et al., 1988). A modeling study similar to the CFD model reported here found that 100 kg s^{-1} and 10
115 kg s^{-1} $Ca(OH)_2$ addition resulted in 1/166 and 1/52 dilution, respectively, over a ~ 30 second period in the near
116 field of the wake zone (Caserini et al., 2021). Despite different ship dimensions and other model inputs including
117 dispersion rate, the dilution rate of 1/1000 over a 2 minute-period (this study) was similar for the near field of
118 the wake. Another study from the Cefas Burnham Laboratory, in which maximum (but safe levels of) discharge
119 of industrial waste from ships was sought after, calculated ship discharge dilutions rates of 1/10,000 within 5
120 minutes was possible (C.Vivian, pers.comm.), however maximum dispersal (discharge) is not the sole criteria for
121 ocean alkalinity enhancement, but rather an intermediate between a high dispersal rate for maximum input and

122 a low dispersal rate to promote maximum dissolution for the alkaline material of choice. To investigate biological
123 impact of $\text{Mg}(\text{OH})_2$ and compare it with $\text{Ca}(\text{OH})_2$, cultures of *Tetraselmis suecica* were exposed to these three
124 alkaline minerals during a simulated dispersion phase (as described above) followed by a regrowth phase (Fig 1).
125 In the dispersion phase, 30 mL of *Tetraselmis suecica* cultures (see further down), in exponential growth with a
126 cell density range within 2.6×10^5 - 1.4×10^6 cells mL^{-1} , were exposed to the alkaline minerals in 50 mL glass
127 beakers with continuous mixing at approximately 300 rpm with a magnetic stirrer (VELP Scientifica) for 1 hour.
128 To achieve similar concentrations of hydroxide ions in the different alkaline mineral treatments, algae were
129 exposed to either 100 g L^{-1} (or 1.7 M) of $\text{Mg}(\text{OH})_2$ or 127 g L^{-1} (or 1.7 M) of $\text{Ca}(\text{OH})_2$ (Fig.1).

130 In the regrowth phase, a subsample from each exposure media was diluted by 10,000 in local seawater and algal
131 cell density was monitored for 6 days. The dilution was performed by mixing 0.25 mL subsample to 2.5 L ambient
132 60 m deep seawater from the Oslofjord (Fig.1). The diluted subsamples were incubated in 3 L glass beakers in a
133 20°C temperature-controlled climate room with 24h light (2x 21W Philips Pentura Mini) and continuous mixing
134 with a magnetic stirrer (VELP Scientifica; 100 rpm approximately). The measured light intensity was within 20-
135 $60 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$. As the beakers were left uncovered, evaporated water volume was replaced every 24h
136 (except for week-end period) by an equivalent volume of ultrapure water. Effects of each alkaline mineral were
137 investigated in triplicates, including both the exposure and regrowth phases; resulting in total of nine bioassays
138 which were conducted in NIVA's laboratory in Oslo between November 2021 and January 2022. Each bioassay
139 study was conducted with one or two alkaline minerals in parallel and were repeated three times for each alkaline
140 mineral with new cultures of *Tetraselmis suecica*, except for two of the NaOH studies which were started on the
141 same day from the same algal culture. In addition, control bioassays excluding the addition of alkaline minerals
142 were performed in parallel to each alkaline mineral exposure including a dispersal phase followed by a regrowth
143 phase.

144 The ambient Oslofjord seawater was unfiltered and unsterilized water collected from 60 m depth just outside of
145 NIVA's marine research station located at Drøbak, 40 km south of Oslo. The water quality of this seawater is
146 stable year-round with a temperature of approximately 7°C . This water is representative of ocean regions; i.e. rich
147 in oxygen but poor in inorganic and organic contents, with 0.7 mg C L^{-1} of particulate carbon (POC), 1.1 mg C L^{-1}
148 of dissolved organic carbon (DOC), 6 mg L^{-1} of total suspended solids (TSS) and very low biological load with
149 $< 1 \text{ cell mL}^{-1}$ of algae and less than 500 CFU mL^{-1} of heterotrophic bacteria.

150

151

152 **Figure 1. Schematic illustration of the experimental set-up including the dispersion phase in 50 mL glass beakers**
 153 **followed by the dilution step and the regrowth phase of the exposed algal cells in 3 L glass beakers.**

154

155 Before exposure, the algae were collected from 1 L laboratory cultures of *Tetraelmis suecica* (NIVA-3/10;
 156 Norwegian Institute for Water Research, Oslo, Norway). At first, a 50 mL algal culture was prepared by semi-
 157 static cultivation in a 100 mL glass flask with 50 mL of autoclaved 20% Z8 culture medium with addition of
 158 vitamins (Kotai, 1972). The medium culture was inoculated with 5-10 mL of the *T. suecica* culture from NIVA's
 159 algal culture collection. The culture was incubated for ~1 week with fluorescent light tubes giving 20-60 μmol
 160 photons m⁻² s⁻¹, provided by cool-white fluorescence lamps (TLD 36W/950, Philips, London, UK), on an Infors
 161 Multicrom 2 incubator shaker (Infors AG, Bottmingen, Switzerland) at 20 ± 2°C, with orbital shaking at 90 rpm.
 162 After incubation, the culture was used for the inoculation of the 1L culture, except for ~10 mL which was held

163 back to start a new 50 mL culture by adding 40 mL of freshly prepared Z8 medium in same culture conditions as
164 described above. The 1 L culture was prepared by static cultivation with 1 L autoclaved 20 % Z8 medium with
165 addition of 1 mL L⁻¹ vitamins in 2-liter glass culture bottles. Approximately 40 mL of the 50 mL stock culture
166 was added to 1 L of medium. The culture was exposed to fluorescent light tubes of 20-60 μM m⁻² s⁻¹ and placed
167 in a 20°C temperature-controlled room for approximately one week.

168 The culture medium was prepared at least 24 h before usage to allow the equilibrium of media components. The
169 20% Z8 culture medium was made by mixing 0.2 L of Z8 medium into 0.8 L seawater, and shortly aired with CO₂
170 (< 1 min) to avoid precipitation of salts during autoclaving. The seawater was pasteurized seawater collected from
171 60 m depth in the Oslofjord. The medium was autoclaved for 15 minutes at 121°C. 1 mL L⁻¹ of vitamins stock
172 solution was added to the 20% Z8 medium (Kotai, 1972).

173 The studied alkaline minerals were magnesium hydroxide (CAS number: 1309-42-8), calcium hydroxide (CAS
174 number: 1305-62-0) and sodium hydroxide (CAS number: 1310-73-2); all with ≥97.0% purity. Magnesium
175 hydroxide (Batch No. 18417-01A) was provided by Negative Emission Materials, Inc. via a factory in Canada
176 producing the mineral by hydrometallurgy process and purification from natural magnesium silicate. The two
177 other alkaline minerals were purchased from Sigma-Aldrich (United Kingdom).

178 Density of living *Tetraselmis suecica* was determined by using the double staining method with Fluorescein
179 Diacetate (FDA) and 5-chloromethylfluorescein diacetate (CMFDA) (NSF, 2010). For each analysis, a 4 mL
180 subsample was collected and added 4 μl of 10% HCl, bringing the pH back to approximately 8 prior to staining.
181 The sample was then stained by adding 5 mM FDA and 2.5 mM CMFDA stains, as final concentration, and
182 incubated during 10 minutes in the dark. The stained *Tetraselmis suecica* cells were counted in triplicate (3x 1
183 mL) in a Sedgwick Rafter counting chamber using fluorescence microscope (Leitz Aristoplan, CoolLED pE-300
184 lite) with 485-530 nm excitation-emission filter combination and 100x magnification. The untreated algal samples
185 without alkaline mineral were used as positive controls. Both *T. suecica* and local diatoms are nearly 100%
186 stainable with these stains according to our 15 years of experience with this method in our local seawater. Samples
187 treated with sodium hydroxide (NaOH) to increase the pH to approximately 14 were used as negative controls.
188 No fluorescence could be observed in the negative controls, indicating an instant kill effect of the algal cells. This
189 study was focusing on the regrowth capability of the algal cells over several days indicated by increasing density
190 of fluorescent cells over time, compared to the control samples. This double staining method FDA/CMFDA is
191 based on the validation work of US Navy Research Laboratory to distinguish between living and dead cells after
192 disinfection by a ballast water treatment (Steinberg et al., 2011). This viability method is the only one recognized
193 by both International Maritime Organization (IMO) and United States Coast Guard (USCG) for approval of ballast
194 water discharge from 70,000 commercial ships at global scale (USCG, 2012, IMO, 2018).

195 Temperature, salinity and pH in the bioassays were measured in-situ by using a calibrated handheld WTW
196 Multimeter (WTW Multi 3620 IDS/3420 IDS displayer) with a conductivity probe (TetraCon 925 Xylem) and a
197 pH-electrode (SenTix 945P). The three-point calibration method with Hamilton pH-buffer solutions (4, 7 and 10)
198 was used for the calibration of the pH electrode, according to WTW instructions. The temperature in the test
199 waters varied within a range of 18-23°C for all experiments during the 6 days of regrowth phase as all experiments
200 were conducted at room temperature. The same temperature was registered in the alkaline test waters compared

201 to the corresponding control waters. The salinity of the test waters, with or without alkaline mineral, was around
202 32-33 PSU at the start of the 6 days regrowth phase for all experiments. The salinity stayed relatively stable for
203 most of the regrowth phase, except for the last day with an increase up to 35-36 PSU in average. This increase
204 was due to the evaporation of the test water at room temperature during the week-end period included at the end
205 of the 6 days of experimentation.

206

207 **2.2 Whole Effluent Toxicity (WET) test**

208 The WET test consisted of a marine algal growth inhibition test of 72 hours performed by NIVA's ecotoxicity
209 laboratory according to NIVA's standard procedure which is based on International Standard ISO 10253: Water
210 Quality – Marine algal growth inhibition test with *Skeletonema costatum* and *Phaeodactylum tricorutum*. In this
211 study, the diatom *S. costatum* (NIVA-strain BAC 1) was used as test organism.

212 A 100 mg L⁻¹ Mg(OH)₂ sample was diluted by using a modified ISO 10253 media, except that no Fe-EDTA stock
213 solution was added, as the tested compound Mg(OH)₂ showed to be affected by the presence of EDTA causing
214 precipitation of Mg(OH)₂. A preliminary study was made to verify the microalgal growth in this modified media.
215 Although less growth was observed when compared to normal ISO 10253 media, the specific daily growth rate
216 was still greater than 0.9 d⁻¹, which was considered as valid. A total of six concentrations of Mg(OH)₂ was tested
217 (1, 10, 25, 50, 75 and 100 mg L⁻¹). The test was performed with 15 mL samples in 30 mL glass vials. Each
218 concentration was tested in triplicate with 6 replicates for each control (one control set with normal ISO 10253
219 and another control set with modified ISO 10253); same number of replicates for analysis of blank samples but
220 without microalgae added.

221 All samples were inoculated with 5 x 10⁶ cells L⁻¹ of *S. costatum* from an exponentially growing laboratory culture
222 and incubated on a shaking table at 20±1°C under continuous illumination of 63 µM m⁻² s⁻¹ of photosynthetic
223 active radiation (PAR).

224 The cell density was determined by fluorescence with SpectraMax iD3 microplate after approximately 24, 48 and
225 72 hours (±2h). The fluorescence measurements were directly correlated to the algal density as a correlation factor
226 (r²) of 1 between the measured fluorescence and the cell density was calculated. The fluorescence values of the
227 exposed samples without algae (blanks) were measured to investigate potential biases caused by effect of the
228 tested substance on the fluorescence readings. As no such effects were detected, no further transformation of data
229 was necessary.

230 The temperature, pH and salinity were measured in-situ at the beginning and at the end of each WET test. The
231 temperature varied from 19.9 to 20.3°C for both WET tests. The pH at the start of the experiment varied from
232 8.089 to 9.376 in all vials for both tests, with increasing pH for increasing Mg(OH)₂ concentrations as expected.
233 The pH at the end of the experiment varied from 8.270 to 8.540 in all vials for both tests. The salinity was stable
234 with 32-35 PSU in all vials during the entire experiment for both tests.

235 **2.3 Natural assemblage of ambient marine algal test**

236 For the preparation of the ambient algal culture, either a 25 L grab-sample from the surface water of Oslofjord
237 was directly used for the test or a 2 L subsample was mixed to 2 L of 60 m deep seawater from Oslofjord for

238 further algal growth. For growth, the culture was incubated in a 5 L glass beaker in a climate-room at 20°C and
239 with constant light from fluorescent light tubes of 20-60 $\mu\text{M m}^{-2} \text{s}^{-1}$ for four days. The total density of algal cells
240 in the culture after incubation was approximately 1000 cell mL^{-1} . 500 mL of the culture was then mixed, in a 2 L
241 glass beaker with a magnetic stirrer at approximately 90 rpm, added to 1500 mL of a prepared $\text{Mg}(\text{OH})_2$
242 suspension resulting in $\text{Mg}(\text{OH})_2$ concentrations of 1, 10, 25, 50, 75 and 100 mg L^{-1} and initial algal density of
243 approximately 125-250 cell mL^{-1} . The $\text{Mg}(\text{OH})_2$ suspensions were prepared by mixing 2.7 mg, 27 mg, 66 mg,
244 133 mg, 200 mg or 270 mg of $\text{Mg}(\text{OH})_2$ in 1.5 L of unfiltered 60 m seawater from Oslofjord, with a magnetic
245 stirrer (300 rpm) over the night prior test start. The final solutions were slowly mixed continuously with a magnetic
246 stirrer at approximately 90 rpm, in a climate room at 20°C and with constant light from fluorescent light tubes of
247 20-60 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ for 72 hours. The water quality and algal density was monitored daily in each beaker,
248 using the same methods described in Chapter 2.1. For the control treatments, 500 mL of the ambient algal culture
249 was mixed with 1.5 L of unfiltered 60m deep seawater from Oslofjord, without $\text{Mg}(\text{OH})_2$, and incubated as
250 described above. Those tests were carried out on different weeks. Therefore, different control treatments applied
251 for 1-10 $\text{mg/L Mg}(\text{OH})_2$ treatments, 50-75 $\text{mg/L Mg}(\text{OH})_2$ treatments and 100 $\text{mg/L Mg}(\text{OH})_2$ treatment (see
252 Appendix C). Aliquots from the 100 mg L^{-1} treatment were collected from the initial timepoint and final timepoint
253 (t=3 d) for microscopy-based assessment of community composition by taxa.

254 255 **2.4 Data analysis**

256 Effects on *T. suecica* cell survival with $\text{Ca}(\text{OH})_2$, and $\text{Mg}(\text{OH})_2$ in simulated dispersions from a moving ship were
257 analyzed with a Student's t-test with type of alkaline mineral as independent grouping variable and % survival
258 compared to control treatments after the regrowth phase as the dependent variable.

259 In the WET test, the growth rate of *S. costatum* in each $\text{Mg}(\text{OH})_2$ sample was calculated from the logarithmic
260 increase of cell density from start to 72 hours, and expressed as percentage of the growth rate of control samples.
261 The concentrations causing 50% growth inhibition (EC_{50}) were calculated using a non-linear regression analysis
262 of the growth rate versus log cell concentration of control water (Hill, 1910; Vindimian et al. 1983). The non-
263 observed effect concentration (NOEC) and the lowest observed effect concentration (LOEC) were calculated
264 using Dunnett's test/ t-test for non-homogenous variance and Williams Multiple Sequential t-test for homogenous
265 variance.

266 Effects of $\text{Mg}(\text{OH})_2$ on the natural marine algal assemblage was investigated by dividing the different exposure
267 concentrations (1, 10, 25, 50, 75 and 100 mg L^{-1}) within two groups based on the LOEC (25 mg L^{-1}) from the
268 WET test. This resulted in one low concentration group (1, 10 and 25 mg L^{-1}) and one high concentration group
269 (50, 75 and 100 mg L^{-1}). The difference in % survival compared to control treatment between the high and low
270 concentration groups was investigated by a Student's t-test. This approach, with three replicates in each group,
271 allowed us to investigate effects of increased $\text{Mg}(\text{OH})_2$ concentrations.

272 **3 Results**

273 **3.1 Exposure of *Tetraselmis suecica* to simulated dispersion of alkaline minerals from a moving ship**

274 There were significant differences in living cells of *Tetraselmis suecica* (% survival compared to control
275 treatments; Table 1) between the alkaline minerals in the end of the regrowth phase (Student's t-test; t=2.9,

276 P<0.05), which were reflected in both the dispersion and the regrowth phases. At the start of the regrowth phase,
 277 the surviving cell densities in the Mg(OH)₂ treatments were similar to the ones observed in control treatment,
 278 while only one living cell was observed in one of the Ca(OH)₂ treatments (Day 0; Table 1). In the Mg(OH)₂ and
 279 Ca(OH)₂ treatments, algal cell densities increased during the regrowth phase (Day 1-6; Table 1). At the end of the
 280 regrowth phase, the algal cell densities in the Mg(OH)₂ treatments were similar as in control treatments, while the
 281 algal cell densities in Ca(OH)₂ treatments showed lower values than in control treatments (Fig.2).

319

320

321 **3.4 Natural assemblage of ambient marine algal species**

322 There was a significant difference in algal survival between the low concentrations group (1, 10 and 25 mg L⁻¹
 323 Mg(OH)₂) and the high concentrations group (50, 75 and 100 mg L⁻¹ Mg(OH)₂) after three days of exposure (t₍₄₎=
 324 5.8, P<0.01; Table 3). The analysis of the algal biodiversity composition in the 100 mg L⁻¹ Mg(OH)₂ suspension
 325 showed that the dominant surviving species were diatoms, including *Skeletonoma spp.*, with 80% and 94% of the
 326 total on Day 0 and Day 3, respectively. The biodiversity composition of the natural algal assemblage in beginning
 327 and at the end of the experiment for the 100 mg L⁻¹ Mg(OH)₂ treatment is given in Table 4.

328 **Table 3. Densities of living ambient algal cells (cell mL⁻¹), and their survival in percentage compared to corresponding**

335

336 **4 Discussion**

337 **4.1 Regrowth of *Tetraselmis suecica***

338 Similar algal densities were observed in both control and Mg(OH)₂ treatments at the beginning of the regrowth
 339 phase (Day 0, Table 1). This could be related to the short exposure time or to the low solubility of Mg(OH)₂; 0.012
 340 g L⁻¹ in pure water and around 0.008 g L⁻¹ in seawater (Yang et al., 2023). For comparison, the solubility of
 341 Ca(OH)₂ is 1.73 g L⁻¹ at 20-25°C. Accordingly, pH increased during the dispersion phase from approximately 8.0
 342 to 9.5 in the Mg(OH)₂ treatment which was lower compared to the expected pH of 12 in Ca(OH)₂ (Hartmann et
 343 al., 2022). However, pH was similar at the beginning of the regrowth period for both alkaline mineral treatments
 344 at ~8.3-8.6 (Fig. 3), giving similar potential regrowth conditions. The similar growth rates observed in controls,
 345 Mg(OH)₂-added and Ca(OH)₂-added treatments (Fig. 2) suggests that the algae previously exposed to 100 g L⁻¹
 346 Ca(OH)₂ were able to recover during this phase, at least when the algae were incubated in optimal culture
 347 conditions which might not be the case in natural oceanic conditions. Taken together, our data indicated high algal
 348 mortality in Ca(OH)₂ at the high concentrations of 127 g L⁻¹ during the first hour after the alkaline mineral

349 discharge from a moving ship, while no such toxic effect was observed when algae were exposed to $\text{Mg}(\text{OH})_2$.
350 This emphasizes that the local and temporary biological impact of alkaline mineral discharge in the initial phase
351 of the dispersion, in addition to alkalinity increase capability, needs to be considered when evaluating mCDR
352 strategies. Following this, it is important to keep in mind that in this study the toxicity comparison was based on
353 the criteria that each alkaline mineral should have the same hydroxide content, not taking in account difference in
354 alkalinity enhancement between the alkaline minerals.

355 **4.2 Growth inhibition test with *Skeletonoma costatum***

356 The results from the WET tests indicate that no growth inhibition of *S. costatum* was observed for $\text{Mg}(\text{OH})_2$
357 concentrations equal or below to 25 mg L^{-1} (NOEC). This is somewhat in accordance with the simulated dispersion
358 test, showing no growth inhibition of *T. suecica* during the 6 days of regrowth phase in 10 mg L^{-1} magnesium
359 hydroxide. The results from dispersion phase indicate no or low effect of 1 h of exposure with 100 g L^{-1}
360 magnesium hydroxide on *T. suecica*. The WET tests indicated a 50% growth inhibition effect of $\text{Mg}(\text{OH})_2$
361 concentrations (EC_{50}) between 82 and 111 mg L^{-1} after 72 h of exposure. This toxicity effect might be explained
362 by the temporary local CO_2 limitation impact, limiting the algal growth, due to increasing pH at these high alkaline
363 mineral concentrations. These EC_{50} values were much higher than $\text{Mg}(\text{OH})_2$ solubility of $\sim 12.2 \text{ mg L}^{-1}$ in pure
364 water (Yang et al., 2023). This raises questions regarding the cause of growth inhibition in the current study. It
365 has been suggested that trace metals, such as Cr, Mo, Ni, Pb in industrial and natural mineral products used as
366 alkaline minerals may impair organism growth (Bach et al., 2019; Hartmann et al., 2022). However, this might
367 not be the case here as the $\text{Mg}(\text{OH})_2$ powder used in this study was 97-98% ultrapure with $<0.01\%$ Ni or Cr.
368 Further studies are needed to verify and investigate the underlying mechanism for the growth inhibition of *S.*
369 *costatum* observed in the current WET tests.

370 **4.3 Regrowth test with assemblage of ambient algal species**

371 The same toxicity effect of $\text{Mg}(\text{OH})_2$ was observed in the tests performed with local marine algal species; i.e. no
372 significant toxicity effect of $\text{Mg}(\text{OH})_2$ concentrations below 25 mg L^{-1} but significant toxicity effect for
373 concentrations above 50 mg L^{-1} . *Skeletonoma spp.* was represented in the natural assemblage, as one of the
374 dominant species, while *Skeletonoma costatum* was used in the WET tests. This suggests that the results from the
375 WET tests using laboratory monoculture are still representative and applicable to similar species growing in
376 natural marine environment. The biological biodiversity (Table 4) of the local source water included both algal
377 species with hard cell wall made of silicate (diatoms as *Chaetoceros spp.* and *Skeletonoma spp.*), dinoflagellates,
378 monads, and unspecified flagellates. Thus, the results from the natural seawater test demonstrated that toxicity
379 effects observed with $\text{Mg}(\text{OH})_2$ on laboratory cultures might be applicable to a wider range of marine algal
380 species.

381 Thus, both the simulated dispersion scenario, the WET tests and ambient algal tests results suggest that $\text{Mg}(\text{OH})_2$
382 is a suitable alkaline enhancement mineral with respect to minimizing biological impacts on marine microalgae
383 during temporary and local extreme alkaline mineral discharge upon initial phase of the dispersion. While our
384 studies focused on marine microalgae, most other studies focused on the impact of OAE on organisms with
385 calcium carbonate containing parts and therefore sensitive to seawater acidification (Cripps et al., 2013, Fakhraee
386 et al., 2023, Gomes et al., 2016, Renforth and Henderson, 2017). Microalgae play an important role as primary
387 producers and impacts may be reflected in the entire marine ecosystem by affecting higher trophic-level

388 organisms, such as zooplankton and fish (Pauly and Christensen, 1995; Chassot et al., 2010). Accordingly,
389 microalgae are considered a useful and crucial indicator to evaluate the deterioration of environmental quality
390 (Lee et al., 2023). Thus, the current study applying microalgae assays to investigate the effects of $Mg(OH)_2$
391 suggests a low negative biological impact of $Mg(OH)_2$. However, it is important to keep in mind that these
392 laboratory assays, in addition to proximate the biological impact, are employed because they are relatively fast
393 and cost-effective. Thus, further studies on other functional groups and species are required for ensuring a low
394 impact of the OAE.

395

396 **5 Conclusion**

397 The bioassays based on initial local and temporary discharge simulation from scenario of alkaline mineral
398 dispersion from ship demonstrated that $Mg(OH)_2$ resulted in lower biological impacts on marine microalgae when
399 compared to $Ca(OH)_2$. Further laboratory studies must be completed to include a wider range of biological
400 biodiversity from different trophic levels and on a larger scale, such as in mesocosm studies, prior to field
401 deployment. The observed low negative biological impact of $Mg(OH)_2$ was confirmed by the standardized toxicity
402 test using a more sensitive marine algae species, but also by the tests with a wider range of local ambient marine
403 algal species. Additionally, there are potentially positive biological impacts of OAE, including remediation of
404 ocean acidification conditions by reducing pH and increasing saturation state of calcium carbonate, which were
405 not addressed in this study. Overall, these results indicate that $Mg(OH)_2$ is a suitable mineral for OAE application.
406 Still, it is important to consider that $Mg(OH)_2$ needs to maintain in suspension right below the ocean's surface to
407 be an effective OAE. Thus, in addition to further toxicity assessment of $Mg(OH)_2$ on aquatic environment,
408 techniques for optimization of its dissolution, including injection and distribution methods, in seawater needs to
409 be performed.

410

411

412 **6 Data availability**

413 The raw data are presented in Appendix A for the Tetraselmis test, in Appendix B for the WET tests and in
414 Appendix C for the natural algal assemblage test.

415

416 **7 Author contribution**

417 SD established the study plan, collected all data for data analyses and drafted the first version of this manuscript.
418 EH was involved in statistical analyzes and writing up the manuscript in collaboration with all authors. TN
419 performed the laboratory experiments (both dispersion and regrowth phases) and recorded the biological and
420 chemical analyses results. AK was involved in the quality assurance of the final manuscript.

421 **8 Competing interests**

422 NIVA received funding from Negative Emissions Material Inc. (Claymont, USA) to perform the study and from
423 Windward Fund (Washington, USA) for the writing of this publication after results disclosure agreement with

424 Negative Emissions Material Inc. The Windward Fund was founded in response to donors who expressed a desire
425 to be more connected to their peers' work, and to partner with experts in conservation nonprofit management to
426 execute bold initiatives. More info here: <https://www.windwardfund.org/about-the-fund/>. The authors declare that
427 they have no conflict of interest.

428 **9 Acknowledgments**

429 We would like to thank Dr. Evgeniy Yakushev (NIVA) for the development of the BROM model for magnesium
430 hydroxide specific application, Dr. August Tobiesen (NIVA) and Dr. Ana Catarina Almeida (NIVA) for their
431 expertise contribution during test plan and/or experiments execution of bioassays and/or WET tests. This material
432 is based upon work supported by funding from Negative Emissions Material Inc. (Claymont, USA) to perform
433 both the bioassays and the WET tests. NIVA has received funding from Windward Fund (Washington, USA) for
434 the writing of this publication under the Master Services Agreement No. Windward-NOR16-MSA-2023.

628 Appendix A – Raw data for the *Tetraselmis* bioassay studies

629

630 The Table 1 of the manuscript was generated from the raw data presented in Table A1.

631 **Table A1. Daily averages (n=3) of density of living *Tetraselmis suecica* (cell mL⁻¹) during the regrowth phase (Day 0 –**
 632 **Day 6) of the triplicate tests mimicking dispersion of the alkaline minerals Mg(OH)₂ or Ca(OH)₂ from a ship. Before**
 633 **the regrowth phase, algae were exposed to either 100 g L⁻¹ Mg(OH)₂ or 127 g L⁻¹ Ca(OH)₂ (resulting in similar molar**
 634 **concentration of hydroxide in the two alkaline mineral suspensions) for 1 hour. After this, subsamples from each**
 635 **treatment were diluted 10 000 times and algae growth were studied during a 6-day regrowth phase. Each alkaline**
 636 **mineral treatment and corresponding control treatment was assayed in triplicates. Values at day zero corresponds to**
 637 **1h after dilution and effects of each alkaline mineral was investigated in triplicates.**

Day/Replicate #	Density averages (n=3) of living <i>Tetraselmis suecica</i> (cell.mL ⁻¹)											
	Mg(OH) ₂						Ca(OH) ₂

645

646 Appendix B – Raw data for the WET tests

647

648 The Table 3 of the manuscript was generated from the raw data presented in Table B1 and Table B2. The
 649 complete laboratory analysis reports can be provided upon request.

650

651 **Table B1. Calibration data for WET Test 1 and for WET Test 2 to correlate the fluorescens measurements to the cell**
 652 **density of *Skeletonoma costatum*. The cell density was determined by fluorescence with SpectraMax iD3 microplate**
 653 **after approximately 72 hours ($\pm 2h$). The fluorescence measurements were directly correlated to the algal density as a**
 654 **correlation factor (r^2) of 1 between the measured fluorescence and the cell density was calculated.**

WET test 1- calibration data		WET test 2- calibration data	
Cell counts	Fluorescence	Cell counts	Fluorescence
9767	21129	7722	20909
34407	91377	28320	60447
105747	194737	169517	267903
581800	1533120	543317	623790

655

656 **Table B2. Fluorescens measurements of the control and Mg(OH)₂ treatments for WET Test 1 and WET Test 2 after**
 657 **72 hours exposure according to ISO 10253:2016. A total of six concentrations of Mg(OH)₂ was tested (1, 10, 25, 50, 75**
 658 **and 100 mg L⁻¹). Each concentration was tested in triplicate, with 6 replicates for each control (one control set with**
 659 **normal ISO 10253 and another control set with modified ISO 10253).**
