24 Key Points:

- 25 ● We perform a sensitivity analysis using the model FATES-Hydro to explore the co-  
26 ordination of leaf, xylem, and root hydraulic traits of pine in Southern Sierra Nevada.  
27 ● We find that rooting depth is the major control on water and carbon fluxes, and that deep-  
28 rooted pines with risky stomata have the highest GPP but also the highest drought  
29 mortality risk.  
30 ● Resolving both the plant water sourcing strategies and subsurface processes are critical to  
31 represent drought impacts on conifer forests.  
32

## Abstract

Extreme droughts are a major determinant of ecosystem disturbance, which impact plant communities and feed back to climate change through changes in plant functioning. However, the complex relationships between above- and belowground plant hydraulic traits, and their role in governing plant responses to drought, are not fully understood. In this study, we use a plant hydraulicshydraulic model, FATES-Hydro, to investigate ecosystem responses to the 2012-2015 California drought, in comparison with observations, for a site in the southern Sierra Nevada that experienced widespread tree mortality during this drought.

We conduct a sensitivity analysis to explore how different plant water sourcing and hydraulic strategies lead to differential responses during normal and drought conditions.

The analysis shows that:

- 1) deep roots that sustain productivity through the dry season are needed for the model to capture observed seasonal cycles of ET and GPP in normal years, and that deep-rooted strategies are nonetheless subject to large reductions in ET and GPP when the deep soil reservoir is depleted during extreme droughts, in agreement with observations.
- 2) risky stomatal strategies lead to greater productivity during normal years as compared to safer stomatal control, but lead to high risk of xylem embolism during the 2012-2015 drought.
- 3) for a given stand density, the stomatal and xylem traits have a stronger impact on plant water status than on ecosystem level fluxes.

Our study reveals the importance of resolving plant water sourcing strategies in order to represent drought impacts on plants, and consequent feedbacks, in models.

## 58 **1. Introduction**

59 Understanding plant water use strategies and the resulting ecohydrologic processes in  
60 forests is critical for predicting surface water and energy exchange, carbon dynamics and  
61 vegetation dynamics of water-constrained ecosystems in a changing climate. Mediterranean-  
62 type climates, as in California, are characterized by dry and hot summers and cool, wet winters,  
63 resulting in asynchronous supplies of energy and water. In addition to these climatic stresses,  
64 plants in California are further subject to high inter-annual variability in precipitation, and  
65 periodic severe drought events, such as the recent 2012 – 2015 drought, which led to widespread  
66 tree mortality (Fettig et al. 2019). Together, these two climatic constraints bring a unique  
67 challenge to the success of forests in California, which are likely to be exacerbated in a warming  
68 climate.

69 On evolutionary timescales, natural selection has led to a wide array of strategies and  
70 functional traits that allow plants to both grow and survive under a range of environment  
71 conditions (Grime 1977,1979; Coley et al. 1985; Westoby et al. 2002; Craine 2002; Reich et al.  
72 2003). Given the centrality of water sourcing on plant physiology, plant hydraulic traits play an  
73 important role in water-constrained ecosystems. Once absorbed by fine roots, water flows  
74 through the vascular system via coarse roots, stems, branches, to leaves where it evaporates  
75 through stomata. The rate of water flow through stems, and thus the supply to leaves, is  
76 determined by the hydraulic conductivity along this pathway. If the water potential of xylem  
77 tissue becomes too low, cavitation can occur and cause a loss of conductivity. Because this  
78 cavitation can damage the xylem network, trees have developed different strategies to mitigate  
79 this effect, all of which come at some cost. These strategies include 1) early stomatal closure or  
80 leaf deciduousness to reduce the flow of water, at the cost of reduced carbon intake; 2) building  
81 cavitation-resistant xylem, at the cost of increased hydraulic resistance; and 3) growing deep  
82 roots to access more moisture, at the cost of higher carbon investment. In this study, we focus on  
83 the potential hydraulic strategies that trees in Californian ecosystems use, with a particular  
84 emphasis on how the co-ordination of hydraulic functional traits at the leaf, stem, and root levels  
85 is critical to carbon assimilation, transpiration, and consequently, the productivity and the  
86 response of trees to drought (Matheny, Mirfenderesgi, and Bohrer 2017; Matheny et al. 2017;  
87 Mursinna et al. 2018a).

88 The traits that regulate stomatal conductivity are the most important hydraulic traits of  
89 leaves and the primary ones through which photosynthesis and transpiration are coupled.  
90 Stomatal behavior falls along a gradient between two extremes: stomata may close early during  
91 water stress to avoid the risk of hydraulic failure, or remain open to maximize carbon uptake  
92 while exposing xylem to a higher risk of embolism (Martínez-Vilalta, Sala, and Piñol 2004;  
93 McDowell et al., 2008; Skelton, West, & Dawson, 2015, Matheny et al. 2017). The sensitivity of  
94 stomata to water stress determines where the stomata operate along the safety-risky gradient, and  
95 thus the degree that carbon intake is traded for preventing the cavitation of xylem. Where the  
96 best stomatal strategy sits along the safety-risky gradient would depend on the physical  
97 environment.

98 The maximum hydraulic conductivity and the vulnerability to cavitation are the two key  
99 xylem hydraulic traits. Differences in the anatomy and morphology of the conductive xylem cell  
100 structure and anatomy (Hacke et al. 2017) lead to differences in maximum conductivity and the  
101 water potential at which cavitation starts to occur (Pockman & Sperry, 2000; Sperry 2003).  
102 Within the conifers, there are at least three mechanisms that lead to a tradeoff between xylem  
103 safety and efficiency. First is the morphology of the xylem conduit. It is widely acknowledged  
104 that narrow (or short) tracheid are safer than wider (or longer) tracheid but have lower  
105 conductance per sap area (Choat and Pittermann 2009). Second are the intervessel pit  
106 membranes. Thicker and less porous membranes prevent the spread of air but increase the  
107 hydraulic resistance of xylem (e.g. Li et al., 2016; Pratt & Jacobsen 2017). The third mechanism  
108 comes from the division of limited space (Pratt and Jacobsen 2017). With the same cross  
109 sectional area of conduits, vessels with a thicker cell wall provide stronger mechanical support,  
110 so that the conduits are less likely to collapse when xylem water potential becomes more  
111 negative, however this reduces the area that can be used for conduits transporting water. While  
112 these physiological constraints require that the tradeoff does exist to some extent, in many  
113 studies, this tradeoff appears to be weak, and there are certainly species that have both safe and  
114 efficient xylem. Further, there are many other plant traits that can affect the safety, such as wood  
115 density (Pratt and Jacobsen 2017), pit anatomy (Sperry & Hacke 2004, Lens et al. 2011), and  
116 biochemistry (Gortan et al. 2011). These traits can have large variation among the different  
117 plant types. The tradeoff will be weakened when grouping plants in at a coarse scale, e.g., by  
118 biomass, families and/or across a range of geological and climatic region. But when focusing on

119 certain species in a particular region, the tradeoff becomes stronger, as demonstrated by many  
120 local studies (e.g. Barnard et al. 2011, Corcuera et al. 2011, Baker et al. 2019). For example,  
121 Kilgore et al. (2021) shows that there is a clear safety-efficiency tradeoff ~~of the across~~ pine  
122 trees in a specific location in the western US. Thus, while we acknowledge that there are many  
123 exceptions to the xylem safety-efficiency tradeoff, it is a useful framework for examining plant  
124 strategies for dealing with drought.

125 The traits that govern the hydraulic function of plant root systems are also critically  
126 important, but the least understood ~~and,~~ studied, and quantified. These traits include the  
127 rooting depth, the root to shoot ratio, the vertical and lateral distribution of roots, and the fine  
128 root density and ~~diameters~~ diameter, all of which are related to water uptake (Canadell et al.,  
129 2007, Allen 2009, Reichstein et al., 2014, Wullschlegel et al. 2014). In general, species with  
130 deeper roots can access water at greater depths, that is unavailable to more shallowly rooted  
131 species (Jackson et al., 1996; Canadell et al., 1996). The vertical root distribution can affect the  
132 water uptake and thus the evapotranspiration (ET) pattern during the dry-down period (Teuling,  
133 Uijlenhoet, and Troch 2006). This in turn affects the seasonal distribution of water over the soil  
134 depth, and thereby the resilience of plants to seasonal droughts (Yu, Zhuang, and Nakayamma  
135 2007). The vertical root distribution is also a means of belowground niche differentiation (Ivanov  
136 et al. 2012; Kulmatiski and Beard 2013), whereas the extent of the lateral root distribution  
137 dictates the competition ~~off~~ for water (Agee et al. 2021). Whether a plant can benefit from  
138 having deep roots is related to the plant's leaf and xylem hydraulic traits (e.g. Johnson et al.  
139 2018, Mackay et al. 2020), thus requiring coordination of rooting and hydraulic traits.

140 Given the strength of the Mediterranean-type climate of California, the coordination of  
141 rooting and hydraulic strategies will play a critical role for ~~the~~ forest dynamics. However, the  
142 interplay of rooting and hydraulic strategies and their impact on ecosystem processes haven't  
143 been well understood. In this study, we address this question at the Soaproot site (CZ2) of the  
144 southern Sierra Nevada of California as the study area. The CZ2 site was strongly affected by the  
145 2012-2015 drought, with extremely high tree mortality rates (~90% of the pine died) (Fettig et al.  
146 2019). While the 2012 - 2015 drought was widespread across California, the highest rates of tree  
147 mortality occurred in the southern Sierra Nevada, centered around an elevation similar to this site  
148 (1160 m to 2015 m, Asner et al. 2016, Goulden and Bales 2019). This mid-elevation region is

149 also characterized by the highest forest productivity along an elevation gradient from foothill  
150 woodlands to subalpine forest (Kelly and Goulden 2016). This leads us to ask whether strategies  
151 associated with high productivity have exposed trees to high mortality risk under prolonged  
152 drought.

153 Specifically, here we use the Functionally Assembled Terrestrial Ecosystem Simulator, in  
154 a configuration that includes plant hydraulics (FATES-Hydro), to explore the tradeoffs  
155 associated with differing hydraulic strategies, and in particular their implications for plant  
156 productivity and risk of drought-induced mortality. We conduct a sensitivity analysis, using  
157 FATES-Hydro in comparison with observations from the CZ2 eddy covariance site, to  
158 investigate how stomatal, xylem and rooting strategies affect the ecosystem and physiologic  
159 processes of the forest, and whether that may explain the high rates of both productivity and  
160 drought-associated mortality of conifers at CZ2. We note that this is not an exhaustive  
161 model parameter sensitivity study. The main purpose is to use a sensitivity analysis to  
162 explore scientific questions around hydraulic trait tradeoffs.

## 163 2. Methods

### 164 2.1 Study site

165 The Soaproot site is a 543-ha headwater catchment at 1100m elevation (37°2.4' N,  
166 119°15.42' W), which is at the lower boundary of the rain–snow transition line with warm, dry  
167 summers and cool, wet winters (Geen et al. 2018). The mean annual temperature is about 13.8°C  
168 (Goulden et al., 2012). Under normal conditions, the annual precipitation is about 1300 mm, but  
169 during a dry year, the precipitation can drop to 300-600mm. (Bales et al. 2018). The site is a  
170 ponderosa pine (*Pinus ponderosa*) dominated conifer ecosystem exhibiting high productivity  
171 (Kelly and Goulden (2016) reported 2.1 tC/ha/year average annual gross stem wood production  
172 averaged). Other species include California black oak (*Quercus kelloggii* Newberry), and incense  
173 cedar (*Calocedrus decurrens*).

174 Soils at the Soaproot site are mainly of the Holland (fine-loamy, mesic Ultic Haploxeralfs)  
175 and Chaix (coarse-loamy, mesic Typic Dystroxerepts) series, which are representative of soils  
176 across a similar elevation band of the western Sierra Nevada (Mooney and Zavaleta 2003). Soils  
177 of the Holland series have sandy loam surface texture and underlying Bt horizons with sandy

178 clay loam textures, while soils of the Chaix series have sandy loam textures throughout the  
179 profile. The regolith depth is estimated to be 15m (Holbrook et al., 2014). The total porosity over  
180 the whole regolith depth of the site is estimated to be 1620 mm and the total available storage  
181 porosity (plant accessible water storage capacity), which is the difference in volumetric water  
182 content between field capacity and permanent wilting point ( $\sim -6\text{Mpa}$ ) to be 1400 mm (Klos et  
183 al. 2017). The available water storage capacity is approximately  $0.20\text{ cm}^3\text{ cm}^{-3}$  in the upper  
184 regolith (0–5 m depth) which decreases to  $0.05\text{ cm}^3\text{ cm}^{-3}$  or less in the lower regolith (below 5  
185 m depth) (Holbrook et al., 2014).

186 An eddy-covariance flux tower was installed at this site in September 2010. The elevation  
187 of the tower is 1160 m above sea level. Instruments on the flux tower track changes in carbon  
188 dioxide, water vapor, air temperature, relative humidity, and other atmospheric properties. We  
189 compare the simulated gross primary productivity (GPP) and latent heat flux with the flux tower  
190 measurements over the period from 2011 to 2015 (Goulden and Bales 2019). We computed the  
191 Root Mean Square Error (RMSE) of the hourly mean diurnal cycle of each month. This allows  
192 us to examine the capacity of FATES-Hydro to predict the carbon and water fluxes. The  
193 transpiration efat the site contributed to the majority of the ET as indicated by the  
194 measurements from an adjacent catchment, as well as the fact that the site is fully vegetated with  
195 an annual LAI around 3 to 4.

196

## 197 2.2 FATES-Hydro model and parameterization

### 198 2.2.1 The FATES-Hydro model

199 FATES is a cohort-based, size- and age-structured dynamic vegetation model, where long-  
200 term plant growth and mortality rates and plant competition emerge as a consequence of  
201 physiological processes. In the model, multiple cohorts grow on the same land unit, share the soil  
202 water, and interact with each other through light competition. FATES is coupled within both the  
203 CLM5 (Lawrence et al., 2019) and the ELM (Golaz et al., 2020) land surface models (LSMs). In  
204 this study, FATES is coupled with the CLM5. FATES-Hydro is a recent development of the  
205 FATES model (Fisher et al., 2015; Koven et al., 2020), in which a plant hydro-dynamic module,  
206 originally developed by Christoffersen et al. (2016), wasis coupled to the existing

207 photosynthesis and soil hydraulic modules. [FATES-Hydro is described in more detail by Xu et](#)  
 208 [al., \(in review, https://doi.org/10.5194/egusphere-2023-278 \) and its supplementary material.](#)

209 Conceptually, plant hydraulic ~~modules~~models can be broadly grouped into ~~to~~ two  
 210 types. The first group represents the plant hydraulic system as analogous to an electrical circuit  
 211 (e.g. Mackay et al. 2011, [Huang et al. 2017](#), Eller et al. 2018, Kennedy et al. 2019). The total  
 212 resistance of the plant is calculated from the resistance of each compartment using Ohm's law.  
 213 There is no storage of water in the plants and the transpiration from plants at any given time step  
 214 is considered to ~~be completed~~come directly from soil storage. The second group represents  
 215 plant hydraulics by a series of connected porous media, corresponding to each plant  
 216 compartment (e.g. Bohrer et al. 2005); , Janott et al. 2011, Xu et al., 2016, Christoffersen et al.,  
 217 2016). The porous media model takes into account the water storage in the plant. The flow  
 218 between two adjacent compartments is driven by the difference in the water potential, mediated  
 219 by the hydraulic conductivity. FATES-Hydro falls in the second group. The various models in  
 220 the second group differ in the exact formulas used to describe the pressure-volume and pressure-  
 221 conductivity relations, as well as different numbers and arrangement of nodes within the soil-  
 222 plant-atmosphere system.

223 In FATES-Hydro, for each plant cohort, the hydraulic module tracks water flow along a  
 224 soil-plant-atmosphere continuum of a representative individual tree based on hydraulic laws,  
 225 and updates the water content and potential of leaves, stem, and roots with a 30 minute model  
 226 time step. Water flow from each soil layer within the root zone into the plant root system is  
 227 calculated as a function of the hydraulic conductivity as determined by root biomass and root  
 228 traits such as specific root length, and the difference in water potential between the absorbing  
 229 roots and the rhizosphere. The vertical root distribution is based on Zeng's (2001) two parameter  
 230 power law function which takes into account the regolith depth:

$$231 \quad Y_i = \frac{0.5(e^{-r_a z_{li}} + e^{-r_b z_{li}}) - 0.5(e^{-r_a z_{ui}} + e^{-r_b z_{ui}})}{1 - 0.5(e^{-r_a z} + e^{-r_b z})} \quad Y_i = \frac{0.5(e^{-r_a z_{li}} + e^{-r_b z_{li}}) - 0.5(e^{-r_a z_{ui}} + e^{-r_b z_{ui}})}{1 - 0.5(e^{-r_a z} + e^{-r_b z})}$$

232 (Eq 1)

233 where  $Y_i$  is the fraction of fine or coarse roots in the  $i$ th soil layer,  $r_a$  and  $r_b$  are the two  
 234 parameters that determine the vertical root distribution,  $Z_{li}$  is the depth of the lower boundary of

235 the  $i$ th soil layer, and  $Z_{ui}$  is the depth of the upper boundary of the  $i$ th soil layer, and  $Z$  is the total  
 236 regolith depth. The vertical root distribution affects water uptake by the hydrodynamic model by  
 237 distributing the total amount of root, and thus root resistance, through the soils.

238 The total transpiration of a tree is the product of total leaf area (LA) and the transpiration  
 239 rate per unit leaf area (J). ~~In this version of FATES-Hydro, we adopt the model developed by~~  
 240 ~~Vesala et al. (2017)~~In this version of FATES-Hydro, we adopt the model developed by Vesala et  
 241 al. (2017) to take into account the effect of leaf water potential on the within-leaf relative  
 242 humidity and transpiration rate:

$$E = LA \cdot J \quad (\text{Eq 2a})$$

$$J = \rho_{am} \frac{(q_l - q_s)}{1/g_s + r_b} \quad (\text{Eq 2b})$$

$$q_l = \exp\left(\frac{k_{LWP} \cdot LWP \cdot V_{H2O}}{R \cdot T}\right) \cdot q_{sat} \quad (\text{Eq 2c})$$

$$E = LA \cdot J \quad (\text{Eq 2a})$$

$$J = \rho_{am} \frac{(q_l - q_s)}{1/g_s + r_b} \quad (\text{Eq 2b})$$

$$q_l = \exp\left(\frac{w \cdot LWP \cdot V_{H2O}}{R \cdot T}\right) \cdot q_{sat} \quad (\text{Eq 2c})$$

245 where  $E$  is the total transpiration of a tree,  $LA$  is the total leaf area ( $\text{m}^2$ ),  $J$  is the transpiration per  
 246 unit leaf area ( $\text{kg s}^{-1} \text{m}^{-2}$ ),  $\rho_{am}$  is the density of atmospheric air ( $\text{kg m}^{-3}$ ),  $q_l$  is the within-  
 247 leaf specific humidity ( $\text{kg kg}^{-1}$ ),  $q_s$  is the atmosphere specific humidity ( $\text{kg kg}^{-1}$ ),  $g_s$   
 248 is the stomatal conductance per leaf area,  $r_b$  is the leaf boundary layer resistance ( $\text{s m}^{-1}$ ),  $k_{LWP}$   
 249  $w$  is a scaling coefficient (unitless), which can vary between 1 and 7, and here we use a value of  
 250 3;  $LWP$  is the leaf water potential (Mpa),  $V_{H2O}$  is the molar volume of water ( $18 \times 10^{-6} \text{m}^3$   
 251  $\text{mol}^{-1}$ ),  $R$  is the universal gas constant, and  $T$  is the leaf temperature (K).

252 The sap flow from absorbing roots to the canopy through each compartment of the tree  
 253 along the flow path (absorbing roots, transport roots, stem, and leaf) is computed

254 according to Darcy's law in terms of the plant sapwood water conductance, the water potential  
 255 gradient:

$$256 \quad Q_i = -K_i [\rho_w g(z_i - z_{i+1}) + (\Psi_i - \Psi_{i+1})] \quad Q_i = -K_i [\rho_w g(z_i - z_{i+1}) + (\Psi_i - \Psi_{i+1})]$$

257 (Eq 3)

258 where  $\rho_w$  is the density of water;  $z_i$  is the height of the compartment(m);  $z_{i+1}$  is  
 259 the height of the next compartment down the flow path (m);  $\Psi_i$  is the water potential of the  
 260 compartment(Mpa);  $\Psi_{i+1}$  is the water potential of the next compartment down the flow  
 261 path(Mpa); and  $K_i$  is the hydraulic conductivity of the compartment ( $\text{kg} \cdot \text{Mpa}^{-1} \cdot \text{m}^{-1}$   
 262  $\text{s}^{-1}$ ). The hydraulic conductivity of the compartments is by the water potential and maximum  
 263 hydraulic conductivity of the compartment through the pressure-volume (P-V) curve and the  
 264 vulnerability curve (Manzoni et al. 2013, Christoffersen et al. 2016).

265 The plant hydrodynamic representation and numerical solver scheme within FATES-  
 266 HYDRO follows Christoffersen et al. (2016). We made a few modifications to accommodate the  
 267 multiple soil layers and to improve the numerical stability. First, to accommodate the multiple  
 268 soil layers, we have sequentially solved the Richards' equation for each individual soil layer,  
 269 with each layer-specific solution proportional to each layer's contribution to the total root-soil  
 270 conductance. Second, to improve the numerical stability, we have an option to linearly  
 271 extrapolate the PV curve beyond the residual and saturated tissue water content to avoid the rare  
 272 cases of overshooting in the numerical scheme under very dry or wet conditions. Third,  
 273 Christoffersen et al. (2016) use three phases to describe the PV curves: 1) dehydration phases  
 274 representing capillary water (sapwood only), 2) elastic cell drainage (positive turgor), and 3)  
 275 continued drainage after cells have lost turgor. Due to the possible discontinuity of the curve  
 276 between these three phases, it leads to the potential for numerical instability. To resolve this  
 277 instability, FATES-HYDRO added the Van Genuchten model (Van Genuchten 1980, July and  
 278 Horton 2004) and the Campbell model (Campbell 1974) as alternatives to describe the PV  
 279 curves.

280 In this study, we use the Van Genuchten model because of two advantages: 1) it is simple,  
 281 with only three parameters needed for both curves, and 2) it is mechanistically based, with both  
 282 the P-V curve and vulnerability curve derived from a pipe model, and thus connected through  
 283 three shared parameters:

$$\Psi = \frac{1}{-\alpha} \cdot \left( \frac{1}{Se^{1/m}} - 1 \right)^{1/n} \quad (\text{Eq 4a})$$

$$FMC = \left( 1 - \left( \frac{(-\alpha \cdot \Psi)^n}{1 + (-\alpha \cdot \Psi)^n} \right)^m \right)^2 \quad (\text{Eq 4b})$$

$$\Psi = \frac{1}{-\alpha} \cdot \left( \frac{1}{Se^{1/m}} - 1 \right)^{1/n} \quad (\text{Eq 4a})$$

$$FMC = \left( 1 - \left( \frac{(-\alpha \cdot \Psi)^n}{1 + (-\alpha \cdot \Psi)^n} \right)^m \right)^2 \quad (\text{Eq 4b})$$

286 where  $\Psi$  is the water potential of the media (xylem in this case) (Mpa);  $FMC$  is the  
 287 fraction of xylem conductivity,  $K/K_{\max}$ , (unitless);  $\alpha$  is a scaling parameter for air entry point  
 288 (Mpa<sup>-1</sup>),  $Se$  is the dimensionless standardized relative water content as  $Se = (\theta - \theta_r) / (\theta_{sat} - \theta_r)$   
 289 with  $\theta$ ,  $\theta_r$ ,  $\theta_{sat}$  are volumetric water content (m<sup>3</sup> m<sup>-3</sup>), residual  
 290 volumetric water content, and saturated volumetric water content correspondingly; and  $m$  and  $n$   
 291 are dimensionless (xylem conduits) size distribution parameters. The model assumes that xylem  
 292 conductance can be restored as xylem water content increases due to increased water availability  
 293 after a dry period without any hysteresis in the FMC curve.

294  
 295 The stomatal conductance is modelled in the form of the Ball-Berry conductance model  
 296 (Ball et al. 1987, Oleson et al. 2013, Fisher et al. 2015):

297

$$g_s = b_{slp} \frac{A_n}{c_s / P_{atm}} \frac{e_s}{e_i} + b_{opt} \beta_t$$

298

(Eq 5)

299

300

301

302

303

304

305

306

where  $b_{slp}$  and  $b_{opt}$  are parameters that represent the slope and intercept in the Ball-Berry model, correspondingly. These terms are plant strategy dependent and can vary widely with plant functional types (Medlyn et al. 2011). The parameter  $b_{opt}$  is also scaled by the water stress index  $\beta_t$ .  $A_n$  is the net carbon assimilation rate ( $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) based on Farquhar's (1980) formula. This term is also constrained by water stress index  $\beta_t$  in the way that the  $V_{\text{cmax},25}$  is scaled by  $\beta_t$  as  $V_{\text{cmax},25}\beta_t$  (Fisher et al. 2018).  $c_s$  is the  $\text{CO}_2$  partial pressure at the leaf surface (Pa),  $e_s$  is the vapor pressure at the leaf surface (Pa),  $e_i$  is the saturation vapor pressure (Pa) inside the leaf at a given vegetation temperature when  $A_n = 0$ .

307

308

309

The water stress index  $\beta_t$ , a proxy for stomatal closure in response to desiccation, is determined by the leaf water potential adopted from the  $\text{FMC}_{\text{gs}}$  term from Christoffersen et al. (2016):

310

$$\beta_t = \left[ 1 + \left( \frac{\Psi_l}{P50_{gs}} \right)^{ags} \right]^{-1}$$

311

(Eq 6)

312

313

314

315

316

317

318

319

where  $\Psi_l$  is the leaf water potential (MPa),  $P50_{gs}$  is the leaf water potential of 50% stomatal closure, and  $ags$  governs the steepness of the function. For a given value of  $ags$ , the  $P50_{gs}$  controls the degree of the risk of xylem embolism (Christoffersen et al. 2016, Powell et al. 2017). A more negative  $P50_{gs}$  means that, during leaf dry down from full turgor, the stomatal aperture stays open and thus allows the transpiration rate to remain high and xylem to dry out, which thus can maintain high photosynthetic rates, at the risk of exposing xylem to embolism and thus plant mortality. Conversely, a plant with a less negative  $P50_{gs}$  will close its stomata quickly during leaf dry down, thus limiting transpiration

320 and the risk of xylem embolism and mortality associated with it, at the cost of reduced  
321 photosynthesis.

322

### 323 2.2.2 Sensitivity analysis and Parameterization

324 The goal of this analysis is to better understand how coordinated aboveground and  
325 belowground hydraulic traits determine plant physiological dynamics and the interplay between  
326 ecosystem fluxes and tissue moisture during the extreme 2012-2015 drought at the Soaproot site.  
327 We thus conduct a global sensitivity analysis on selected hydraulic parameters to explore the  
328 linkages of aboveground and belowground hydraulic strategies. We use a full-factorial design for  
329 the parameter sensitivity analysis in order to best investigate the relationships between  
330 parameters. Because this design requires a relatively small set of parameters or groups of  
331 parameters to vary, we chose parameters that represent the major axes of relatively well-  
332 understood stomatal, xylem and rooting mechanisms/strategies that control the hydraulic  
333 functioning of trees. We set the values of these parameters within the realistic (allowable  
334 biological) range based on online database, and literatures where the species and physical  
335 environment are as close to our system as possible. We list other major parameters and their  
336 estimates that are not varied in the sensitivity analysis (table 2). We acknowledge that the biggest  
337 disadvantage of this study is the lack of sufficient field data to constrain the model. This is a  
338 result of using a natural drought as an experiment of opportunity, which because it was not  
339 anticipated, did not allow for as coordinated planning as would be the case in an experimentally-  
340 manipulated drought. The trees at that site had all died by the time we started this study.

341 The parameters that we vary here are 1) the pair of  $r_a$  and  $r_b$ , which control vertical root  
342 distribution as deep vs shallow roots, 2) two sets of xylem parameters ( $P_{50x}$ ,  $K_{max}$ ,  $m$ ,  $n$ , and  $\alpha$ )  
343 that jointly represent two distinct xylem strategies: efficient/unsafe and inefficient/safe xylem  
344 within the range observed for temperate conifer trees, and 3) the stomatal parameter  $P50_{gs}$ , which  
345 represents the stomatal strategy along a risky to safe gradient (Table 1). The ranges of root  
346 parameters are chosen so that the effective rooting depth, above which 95% of root biomass  
347 stays, varies from 1m to 8m which is the possible range at the Soaproot site, as indicated by  
348 current knowledge of the subsurface structure (see Klos et al., 2017). Note, here we refer to a  
349 higher proportion of roots in deep subsurface layers as ‘deep rooting’ (e.g effective rooting depth

350 = 8m;  $r_a=0.1, r_b=0.1$ ) as compared to ‘shallow rooting’ (e.g effective rooting depth = 2;  $r_a=1, r_b=5$ )  
351 which represents a larger proportion of fine roots in upper layers (Figure 1a).

352 The safety-efficiency tradeoff of xylem has been widely discussed in the literature (e.g.  
353 Gleason et al. 2016; Hacke et al. 2006, 2017; Martnez-Vilalta, Sala, and Piol 2004). Given that  
354 we don’t have any measurements that can be used to a generate vulnerability curve at our study  
355 site, we consult the literature (Domec et al. 2004, Barnard et al. 2011, Corcuera et al. 2011,  
356 Anderegg and Hillerislambers 2016 , Baker et al. 2019, Kilgore et al. 2021) for observed curves  
357 from sites that have-are as similar both in climate (e.g mean annual precipitation and  
358 temperature) and in the set of conifer species (P. Ponderosa) to our study site as possible and  
359 the, as well as values of xylem traits ( $K_{max}$  and  $P50_x$ ) of Ponderosa pine in temperate  
360 regions of the TRY database (Kattge et al. 2020) to determine the two hypothetical vulnerability  
361 curves representing the safe/inefficient and unsafe/efficient xylem strategies. We set the  
362 parameters of the van Genuchten model to represent these two sets of P-V and vulnerability  
363 curves as showingshown in Fig1b and 1c. It is worth noting that with the same  $K_{max}$  and  $P50$ ,  
364 the exact shape of the vulnerability can be different depends differ depending on the  
365 formula used and parameter values. However, this should not be an issue in our study because  
366 the vulnerability curve is mainly constrained by P50 and Kmax. Second, given that there is a  
367 large range of variation of in the observed/ measured values, the effect caused by the exact  
368 shape of the curves is minor. Third, since the objective of our study is not to accurately predict  
369 mortality, but rather to examine the effect of different combination of stoma, xylem, and root  
370 strategies, even if the shape of our vulnerability curve is not the most accurate, as long as the  
371 curve captures the overall pattern of the pressure-conductivity relation, it will not affect the  
372 relative outcome of this study.

373 We follow the theory of Skelton et al. (2015) to define safe vs. efficient stomatal strategy.  
374 In FATES-Hydro, there are two key stomatal parameters:  $P50_{gs}$  and  $a_{gs}$ . Here, we only vary  
375  $P50_{gs}$  while keeping  $a_{gs}$  as a constant because the objective here is to choose the parameters that  
376 are relatively well understood and to catch the safe vs. risky strategies as described by Skelton et  
377 al., rather than to exhaust the parameter space throughout within the model. In essence, the  
378 different combinations of  $P50_{gs}$  and the shape parameter ( $a_{gs}$ ) can generate similar stomatal  
379 response curves. For example, a small negative  $P50_{gs}$  with small  $a_{gs}$  would result in a flat

380 stomatal response curve, which is similar to a large negative  $P50_{gs}$  combined with a large  $a_{gs}$ .  
381 Further,  $P50_{gs}$  is well understood and has more observed data, while  $a_{gs}$  is less studied and barely  
382 has any observed data. With a given  $a_{gs}$ , the variance of  $P50_{gs}$  ~~along~~ for a given  $P_{xylem}$   
383 value, vulnerability curve controls the degree of embolism risk, from a ‘risky’ strategy, where  
384  $P50_{gs}$  is equals to ~~or~~ lower than  $P_{xylem}$ , to a ‘conservative’ strategy, where  $P50_{gs}$  equals a is  
385 higher than  $P_{xylem}$ . The  $P_{xylem}$ s in Skelton et al.’s (2015) are for Fynbos species, therefore are not  
386 appropriate for our study because our species are pine trees, a woody plant. Trees have woody  
387 tissue which contribute to strengthen the conduits and make them less easy to collapse when  
388 embolized, hence allow their stomata to be riskier than herbaceous plants. From the observed  
389  $P50_{gs}$  and xylem traits of closely related pine species in the TRY database (Kattge et al. 2020)  
390 and elsewhere in the literature (Bartlett et al. 2016), as well as the observed soil water potential  
391 at the study site, we choose to vary  $P50_{gs}$  between  $P50_{xylem}$  and  $P20_{xylem}$ , (correspondingly the  
392 point at which xylem have lost 50% and 20% of their maximum conductivity).

393 The emergent behavior of FATES or any model with dynamic ecosystem structure can  
394 make analysis of physiological rate variation difficult, as the stand structure will respond and  
395 thus also vary when parameters are changed. Here, we wanted to first understand the direct trait  
396 control in the absence of structural differences. To overcome ~~this~~ complication of the dynamic  
397 structure, we use a reduced complexity configuration for running the model which we refer to as  
398 ‘static stand structure’ mode. To investigate dynamic competitive effects when growth and  
399 mortality will be the next step. In this mode, the stand structure is initialized from observed  
400 forest census data, and subsequently is fixed, i.e. the model does not permit plant growth or death  
401 to change the vegetation structure. This allows the direct assessment of hydraulic and  
402 physiological parameter variation in the model without the consequent feedback loops associated  
403 with varying ecosystem structure. The stand structure is initialized with census data from the  
404 CZ2 site (Table S1) and thus includes multiple cohorts of different sized trees. Because this  
405 type of model configuration ignores prognostic plant mortality, in the interest of being able to  
406 compare across simulations where mortality rates might otherwise be very high, we use the loss  
407 of xylem conductivity as a measure of mortality risk of conifer trees at CZ2, which has widely  
408 been used as an indicator of drought mortality of forest (e.g. Hammond et al., 2019).

409 To force the model with an atmospheric upper boundary, we use the Multivariate Adaptive  
410 Constructed Analogs (MACA) climate data (Abatzoglou and Brown 2012) from 2008 – 2015 of  
411 a 4km x 4km grid covers the study area. The daily average MACA data are disaggregated to 3-  
412 hourly climate data (see Appendix S2 in Buotte et al. 2018 for detail). ~~To assess the credibility  
413 of model predictions, we compare the model to observations of gross primary productivity (GPP)  
414 and ET, both as inferred from eddy covariance (Goulden and Bales 2019). Here, we use the  
415 Latent Heat Flux (LH) is used as a proxy of ET. We set the initial soil water content to be  
416 75% of saturated water content, close to field capacity. We believe this is a realistic value  
417 because the model is initialized in January, when the study area has high precipitation and trees  
418 are all in a dormant status, and in a year when there is not drought. We also tried to initialize the  
419 soil with higher water content (e.g. saturation), but did not find any differences, as the extra  
420 water drained quickly in the winter when transpiration is low.~~

### 421 3. Results

#### 422 3.1 ~~Impact on~~ Sensitivity of GPP and ET to parameter perturbations

423 The parameter sensitivity analysis shows that in a monthly-mean flux comparison, the  
424 simulations with deep roots give a better match to the overall observed pattern of GPP and ET  
425 (Fig. 2). The simulated transpiration contributes to 90% of the ET in general. The deep-rooted  
426 cases better capture the seasonality (e.g. the peak time) and the declining trend of observed GPP  
427 from 2011 to 2015. The deep-rooted cases also match fairly well the observed ET. The simulated  
428 GPP of shallow-rooted cases are higher than observed values during wet seasons (Dec. to Mar.),  
429 but much lower than the observed values during dry season of the pre-drought period. The  
430 simulated ET of shallow-rooted cases are overall lower than the observed values. To quantify  
431 this assessment, we computed Root Mean Square Error (RMSE) from the hourly mean GPP and  
432 ET of each month each year of all the 40 cases (Fig. S2). We choose RMSE as it is a common  
433 and compact metric of assessing model performance, though we note that other metrics could in  
434 principle be used, each of which has different advantages and disadvantages (e.g. Collier et al.,  
435 2018). The RMSE of GPP and ET decreases with both effective rooting depth and P50gs for  
436 both xylem strategies (Fig. 3). The P50gs has less impact on the RMSE of GPP ~~offor~~ the case  
437 with safe xylem than on that of the case with efficient xylem. In terms of GPP, the effective  
438 rooting depth of 6.5m gives the best fit, as indicated by the darkest color (RMSE of GPP =

439 1.12gC/m<sup>2</sup>/s, RMSE of ET = 250 W/m<sup>2</sup>), suggestingunderscoring the importance of deep roots  
440 in maintaining transpiration and photosynthesis during the dry season, as well as the role of deep  
441 roots in increasing the relative decline in these fluxes during the drought.

442 Among the parameters we varied in the sensitivity analysis, the vertical root distribution  
443 has the largest impact on GPP and ET at CZ2. Figures 2a-2b show the monthly mean GPP and  
444 ET of the end members of the sensitivity analysis (see Fig. S1 for the complete set of outcomes).  
445 We acknowledge that the variation in rooting depth across the ensemble is large, but point out  
446 that so is uncertainty in plant rooting depth, and moreover that the uncertainty in rooting depth is  
447 less well-quantified than other plant traits such as P50, such that this wide variation reflects a  
448 real and deep uncertainty in plant rooting profiles. Deep roots result in substantially higher GPP  
449 and transpiration during normal years (2011 and 2012). During long-term droughts, when deep  
450 soil moisture is depleted, the relative advantage of deep roots over shallow roots is reduced.  
451 Shallow roots result in substantially lower GPP and transpiration during the dry season (Aug. to  
452 Oct.), with seasonal maximum occurring earlier, in May, as compared to July with the deep-  
453 rooted cases. The shallow-rooted cases also have much lower GPP and ET during the dry  
454 seasons of the pre-drought period. During the late stage of drought (2014 and 2015), the GPP and  
455 ET of the different cases become more similar between the shallow- and deep-rooted cases.

456 The second set of parameters in importance to rooting depth for controlling carbon and  
457 water fluxes is the stomatal strategy. The simulations with a more risky strategy (P50<sub>gs</sub>=P50<sub>x</sub>)  
458 gives higher GPP and ET than the simulations with a safer strategy (P50<sub>gs</sub>=P20<sub>x</sub>) during pre-  
459 drought periods and the early stage of the drought (2011 to 2013), but slightly lower GPP and ET  
460 at the late stage of the drought (2014 and 2015) for the deep-rooted cases. However, risky  
461 stomata gives slightly higher GPP and ET at all times for shallow-rooted cases. The xylem  
462 strategy has the smallest effect on GPP and ET of the parameters we varied (e.g., RMSEs of ET  
463 are both around 260 W/m<sup>2</sup>m<sup>2</sup> for safe and efficient xylem, respectively, with P50<sub>gs</sub> = P20<sub>x</sub> and  
464 8m effective rooting depth). In deep-rooted cases, the safe xylem and efficient xylem strategy  
465 result in almost the same GPP and ET, which can be seen via the widespreadwides overlap  
466 between the dashed and solid lines in figure 1. In shallow-rooted cases, with safe stomata, safe  
467 xylem generates slightly higher GPP and ET than efficient xylem. In addition, how strong the

468 strength of effects of stomatal and xylem strategy also depend on the rooting depth. The deeper  
469 the effective rooting depth, the less significant the impacts of stomatal strategy (Fig. S1).

470

### 471 3.2 ~~Impact on~~Sensitivity of plant water status to parameter perturbations

472 We examine the impact of vertical root distributions, stomatal and xylem strategies on the  
473 seasonal variation of three plant physiologic variables that serve as indices of plant water stress  
474 (fig. 4): the fraction loss of xylem conductivity of stem (SFL), leaf water potential (LWP), and  
475 an overall absorbing ~~roots~~root water potential (AWP). In the model, absorbing roots in  
476 different soil layers have different water potentials, associated with the soil water potential of  
477 that layer. We calculate a cohort-level effective AWP as the root-fraction-~~weighted~~ average  
478 of water potential in absorbing root across all soil layers. In this way, the AWP represents the  
479 overall rhizosphere soil moisture condition that is sensed by the tree. These physiological  
480 variables are tracked for each cohort. For any given case, the differences in these variables  
481 among differently-sized cohorts are negligible (Fig. S3). Therefore, we present the outcome of  
482 ~~the all~~ cohort-class-s with a diameter at breast height (DBH) between 50 – 60cm, the size  
483 class that is most abundant at CZ2.

484 Stomatal and rooting strategies together control the loss of xylem conductivity during the  
485 dry season of the pre-drought period and the whole period of the long-term drought (Fig 4a). In  
486 all cases, the xylem conductivity reaches a maximum during the wet season (Dec. to Jan.), starts  
487 to decline during the growing season (Apr. to Jun.), then reaches its minimum in the dry season.  
488 With the same stomatal strategy, deep roots lead to less-extreme loss of xylem conductivity than  
489 shallow roots. A deep rooting strategy is also able to maintain very little loss of xylem  
490 conductivity with very little seasonal loss during the pre-drought period, but as deep soil  
491 moisture is depleted, this effect is reduced. With a shallow rooting profile, the xylem  
492 conductivity starts to decline earlier and the minimum is much lower than that of a deep rooting  
493 profile. For example, with risky stomata, the minimum fraction of xylem conductivity of deep-  
494 rooted cases at in 2012 is 0.4, but is lower than 0.2 with shallow roots. Unlike deep-rooted  
495 cases, in shallow-rooted cases, the seasonal variation of the loss of xylem conductivity does not  
496 differ too much during pre-drought and drought periods. During the very late stage of the

497 drought, deep-rooted cases have a lower fraction of xylem conductivity than shallow-rooted  
498 cases (e.g., [in](#) Jan. 2015).

499 In general, risky stomata ~~cause~~allow a greater loss of xylem conductivity ( $K/K_{max}$ ) than  
500 safe stomata, but the extent depends on the vertical root distribution. The effect of the stomatal  
501 strategy is more obvious in shallow-rooted cases. Risky stomata combined with shallow roots  
502 ~~results~~result in increasing the duration of 50% loss of xylem conductivity, as well as the  
503 maximum loss of xylem conductivity during the dry season. With a deep rooting strategy, the  
504 difference in the percentage loss of xylem conductivity between safe stomatal and risky stomatal  
505 cases increases with the progression of the drought, but with a shallow rooting strategy, this  
506 difference remains more or less the same over time. In addition, in 2011, a very wet year, with  
507 deep roots, a safe xylem strategy is able to maintain the maximum xylem conductivity even  
508 during dry season (Fig 4a). The impact of xylem strategy on the percentage loss of xylem  
509 conductivity is relatively weak. For both deep- and shallow-rooted cases, trees with safe xylem  
510 lose less xylem conductivity during the wet season but lose more conductivity during the dry  
511 season.

512 The safe stomata & safe xylem cases for both deep- and shallow-rooted trees experience  
513 greater declines in stem conductivity as compared to the safe stomata and efficient xylem for the  
514 corresponding rooting depths (Fig. 4a). This is because with safe stomata, trees operate at the  
515 right end of the vulnerability curve shown in fig. 1b, where the hydraulic conductivity of  
516 efficient xylem is much higher than that of the safe xylem. Thus, when transpiring the same  
517 amount of water, the efficient xylem will lose less water potential as compared to safe xylem.  
518 This keeps the xylem water potential of a plant with efficient xylem higher than one with safe  
519 xylem, and consequently also keeps the xylem conductivity,  $K$ , higher. This is also because we  
520 set  $P_{50_{gs}}$  based on  $P_{xylem}$ , thus the  $P_{50_{gs}}$  of safe stomata for plants with efficient xylem is higher  
521 (less negative) than that of plants with safe xylem, thus resulting in lower transpiration rates,  
522 which in term reduces the loss of xylem water potential. As a result, plants with both safe  
523 stomata and efficient xylem not only transpire less water but also lose less water potential per  
524 volume of water transpired. Together, these two mechanisms contribute to keep the xylem  
525 conductivity of the efficient xylem cases higher.

526 Stomatal, rooting, and xylem strategies have similar impacts on the seasonal variation of  
527 both leaf and fine root water potentials (Fig4c and 4d). Leaf and fine root water potentials peak  
528 during the winter, then start to decline in early spring, and reach their lowest point in the dry  
529 season. Deep roots, safe stomata, and safe xylem traits all contribute to the maintenance of  
530 higher leaf and fine root water potentials during the growing and dry seasons. With deep roots,  
531 there is less difference in leaf and fine root water potential between stomatal and xylem  
532 strategies in the very wet year 2011. Plants that combine safe stomata and/or safe xylem with  
533 deep roots can keep the leaf and fine root water potentials relatively high (less than -5 Mpa)  
534 during the dry season of the drought period. However, while plants that combine risky stomata or  
535 efficient xylem with deep roots can keep the dry season leaf water potential above -5 Mpa during  
536 the pre-drought period, their traits lead to the dry season leaf water potential dropping below -8  
537 Mpa or even below -10 Mpa during the drought period. In both deep-rooted and shallow-rooted  
538 cases, safe xylem leads to much lower leaf and fine root water potentials during the dry season.  
539 The seasonal and inter-annual variation of fine root water potentials are almost identical to the  
540 leaf water potential, except that the water potential of fine roots is slightly higher (~ 0.5 Mpa)  
541 than the leaf water potential.

542

### 543 3.3 ~~Impact on~~ Sensitivity of subsurface hydrology to parameter perturbations

544 In the simulation outcomes, the vertical root distributions again have the largest impact on  
545 hydrologic processes and subsurface water content and the way that they change over the  
546 drought. With deep roots, there is less drainage loss from surface and subsurface runoff as  
547 compared to shallow roots, especially during the growing season (Figure 5a,c,e,g). The  
548 subsurface water content shows different vertical and temporal patterns between the cases with  
549 different vertical root distributions. In the deep-rooted cases, during the pre-drought period, the  
550 water content in the deepest layers fluctuates between wet and dry seasonally; during the first  
551 year of the drought, the water content of the deepest layers (6 to 8m) slightly increases during the  
552 wet season, but with the progression of the drought, the soil water content becomes consistently  
553 depleted in the middle and deep layers (between 5 and 8 m depth) and only the shallow layer  
554 (<0.16 m) water content increases during wet season. In the shallow-rooted cases (Figure  
555 5b,d,f,h), soil moisture in the surface layers (top 2m) shows seasonal variation, but this seasonal

556 variation becomes weaker over depth and the soil moisture at 6-8m depth stays consistently high  
557 throughout the year during pre-drought period, and remains slightly low through the entire  
558 drought period; while the water content of the middle and upper layers of the shallow-rooted  
559 case have a similar pattern of seasonal variation before and during the drought.

560 Stomatal strategy, as quantified by  $P50_{gs}$ , has a weak impact on hydrologic processes and  
561 soil moisture. In both the deep- and shallow-rooted cases, riskier stomata lead to a slightly lower  
562 total subsurface water content (Figure 6a). The effect of  $P50_{gs}$  is less significant during the pre-  
563 drought period for both the deep-rooted and shallow-rooted cases, and becomes more significant  
564 as the drought progresses. The effect of  $P50_{gs}$  on total subsurface water content is less significant  
565 in shallow-rooted cases. Figure 5c shows the effect of  $P50_{gs}$  on the water content of shallow and  
566 deep soil layers. In both the shallow- and deep-rooted cases, increasing  $P50_{gs}$  has a negligible  
567 impact on the water content of the shallow layers during both the pre-drought and drought  
568 periods (Figure 5c left). For deeper layers, in the shallow-rooted case,  $P50_{gs}$  has no impact on the  
569 water content at all times; in the deep-rooted cases, a risky  $P50_{gs}$  results in lower dry season  
570 water content of deep layers (7-8m) during the pre-drought period (indicated by the red cycles of  
571 Figure 5a and 5c), but decreases the water content of those layers year round during the drought  
572 period (Figure 5a and 5e). In deep-rooted cases, safe stomata with efficient xylem lead to a  
573 slightly higher water content in deep layers (5m to 8m) during the pre-drought period, and in  
574 shallow layers (0 to 3m) during the drought period (Figure 6a). Risky stomata with safe xylem in  
575 deep-rooted cases are most effective in accessing soil water. Though the soil water contents are  
576 generally high in shallow-rooted cases, stomatal and xylem strategies show a similar impact on  
577 the soil water storage as those in the deep-rooted cases (Fig S4).

578 Simulations with deep roots have almost no loss of soil water to drainage during the dry  
579 season in normal years, or during the whole drought period; while with shallow roots, the  
580 drainage loss is high during the pre-drought period and decreases through the drought period, but  
581 still with some runoff even at the end of the drought period (Figure 6a). The observed total  
582 annual runoff from the 2008 to 2011 pre-drought period was about 250 mm/year, but was zero  
583 during the 2012 – 2015 drought period (from figure 4, Bales et al. 2018). This observed  
584 difference in runoff between the pre-drought (~290mm/year, 2011 - 2012) and drought periods  
585 (~0 mm/year) from the deep-rooted case is consistent with the predicted pattern. During the pre-

586 drought period, the wet season total subsurface water contents from Dec. to Feb. are similar  
587 between the cases with deep and shallow roots, but during the dry season (from June to Sep.) the  
588 total subsurface water content with shallow roots is substantially higher than the case with deep  
589 roots (Figure 6b).

## 590 **4. Discussion**

### 591 4.1 Vertical root distribution as the first order control

592 The outcome of our simulations indicates that the vertical root distribution exerts the first  
593 order control over both ecosystem level fluxes and plant physiology at CZ2. This dominance of  
594 rooting strategy over other hydraulic traits is related to the nature of the rainfall pattern of the  
595 Mediterranean-type climate of that region. The CZ2 site receives effectively all of its rain during  
596 winter. This water is stored in the soil column and slowly released through the growing season.  
597 The root zone soil moisture has strong seasonal variation, which constrains plant water use and  
598 gas exchange as a function of the gradual drying of the soil column (Bales et al., 2018). In the  
599 model, the stomatal behavior is controlled by the leaf water potential, which itself is strongly  
600 affected by the root zone soil moisture. In our simulations, the daytime average leaf water  
601 potential of a 55cm DBH cohort is well correlated with the fine root water potential and is  
602 always about 0.5 Mpa lower (fig S5). This offset is consistent with the relationship between mid-  
603 day leaf water potential and pre-dawn leaf water potential found by Martínez-Vilalta et al. (2014)  
604 at the global scale.

605 With deep roots, trees use more subsurface storage capacity at the CZ2 site, and thus a  
606 higher amount of total rainfall. In a wet year such as 2011, the root zone water potential of deep-  
607 rooted trees is kept relatively high (Figure 4b) and the trees operate at the upper end of their  
608 vulnerability curve through the year, with typical loss of conductivity < 10% (Fig 7). Therefore,  
609 we don't see much effect of the stomatal strategy on GPP and transpiration in a wet year. At the  
610 upper end of the vulnerability curve, stomata are fully open regardless of the stomatal strategy  
611 (either to be safe or risky). When the drought began in late 2012, annual rainfall fell below the  
612 total root zone storage, thus the deep storage remained depleted throughout the year. During the  
613 drought, the deep-rooted trees were able to operate at the high end of the vulnerability curve in  
614 the wet season, when the rainfall recharged the surface layer. As the surface layers dry, water

615 ~~potentials~~potential then gradually falls to the lower end of the vulnerability curve;  
616 consequently the photosynthesis and transpiration start to drop as the dry season progresses.  
617 With risky stomata, trees can drive the soil moisture ~~a little further down to~~ lower values . This  
618 is why we see the difference in the effect on GPP and transpiration between different stomatal  
619 strategies during the dry season when the drought progresses.

620 With shallow roots, trees can only use surface soil moisture storage. As a result, the  
621 surface water storage is quickly used up after the wet season, and the root zone water potential  
622 drops near the low end of the vulnerability curve during the dry season. Thus, the shallow-rooted  
623 trees operate along the full extent of the vulnerability curve year-round, both during the pre-  
624 drought and drought periods. Therefore, as for the deep-rooted cases, we don't see a strong effect  
625 of stomatal strategy on GPP and transpiration during the wet season, but unlike the deep root  
626 cases, the effect of stomatal strategy on GPP and transpiration during the dry season can be seen  
627 throughout the whole simulation period.

628 Rooting strategies greatly control the spatial pattern of vertical soil water content (Figure  
629 5). With deep roots, the vertical soil moisture variation is more homogeneous due to the  
630 extensive root distribution. With shallow roots, the soil becomes extremely dry at the surface  
631 (<1m) and extremely wet in deep layers (>5m) resulting from the aggregated root distribution  
632 ~~at~~in the upper layers. Our finding is similar to a recent study conducted by Agee et al. (2021),  
633 where the authors found that the extensive lateral root spreading results in homogeneous soil  
634 moisture distribution. The homogeneous soil moisture pattern may contribute to a more energy  
635 efficient system that reduces plant water stress (Agee et al. 2021) because that minimizes the  
636 energy dissipation loss through water transport (Hildebrandt et al. 2016). Both Agee et al (2021)  
637 and our studies emphasize the importance of the means by which the root distributions determine  
638 how the subsurface storage is utilized.

639 Given the shape of the vulnerability curves, in all these simulations, plants will stop  
640 transpiring when their leaf water potential reaches around -10Mpa with efficient xylem or -  
641 15Mpa with safe xylem, depending on their stomatal strategy (Fig 7). Because we are here  
642 holding the stand structure and leaf area constant to allow comparison between cases, the  
643 simulated leaf water potential of the shallow rooted, risky stomata combination can get as low as  
644 -15Mpa (Figure 4b) during dry seasons even during pre-drought period, which is well below the

645 lowest possible leaf water potential observed (-10Mpa) (Vesala et al., 2017). Leaves will likely  
646 be wilted before the water potential drops below -10Mpa and the tree would have already shed  
647 the leaves due to canopy desiccation. But we specifically do not permit that to occur in these  
648 simulations, so as to keep the different cases comparable. Although it might be unrealistic, the  
649 leaf water potential can serve as an ~~indieate~~indicator of the degree of canopy desiccation. With  
650 no or very little ~~leafleaves~~, trees would rely on the storage carbon to support respiratory  
651 demand until the wet season comes to regrow leaves.-\_\_ Depending on the duration of the dry  
652 season, trees may exhaust the stored carbon and die from carbon starvation.-\_\_ Risky stomata  
653 can generate higher GPP (Figure 1a), but also result in longer duration of more negative leaf  
654 water potential (Figure 4b). This suggests that shallow rooted pines at CZ2 with risky stomata  
655 will benefit from allocating more net primary productivity to their storage pools rather than  
656 growth in order to reduce the carbon-starvation mortality. Therefore, even though the model  
657 generates unrealistically low leaf water potentials, the extent and the duration of the simulated  
658 very low leaf water potential allows us to gain some insight on the interaction of plant hydraulic  
659 strategy and the life history strategy of conifer trees under a Mediterranean-type climate.  
660 Further, the unrealistic leaf water potential from the shallow root simulations indicates that the  
661 trees at that site must have really deep roots to exist at this site, which is in agreement with the  
662 conclusions of Goulden and Bales (2019).

663 In this simulation, the impacts of xylem traits on GPP and ET are weak and subtle. This is  
664 the result of the relative position of the two vulnerability curves, in particular, the intersection of  
665 the two vulnerability curves in absolute conductivity. When the absolute conductivity is plotted  
666 as a function of pressure (fig. 1b and solid lines in fig. S6), it can be seen that, on the left side of  
667 the intersection, the safe xylem is not only safe but also efficient, and a safety-efficiency tradeoff  
668 of xylem thus only occurs on the right side of the intersection point. Therefore, in shallow-rooted  
669 cases, when the root zone water content—and hence plant water status—is low, safe xylem can  
670 generate slightly higher GPP and ET than unsafe xylem. Furthermore, the two pressure-  
671 conductivity curves diverge mainly at the wet end (corresponding to the wet season). This is  
672 likely because the xylem structures of conifers are very similar, and the range of variation of  
673 xylem traits in the sensitivity analysis are limited to the dominant species at the site. Therefore,  
674 the difference in the xylem traits of conifers do not cause significant impacts on the ecosystem  
675 level fluxes under the Mediterranean-type climate of CZ2, where the ecosystem fluxes are

676 constrained by energy during the wet season (Goulden et al., 2012). In addition, the maximum  
677 rate of GPP and ET are co-constrained by the stand density, the total leaf area, the maximum  
678 stomatal conductance, and VPD. In this study, we used the static stand structure mode of  
679 FATES-Hydro, whereby the stand density and the total leaf biomass (so as total leaf area) of the  
680 trees are held constant. This further limits the effect of xylem traits on GPP and ET.

681

#### 682 4.2 Balancing productivity and mortality risk

683 The hydraulic traits that contribute to high carbon fixation rates often make trees more  
684 susceptible to drought. Stomatal strategy ( $P_{50_{gs}}$ ) can have both positive and negative impact on  
685 the trees, creating a tradeoff in the balance between productivity and physiological stress. The  
686 risky stomata ( $P_{50_{gs}} = P_{50_x}$ ) can generate higher GPP but also result in a greater loss of xylem  
687 conductivity and lower leaf water potential. The tradeoff varies depending on the plant's root  
688 strategy—i.e. having a deep vs. a shallow root distribution—and the moisture state.

689 To better understand the tradeoff between productivity and mortality risk, we plot the  
690 simulated annual average GPP for each year against the fraction of conductivity ( $K/K_{max}$ ) of a  
691 55cm DBH cohort for two scenarios: deep roots (Fig. 8a) and shallow roots (Fig. 8b), with  
692 different combination of xylem and stomatal strategies. In both scenarios, for each pair of xylem  
693 and stomatal strategies, the GPP per tree increases almost linearly with the  $K/K_{max}$ . But, with  
694 increasing the safety of the stomata, the GPP declines faster with loss of conductivity. This  
695 response is stronger in deep-rooted scenarios. Efficient Having e fficient xylem only slightly  
696 increases the steepness of the lines. The stomatal strategies thus represent points along a  
697 gradient of the tradeoff between growth and mortality risk - the safer the stomata, the more GPP  
698 is traded for reducing the mortality risk.

699 Along this tradeoff space, where trees can maximize their net carbon gains likely depends  
700 on the xylem traits. Studies have shown that trees may temporarily lose xylem conductivity  
701 during mild drought, which can recover once the soil water becomes available. However, under  
702 an extreme drought, their xylem could collapse and permanently damage the xylem conduits. In  
703 this case, trees rely on new sapwood growth to support the transpiration (Brodribb et al. 2010,  
704 Anderegg et al. 2013). At one extreme, if the stomatal behavior is too safe, it will give low GPP

705 and the tree will be outcompeted for light due to faster-growing neighbors, but at the other  
706 extreme, if the stomata behave very aggressive (risky), it will give high GPP but also empty the  
707 subsurface storage quickly, consequently leading to a prolonged dry period of soil moisture. This  
708 would lead to substantial xylem damage (and/or root death), and then the carbon needed to grow  
709 new sapwood (or roots) can exceed the benefit of getting the additional GPP. So, the optimal  
710 location along the gradient would probably be located slightly below the  $K/K_{max}$  associated  
711 with that critical xylem water potential. Currently, the xylem refilling and associated carbon cost  
712 are not incorporated in ~~the~~ FATES-Hydro. These two processes should be implemented in the  
713 model to better understand the water-carbon balance-, and thus remains as future work.

714 In the deep-rooted scenario, the values of the pre-drought period and early drought stage  
715 are clustered at the upper-right corner, above  $K/K_{max}$  of 0.6. (Fig. 8a). In this region, the stress  
716 from the loss of xylem conductivity likely won't be high enough to cause severe consequences, if  
717 using 50 percent loss of xylem conductivity as the threshold for mortality and/or permanent  
718 xylem damage. The deep-rooted tree can thus benefit by trading less GPP for maintaining xylem  
719 conductivity with a risky/more-productive stomatal strategy during normal years. But, during the  
720 late stage of the drought (2014 and 2015), the conductivity values become much lower. If this  
721 mega drought stopped earlier, e.g. if it were a mild drought that only lasted for two years, the  
722 additional GPP obtained from risky stomata may outweigh the carbon cost for repairing xylem  
723 damage. This suggests that, if the 2012 – 2015 drought was not common in California, natural  
724 selection might favor the risky/more-productive stomatal strategy for deep-rooted trees.  
725 However, this same strategy also exposes trees to high mortality risk under severe droughts.

726 In the shallow-rooted case (Fig. 8b), the values are all clustered lower and to the left, as  
727 compared to deep rooted scenario, irrespective of the drought status. Thus, for shallow roots,  
728 risky/more-productive stomatal behavior results in a similarly high mortality risk during both the  
729 pre-drought and drought period. Thus, under the long-term climate conditions seen at CZ2,  
730 whether or not severe droughts were frequent, the only shallow-rooted trees that could persist  
731 would have to follow the safe and less-productive stomatal strategy. And, this safe and  
732 less-productive stomata also protects the shallow-rooted tree plant from mortality risk during  
733 drought.

734 The model outcome indicates that under drier root zone soil conditions, if pines were to  
735 follow a shallow rooting strategy, they would benefit from a safer stomatal strategy, with more  
736 conservative water use; but if they follow a deep rooting strategy, pines would benefit from  
737 riskier stomata. This is consistent with Anderegg et al.'s (2016) finding on the relative stomatal  
738 conductance (gs) across elevation. They found that at low elevation (lower precipitation) site,  
739 Ponderosa pine has lower relative stomatal conductance and less loss of % xylem conductivity,  
740 equivalent to safer stomata in our study, while at mid elevation (higher precipitation) site, pine  
741 has higher relative stomatal conductance and ~~more~~ greater loss of % xylem conductivity,  
742 equivalent to risky stomata in our study. The simulation results are consistent with the idea that  
743 the CZ2 region is dominated by deep-rooted trees. This is supported by previous studies. In situ  
744 measurements of regolith structure (particularly the porosity) indicates that at CZ2, there is a  
745 layer of thick semi-weathered bedrock that allows the trees to grow deep roots (Holbrook et  
746 al., 2014). Growing deep roots to access rock moisture to support plant water use has also been  
747 observed in the Eel River CZO catchment (Rempe et al., 2018), another Mediterranean-type  
748 ecosystem along the west coast. Observed net CO<sub>2</sub> exchange and ET during the pre-drought  
749 period suggest that during a wet year, deep moisture supported summer transpiration and  
750 productivity when the upper layer moisture was low (Goulden et al. 2015). Because the deep  
751 rooting strategy is sufficient in most cases to avoid the main effects of dry seasons and short  
752 droughts, and that, conditional on having deep roots, the risky stomatal strategy confers a  
753 productivity advantage at little increased risk of vulnerability, then we would expect that plants  
754 with these traits would dominate. However, under extreme cases such as the 2012 - 2015  
755 drought, which ranked as one of the most severe in California in the last 1200 years (Lu et al.  
756 2019), we would expect that plants with this deep-rooted, risky stomatal strategy would be  
757 highly vulnerable to drought, which is consistent with the ~90% mortality of the pine observed at  
758 CZ2 during the drought (Fettig et al. 2019). The water balance of the catchment based on the  
759 long-term observation from precipitation, stream flow, and ET (Bales et al. 2018, Goulden and  
760 Bales 2019) also support that it was the slow depletion of deep moisture that caused tree  
761 mortality in the late stage of the prolonged 2012 – 2015 drought.

762 The finding of our study indicates that the future drought mortality would likely occur in  
763 the ecosystems which are co-limited by water and other factors. In those ecosystems, trees can  
764 benefit from having more efficient but less safe hydraulic traits, which allow them to be more

765 competitive for water, and bring in higher GPP. The extra carbon gain can be used to develop  
766 measures to deal with other constraining factors, such as increase storage carbon to lower the risk  
767 of carbon starvation, or build thicker bark to resist fire, and to grow more roots which further  
768 enhance their capacity to compete for water.

## 769 **5. Conclusions**

770 Our analysis indicates that, in root distribution can affect the most competitive stomatal  
771 traits. In a Mediterranean-type climate where the supply of energy and water is  
772 desynchronized and accessible subsurface water storage capacity is close to annual precipitation,  
773 deep roots combined with risky stomata represent a beneficial strategy for high productivity in  
774 normal years with low mortality risk, but exposes trees to high mortality risk during multi-year  
775 droughts. While such a strategy enables trees to fully utilize subsurface storage and precipitation  
776 for productivity over the regular years, the lack of deep water storage recharge during droughts  
777 exposes trees to high drought stress and makes this strategy unfavorable under severe and  
778 prolonged drought. In contrast, shallow roots combined with safe stomata represent a strategy for  
779 drought resistance, albeit at the cost of considerably reduced productivity, as such a combination  
780 only allows trees to use shallow subsurface storage while leaving deep moisture untouched, thus  
781 less precipitation is used for productivity. But this strategy leaves trees to be less susceptible to  
782 drought-induced mortality should the deep reservoir be depleted. In contrast , shallow roots  
783 with risky stomata leads to high mortality even during non-drought years, thus an uncompetitive  
784 combination at the site. These results suggest that stomatal strategy is controlled by root zone  
785 soil moisture and regulated by root distribution in that region. Thus, our study underscores the  
786 importance of considering plant rooting and hydraulic strategies within the larger context of  
787 plant ecological strategies.

# Figures

## Figure 1

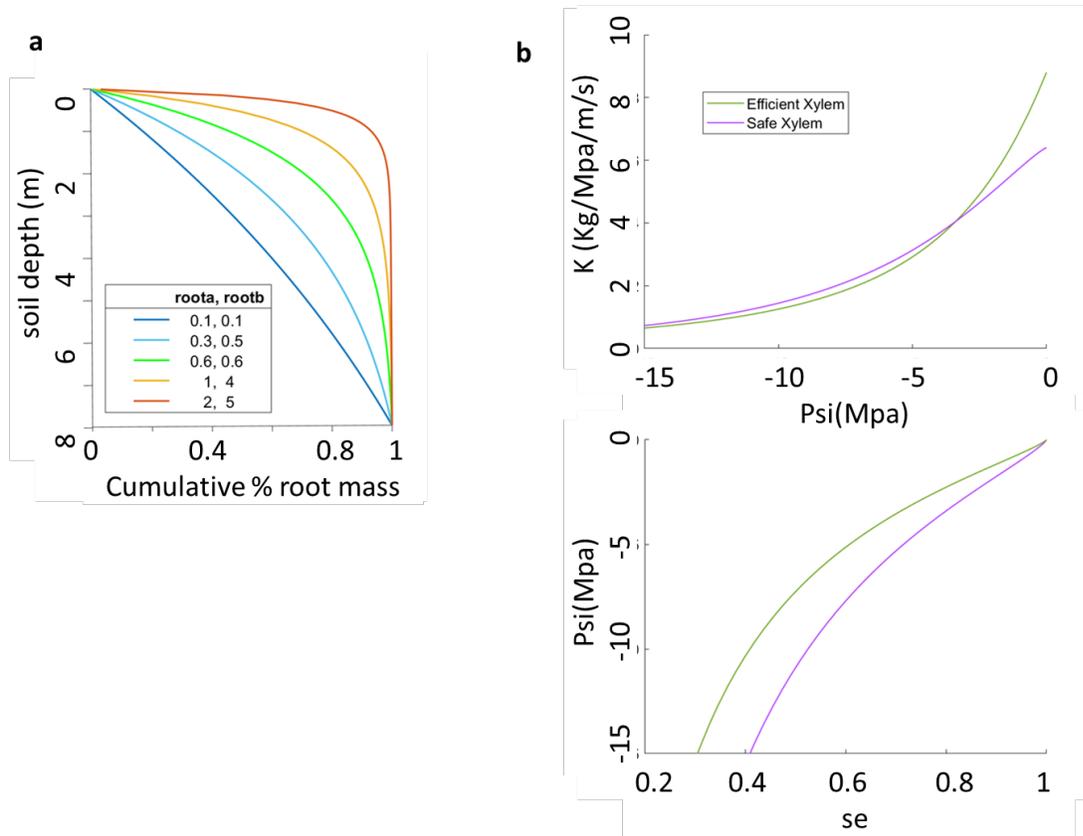

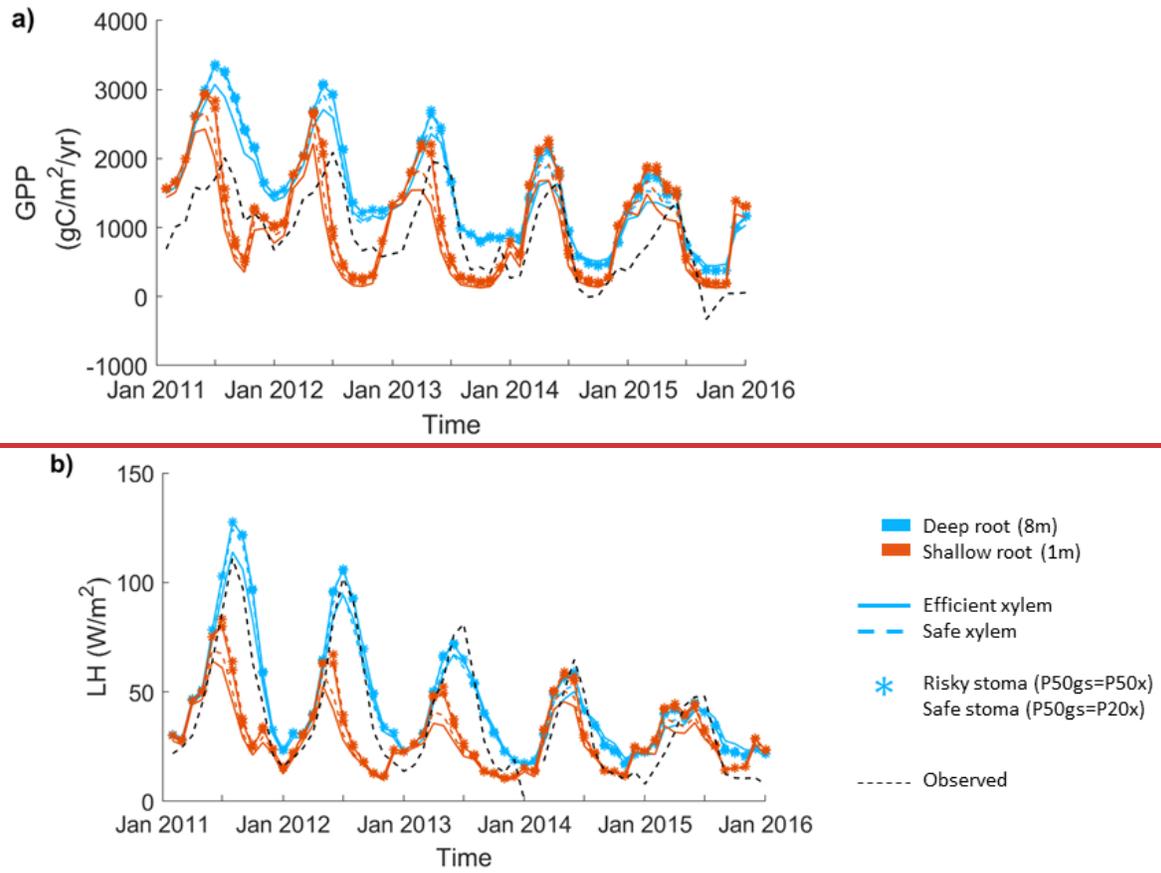

Figure 1. Sensitivity analysis set up for: a) root parameters that give five root distribution scenarios with effective rooting depths of 1m, 3m, 5m, 6.5m, and 8m , and b) two xylem scenarios for safe xylem ( $P_{50x}=-4.8$ ,  $K_{max}=0.64$ ), and efficient xylem ( $P_{50x}=-2.5$ ,  $K_{max}=0.88$ ).

Figure 2

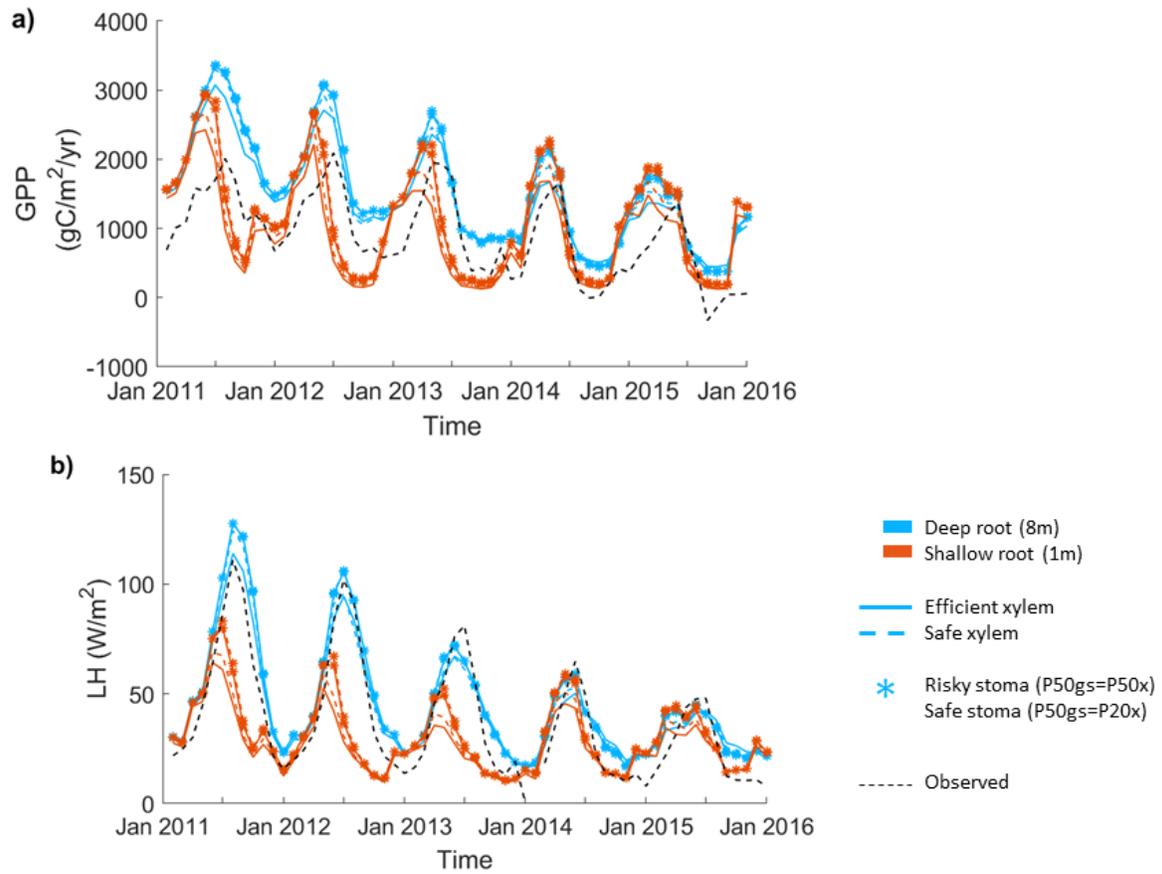

Figure 2. Impact of hydraulic strategies on ecosystem water and energy fluxes: a) monthly mean gross primary productivity, and B) monthly mean latent heat flux, of the end member cases.

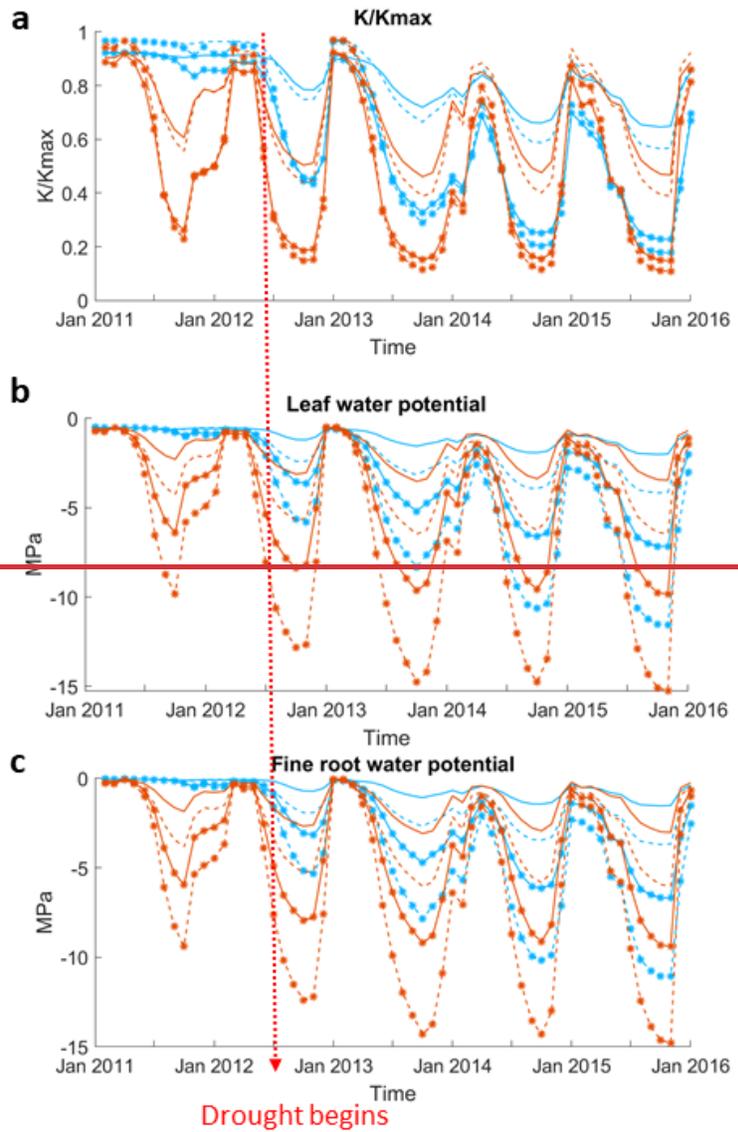

Figure 3. Root mean square error of GPP (a-b), and latent heat flux (c-d) with respect to variation in input parameters.

Figure 4

fig4

- Deep root (8m)
- Shallow root (1m)
- Efficient xylem
- Safe xylem
- \* Risky stoma ( $P_{50gs}=P_{50x}$ )
- Safe stoma ( $P_{50gs}=P_{20x}$ )

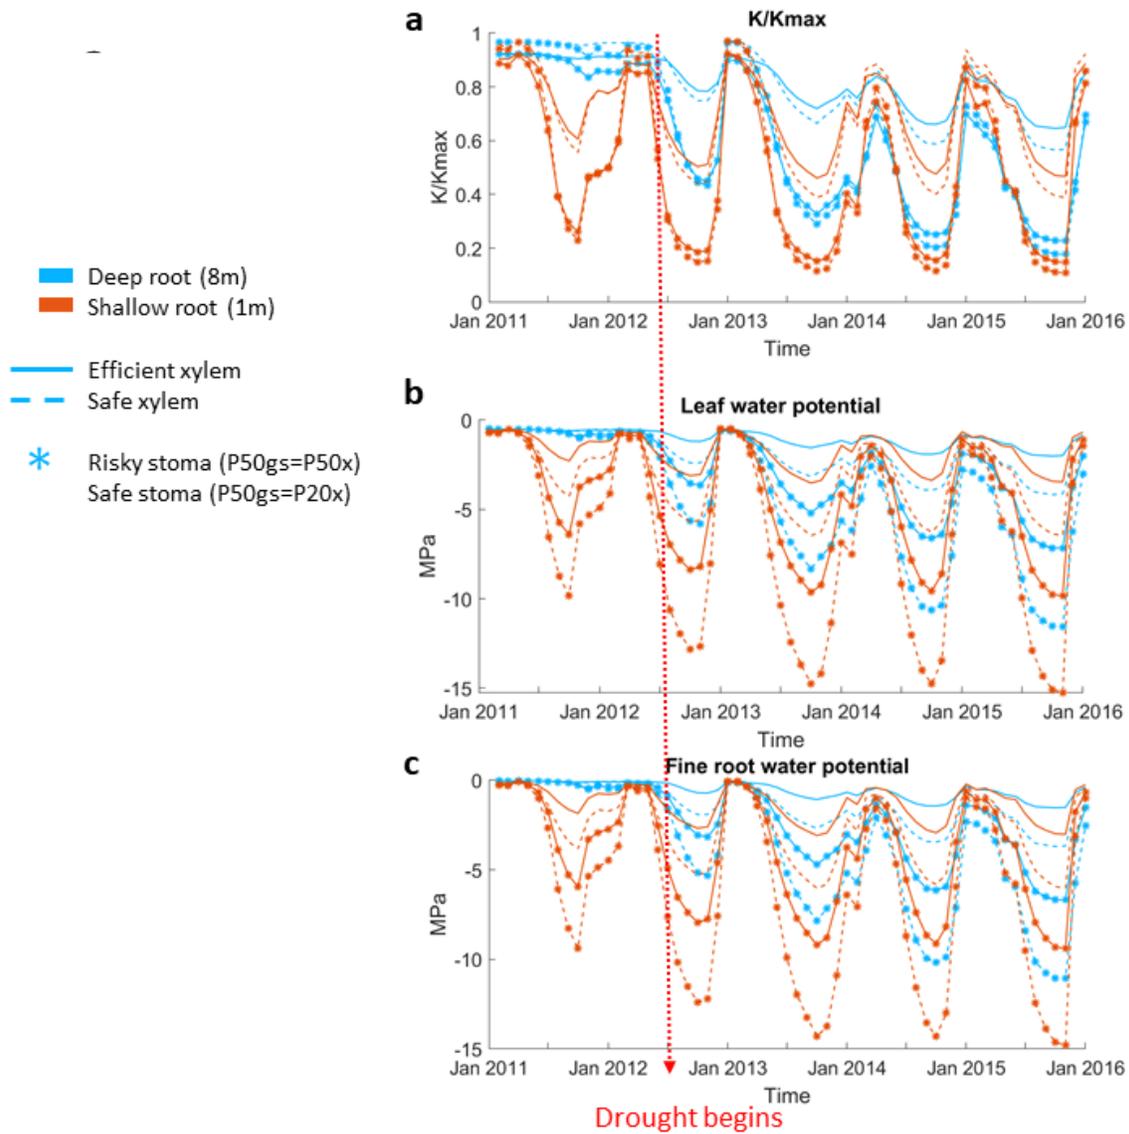

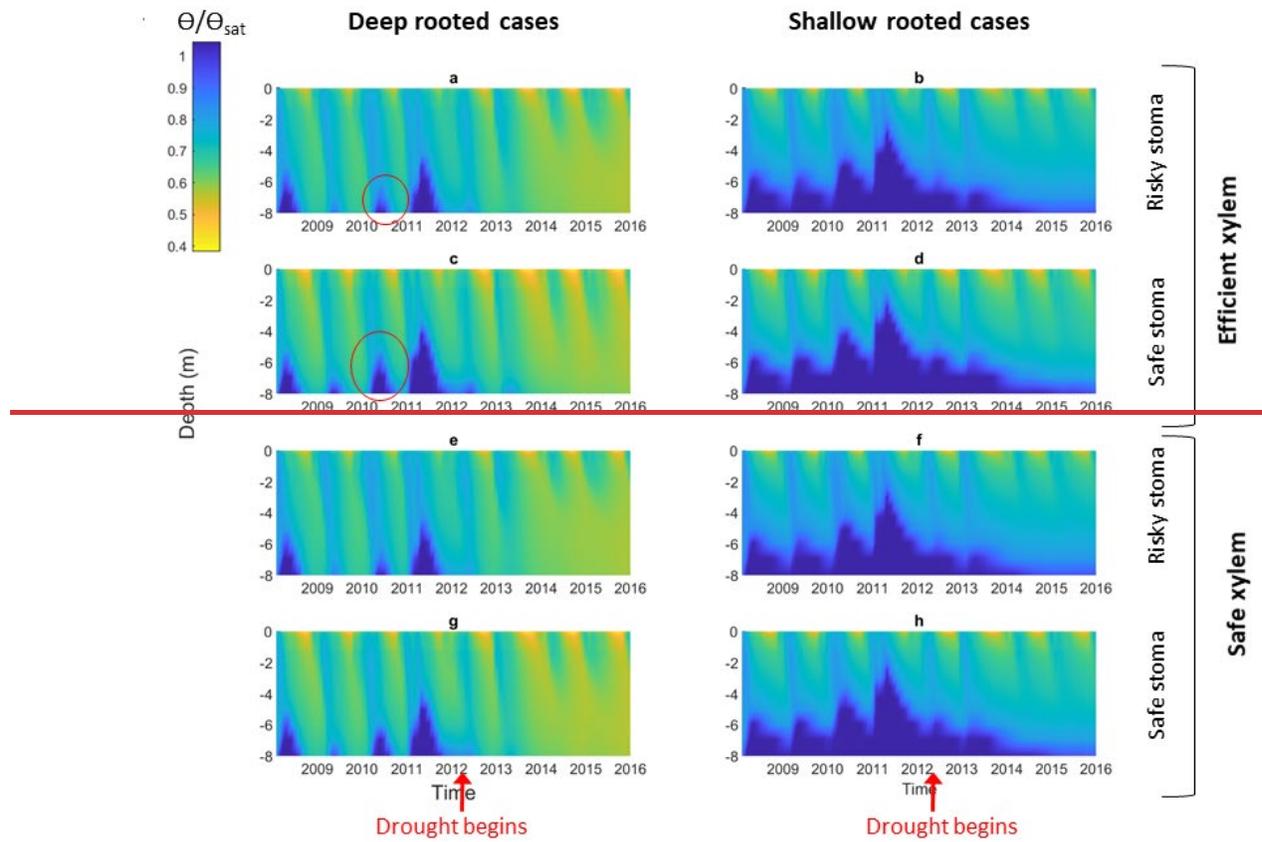

Figure 4. Seasonal and inter-annual variation of plant physiologic characteristics: a) monthly mean stem fraction of conductance  $K/K_{\max}$  (a), monthly mean leaf water potential, and c) monthly mean overall absorbing roots water potential, of the 55cm DBH cohort throughout the 2011-2015 period.

Figure 5

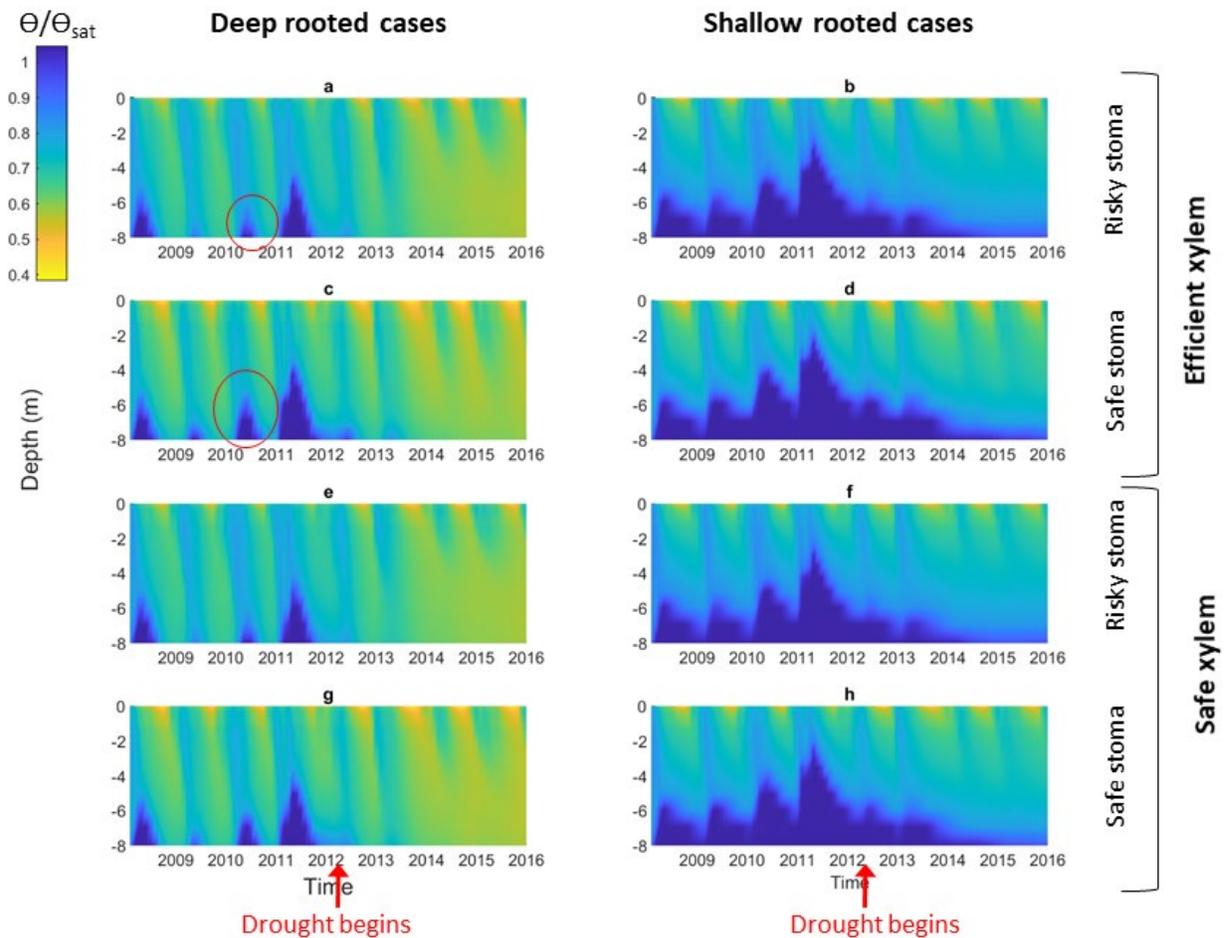

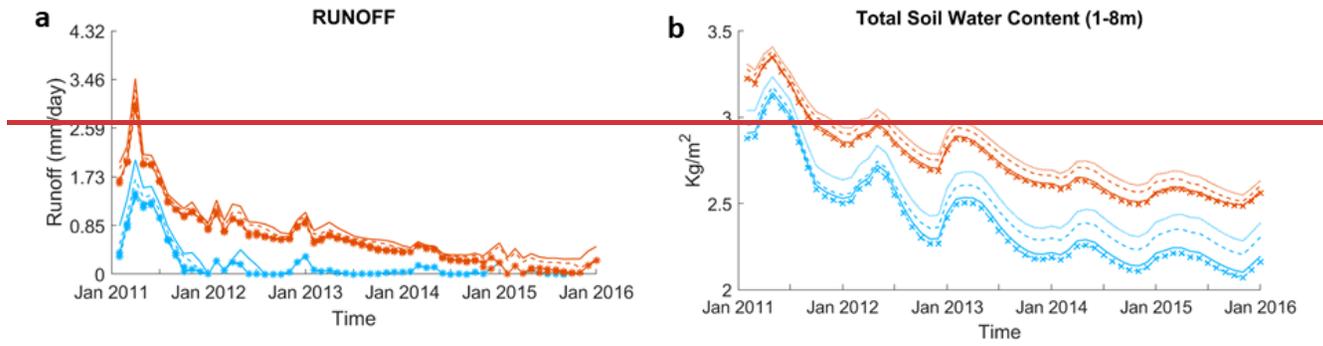

Figure 5. Impact of different combination of rooting depth, xylem and stomatal traits on soil moisture; left column shows deep rooted cases with a) efficient xylem and risky stoma, c) efficient xylem and safe stoma, e) safe xylem and risky stoma, g) safe xylem and safe stoma. Right column shows shallow rooted cases with b) efficient xylem and risky stoma, d) efficient xylem and safe stoma, f) safe xylem and risky stoma, h) safe xylem and safe stoma; red cycle highlights the effect of stomatal traits on deep water storage during the wet season of the pre-drought period

Figure 6

fig6

- Deep root (8m)
- Shallow root (1m)
- Efficient xylem
- - Safe xylem
- \* Risky stoma (P50gs=P50x)
- Safe stoma (P50gs=P20x)

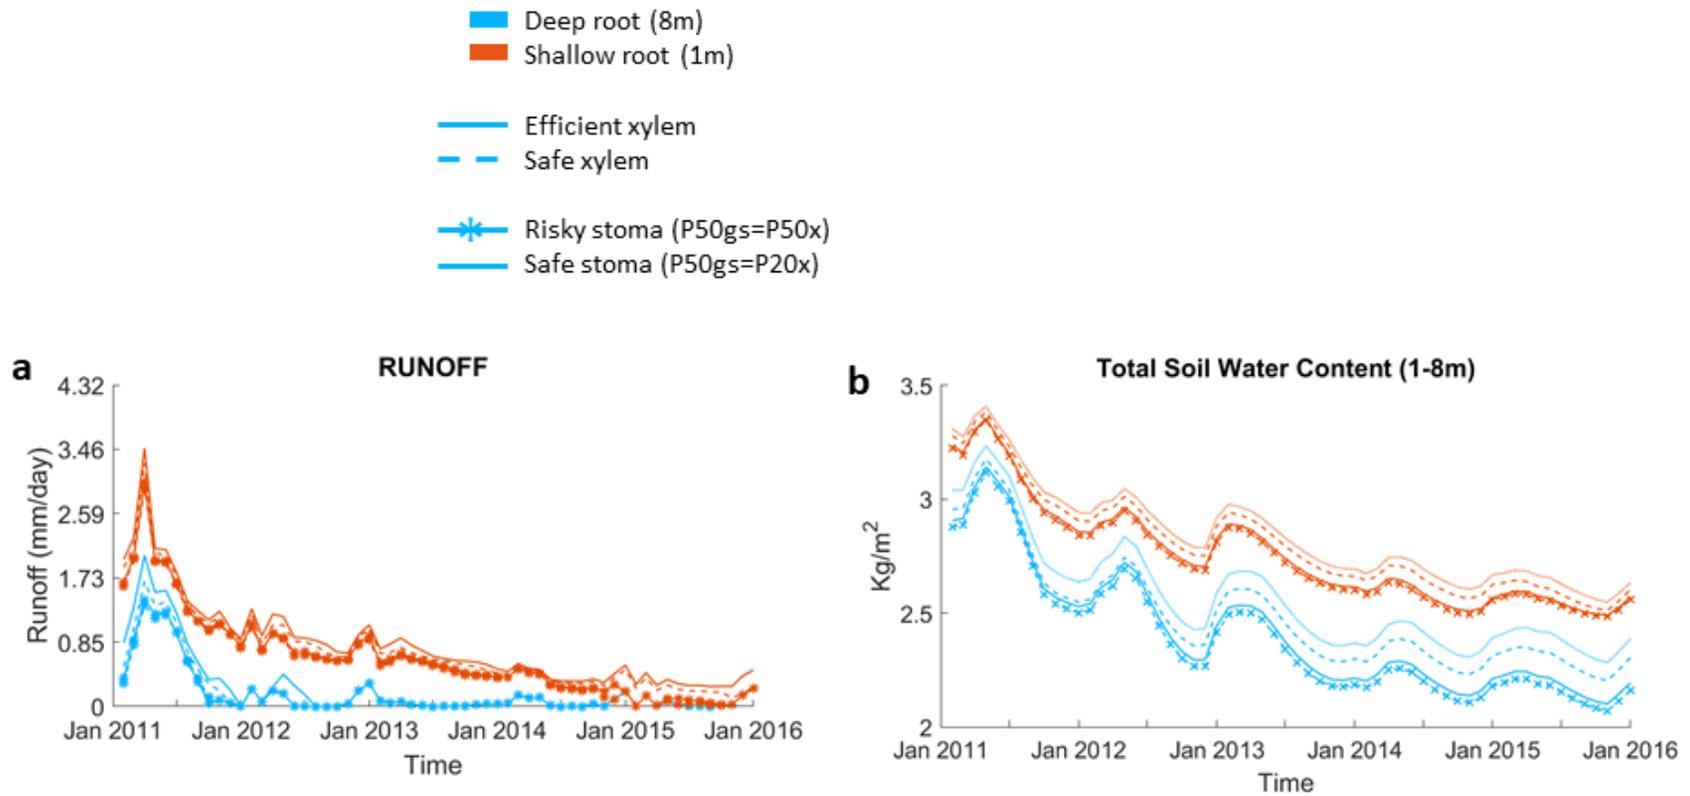

Figure 6. Impact on hydrologic processes: a) mean monthly total runoff, and b) monthly mean total soil water content of the entire soil column.

Figure 7

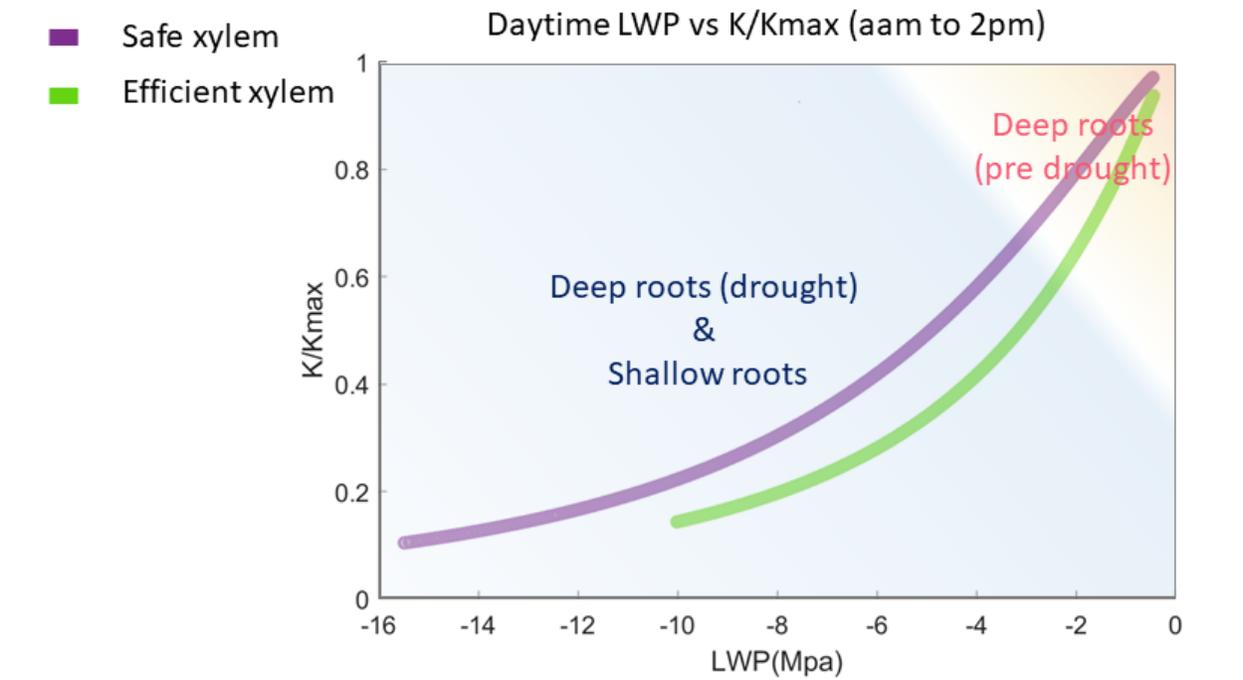

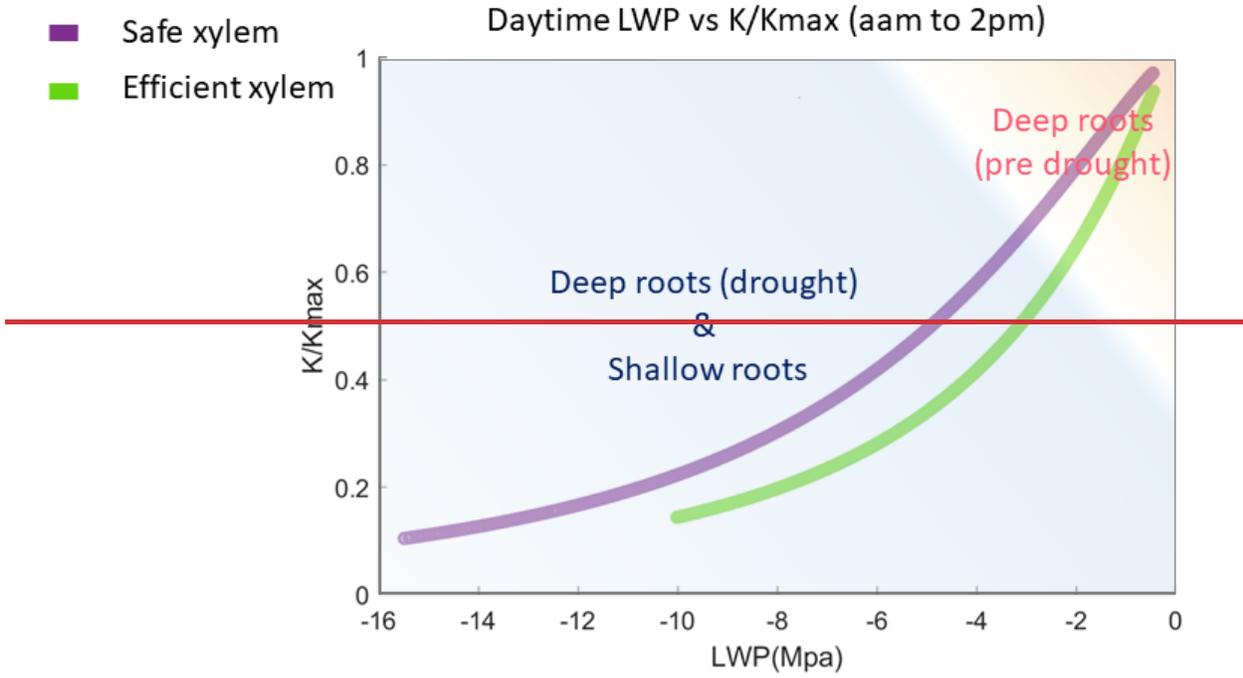

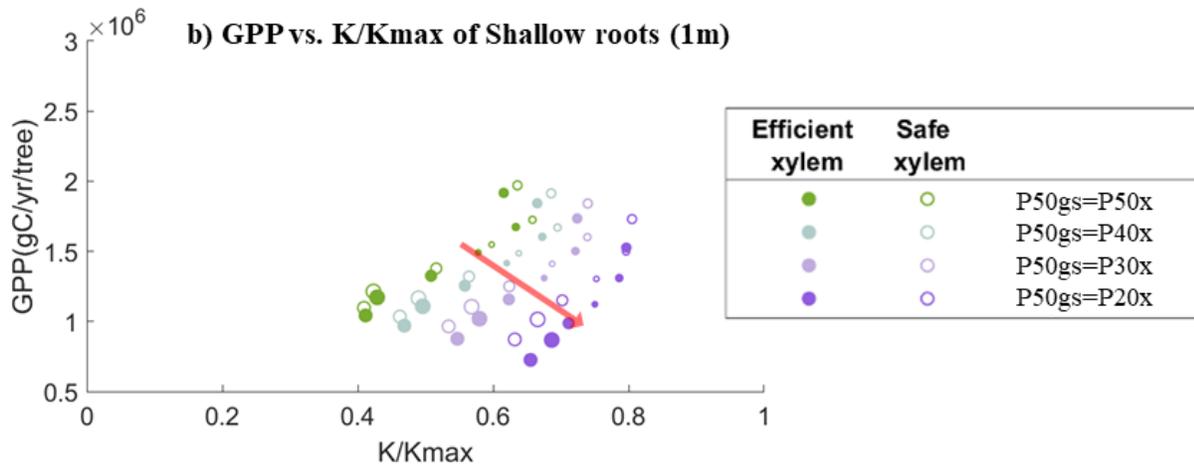

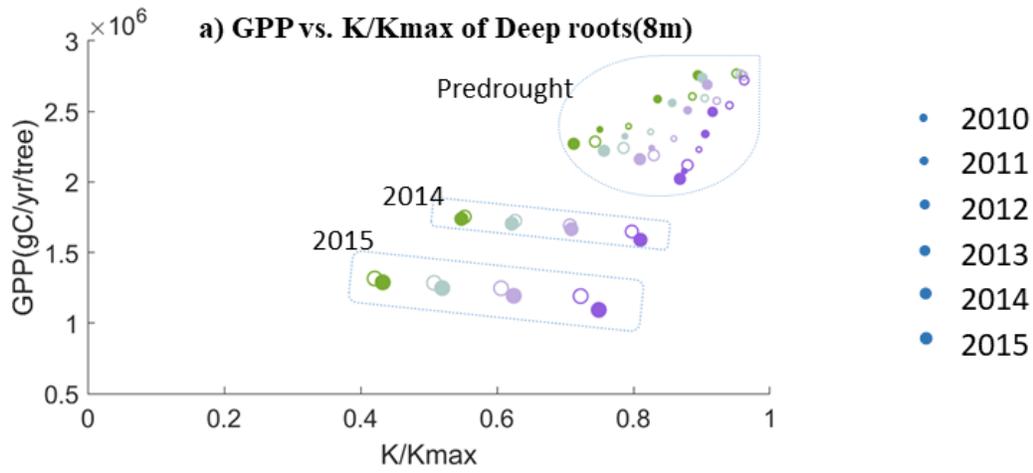

Figure 7. Simulated leaf water potential and fraction loss of conductivity ( $K/K_{max}$ ) of all the cases, which follow the two vulnerability curves.

Figure 8

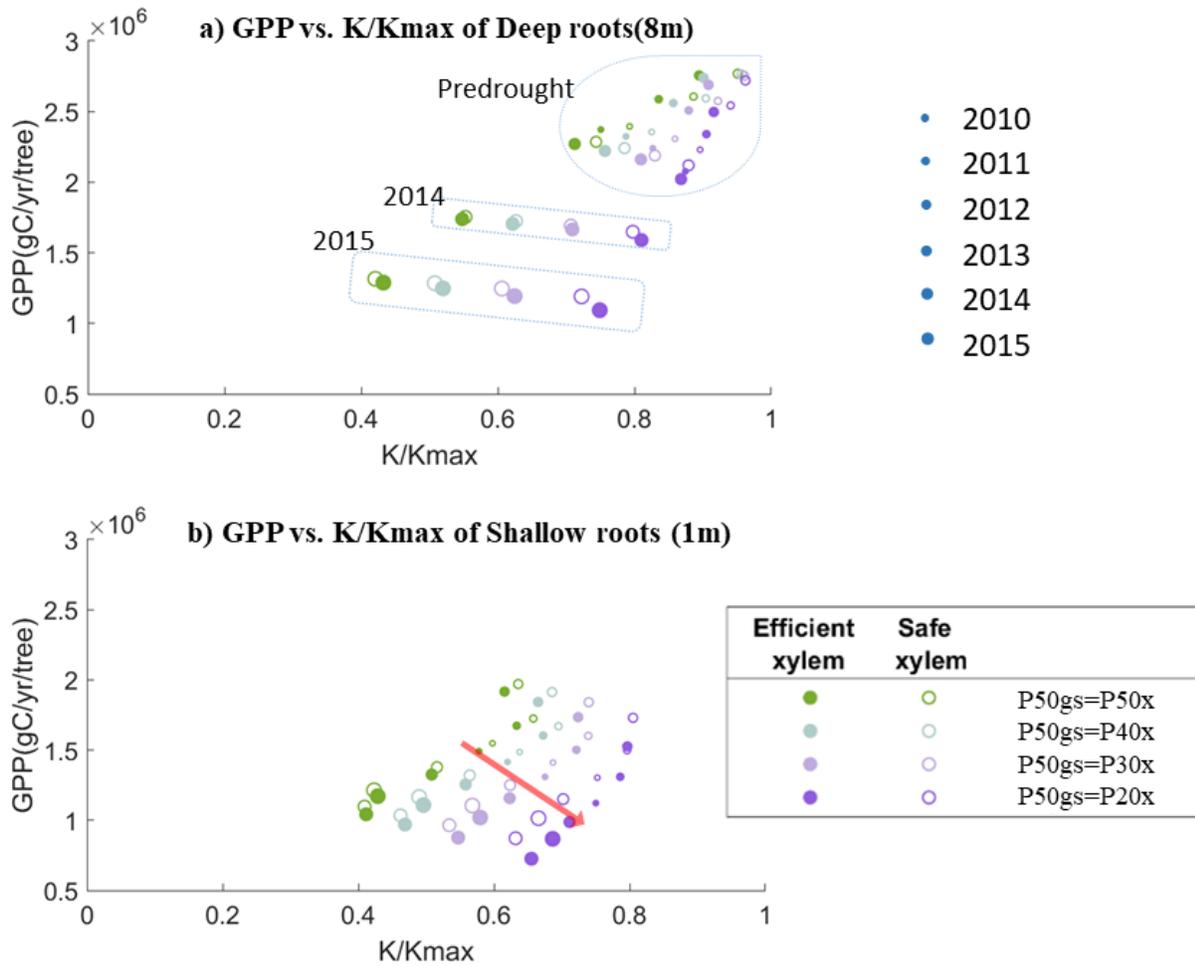

Figure 8. Simulated average annual GPP and fraction of conductance of a 55cm DBH cohort with a) deep roots (effective rooting depth= 8m) and b) shallow roots (effective rooting depth= 1m).
