17

18 **Abstract.** Due to large losses of seagrass meadows worldwide, restoration is proposed as a key strategy for  
19 increasing coastal resilience and recovery. The emergence of a seagrass meadow is expected to substantially  
20 amplify biodiversity and enhance benthic metabolism by increasing primary productivity and respiration. Yet,  
21 open questions remain regarding the metabolic balance of aging seagrass meadows and the roles benthic  
22 communities within the seagrass ecosystem play in overall metabolism.

23 To address these questions, we investigated a chronosequence of bare sediments, adjacent *Zostera*  
24 *marina* meadows of 3 and 7 years since restoration, alongside a natural meadow located within a high-temperate  
25 marine embayment in Gåsö, Sweden. We combined continuous measurements of O<sub>2</sub> fluxes using underwater eddy  
26 covariance with dissolved inorganic carbon (DIC) and O<sub>2</sub> fluxes from benthic chambers during the productive  
27 season (July). Based on the ratio between O<sub>2</sub> and DIC, we derived site-specific photosynthetic and respiratory  
28 quotients, enabling the conversion of eddy covariance fluxes to DIC. We assessed benthic diversity parameters as  
29 potential drivers of metabolic flux variability.

30 We observed high rates of gross primary productivity (GPP) spanning -18 to -82 mmol DIC m<sup>-2</sup> d<sup>-1</sup>,  
31 which increased progressively with meadow age. Community respiration (CR) mirrored the GPP trend, and all  
32 meadows were net heterotrophic (GPP < |CR|), with NCP ranging from 16 to 28 mmol DIC m<sup>-2</sup> d<sup>-1</sup>. While  
33 autotrophic biomass did not increase with meadow age, macrophyte diversity did, elucidating potential effects of  
34 niche complementarity among macrophytes on community metabolism. These findings provide valuable insights  
35 into how community composition and meadow development relate to ecosystem functioning, highlighting  
36 potential tradeoffs between carbon uptake and biodiversity.  
37

38 **1. Introduction**

39 Climate change and concurrent biodiversity loss has motivated restoration of natural ecosystems that can  
40 contribute to climate change mitigation, adaptation and at the same time strengthen local biodiversity. One such  
41 ecosystem is seagrass meadows, which has suffered substantial losses worldwide during the last century (Waycott  
42 et al., 2009; McKenzie et al., 2020). Due to its foundational role in structuring benthic communities, high  
43 productivity and ability to sequester large amounts of carbon, restoring previously lost meadows has been  
44 proposed as a low-regret option to address both the climate and biodiversity crises concomitantly (Duarte et al.,  
45 2013; Gattuso et al., 2018; Orth et al., 2020; Unsworth et al., 2022). Nevertheless, few studies have assessed  
46 whether both these goals are mutually attainable within the same restoration projects, or if there are tradeoffs  
47 between biodiversity conservation and carbon sequestration.

48 The mechanisms through which a seagrass meadow modifies carbon flows are manifold, influencing  
49 both import, export and burial of autochthonous (i.e. seagrass biomass) and allochthonous (i.e. organic matter  
50 from other sources) carbon (Duarte and Krause-Jensen, 2017). While sedimentation of allochthonous carbon is  
51 largely a passive process ultimately governed by local hydrodynamics, autochthonous carbon sequestration is  
52 coupled to the productivity of the seagrass meadow and is thus a function of its metabolic fluxes on timescales  
53 ranging from minutes to years (Smith and Key, 1975; Smith and Hollibaugh, 1993; Duarte and Cebrian, 1996).  
54 Seagrass community metabolism is comprised of gross primary productivity (GPP) and community respiration  
55 (CR) constituted by autotrophic and heterotrophic respiration. The balance between GPP and CR on a daily basis  
56 reflects the net metabolism, hereafter termed net community productivity ( $NCP = GPP - |CR|$ ). The magnitude  
57 and direction of GPP, CR and NCP determine all subsequent carbon flows whereby a positive NCP (net  
58 autotrophy) equals the net carbon fixed available for remineralization, burial or export (Duarte and Krause-Jensen,  
59 2017). Contrarily, if NCP is negative, the meadow is respiring more organic carbon than is fixed and relies on  
60 external or historic inputs of organic matter to sustain metabolism. Empirically assessing community metabolism  
61 is thus imperative to constrain a carbon budget and infer the potential net effect of a seagrass meadow on carbon  
62 sequestration.

63 The vast majority of metabolism studies in seagrass ecosystems to date are based on oxygen fluxes (Ward  
64 et al., 2022). Converting these fluxes into carbon currency often relies on assuming a constant stoichiometric 1:1  
65 ratio between oxygen and dissolved inorganic carbon ( $O_2:DIC$ ) fluxes which may significantly under- or  
66 overestimate actual metabolism (e.g. Barron et al., 2006; Duarte et al., 2010; Turk et al., 2015). For marine  
67 sediments, this ratio has been estimated to range between 0.8 – 1.2 on annual timescales (Glud, 2008 and  
68 references therein) but the variability is poorly constrained and likely higher in seagrass systems and on shorter  
69 timescales (Turk et al., 2015; Trentman et al., 2023). The discrepancy from a 1:1 ratio between benthic oxygen  
70 and DIC fluxes can stem from a wide range of processes, including anaerobic sediment processes, nitrate  
71 assimilation, photorespiration and differences in solubility and air-sea gas exchange rates between  $O_2$  and  $CO_2$   
72 (Weiss, 1970; Trentman et al., 2023). In seagrasses, storage in tissues and transport of oxygen to roots and  
73 subsequent radial oxygen loss (ROL) can also contribute to deviations from the theoretical 1:1 relation (Borum et  
74 al., 2007; Ribaudo et al., 2011; Berg et al., 2019). Assessing carbon cycling in seagrass meadows without  
75 characterizing the marine carbonate chemistry system can thus lead to erroneous conclusions regarding their role  
76 in carbon cycling and ultimately their climate change mitigation potential.

77           Despite the growing number of seagrass restoration projects worldwide, assessments of the effect on  
78 benthic metabolism are lacking. To our knowledge, the only research effort that has specifically addressed benthic  
79 metabolism in restored seagrass was carried out in Virginia Coast Reserve, USA (Rheuban et al., 2014a), where  
80 a large-scale *Zostera marina* restoration project commenced in 2001 (Mcglathery et al., 2012). Rheuban et al.  
81 (2014a) employed a chronosequence approach comprised of a bare site and two stages of development since  
82 restoration (5 years and 11 years) and measured benthic metabolism on diel and seasonal timescales. The authors  
83 found that GPP and |CR| increased up to 25- and 10-fold, respectively with meadow age and this was consistent  
84 through seasons. Yet, NCP was similar, and slightly negative, between the bare site and the oldest restored  
85 meadow on an annual basis, despite the vast differences in autotrophic biomass between the two sites (Rheuban  
86 et al., 2014a). Notably, summer metabolism revealed a net autotrophic state in the five-year-old meadow (NCP),  
87 whereas the older, mature meadow (11 yr) had much higher metabolic fluxes and net heterotrophy on the order of  
88 about  $-50 \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1}$  (Hume et al., 2011; Rheuban et al., 2014a).

89           Although GPP often substantially increases during summer in temperate seagrass meadows, so does CR  
90 to a similar extent (Ward et al., 2022). Consequently, despite large seasonal variability in photosynthesis and  
91 respiration, the metabolic state (NCP) is often relatively stable on an annual basis, granted there are no major  
92 ecosystem shifts. Interannual variability of NCP has been related to seagrass die-off and recovery episodes (Berger  
93 et al., 2020), and seagrass phenology typically dictate fluxes and metabolic state on intra-annual timescales (e.g.  
94 Champenois and Borges, 2012; Rheuban et al., 2014a). However, a seagrass meadow is comprised of several  
95 components that contribute to community metabolic fluxes. Aside from the seagrass itself, these include primary  
96 producers such as macro- and microalgae and heterotrophic organisms ranging from macrofauna to bacteria.  
97 Together, these make up the fluxes of  $\text{O}_2$  and DIC measured in the overlying water column by methods such as  
98 aquatic eddy covariance, benthic chambers or open water mass balance. Isolating fluxes deriving from a single  
99 meadow component is difficult *in situ*, although promising efforts have been made at estimating the role of benthic  
100 fauna in meadow metabolism (Rodil et al., 2019; Rodil et al., 2020; Rodil et al., 2021; Rodil et al., 2022). When  
101 planting seagrass with the stated goals of obtaining both a carbon sink and a biodiversity hotspot, it is essential to  
102 understand the relationship between these two and over what timescales it may change as a meadow develops. It  
103 is therefore necessary to employ a holistic approach and assess biogeochemical and biodiversity parameters in  
104 tandem across multiple stages of seagrass growth. Importantly, both autotrophic and heterotrophic components of  
105 biodiversity are relevant as they are expected to have contrasting effects on metabolism.

106           The overarching goal of this study was thus to evaluate the alterations in metabolic fluxes and  
107 biodiversity across the transition from bare sediment to a mature seagrass meadow subsequent to active seagrass  
108 restoration. We hypothesized that in an early stage, autotrophic biomass is dominating but total biomass is  
109 relatively low, resulting in small diel variability in metabolic fluxes and an overall net autotrophic state. As the  
110 meadow grows, fauna colonization occurs alongside organic matter accumulation, shifting the system toward a  
111 more balanced metabolic state as |CR| increases relative to GPP. Finally, when the meadow has reached maturity,  
112 CR and GPP are tightly coupled in a system characterized by high turnover and a balanced NCP.

113           To test these hypotheses, we utilized a chronosequence of four stages of seagrass development since  
114 restoration located, all situated within the same sheltered bay. We employed non-invasive, high-resolution aquatic  
115 eddy covariance (EC) alongside benthic chamber incubations (BC). This allowed us to simultaneously monitor  
116 fluxes of  $\text{O}_2$  and carbonate chemistry parameters from which we could evaluate daily metabolic fluxes of both

117 oxygen and carbon. Additionally, we investigated multiple aspects of taxonomic and functional diversity among  
118 both macrophytes and benthic fauna and assessed surficial sediment carbon stocks to infer short-term impacts of  
119 seagrass restoration on both carbon cycling and biodiversity.

120 **2. Methods**

121 **2.1 Site description**

122 The study took place between July 4–20, 2022 on the island of Gåsö (58.2325, 11.3984) located at the mouth of  
123 the Gullmar fjord on the NW coast of Sweden (Fig. 1). The area has microtidal characteristics, with an amplitude  
124 of 20-30 cm, while the Gullmar fjord is stratified featuring three pycnoclines occurring between 10 – 50 m  
125 (Sundbäck et al., 2004). Surface water salinity naturally fluctuates between 15-30 in this region due to the  
126 alternating currents of brackish Baltic Sea water and saline North Sea water (Lindahl et al., 1998). The bay of  
127 Gåsö is a semi-enclosed bay spanning ~0.3 km<sup>2</sup> with two narrow inlets and outlets and lacks major surface  
128 freshwater sources. Its sheltered position results in a small fetch and a mild wave climate (Fig.1).

129 **Figure 1 Aerial view and seagrass development stages after restoration. a) Map showing study location (inset) and**  
130 **drone image of Gåsö bay outlining the approximate locations of the sites. b) a schematic illustration of seagrass meadow**  
131 **development in the four sites Bare, 3 yr, 7 yr and Nat which represent different stages of meadow development as**  
132 **indicated by the arrow and text in italics.**  
133

134 The benthos consists of a natural, subtidal continuous eelgrass (*Z. marina*) meadow and large patches interspersed  
135 with bare sediment occurring between 1–4 m depth (Fig. 1; Huber et al., 2022). In 2015 and 2019, as part of the  
136 seagrass restoration program ZORRO ([www.gu.se/en/research/zorro](http://www.gu.se/en/research/zorro)), two plots of *Z. marina* were planted at the  
137 same depth (~2 m), using the same planting methodology (single-shoot) and shoot density (16 shoots m<sup>-2</sup>)  
138 (Gagnon et al., 2023). These plots thus provided a chronosequence of seagrass meadow ages spanning three and  
139 seven years since planting, while the bare sediment area and the natural meadow corresponded to a ‘before’ state  
140 and a mature meadow, respectively. The part of the natural meadow we sampled was estimated to have been  
141 naturally colonized by meadow expansion 13–15 years ago (E. Infantes, pers. obs.). Altogether, this yielded four  
142 sites within 100 m distance from each other representing four different stages in the development of a seagrass

143 meadow (Fig. 1; Table S1). Importantly, the validity of applying a chronosequence methodology to investigate  
144 age-related differences in seagrass metabolism relies on assumptions that the sites compared experienced similar  
145 abiotic conditions after planting and during sampling (Fig. S2; Table S2). Utilizing adjacent sites within a semi-  
146 enclosed bay addresses most of those matters but to further control assumptions, we monitored *in situ* flow  
147 velocity, photosynthetic active radiation (PAR), temperature, turbidity, salinity and wind conditions during all  
148 deployments and assessed the variation in oxygen fluxes explained by each variable using linear mixed effects  
149 models (see below).

150

## 151 **2.2 Benthic fluxes**

### 152 **2.2.1 Aquatic eddy covariance (EC)**

153 The EC system (Berg et al., 2003) consisted of a stainless-steel tripod frame with an acoustic doppler velocimeter  
154 (ADV Vector, Nortek) and a fast-responding oxygen microsensor (430 UHS, Pyroscience GmbH) programmed  
155 to log data continuously at 16 Hz from co-located measurements of velocity and oxygen concentration. In addition,  
156 two PAR sensors (LI-192, RBR) were mounted to the frame where one was facing upwards to record incident  
157 light and one was directed downwards to record reflected light. This made it possible to calculate the fraction of  
158 absorbed light ( $fAPAR$ ) during deployments. Dissolved oxygen optodes (miniDOT, PME and U26 HOBO, Onset)  
159 were mounted on the leg of the frame and recorded ambient dissolved oxygen concentration (DO) within the  
160 canopy at 1 min intervals. In addition, a salinity sensor (U24 HOBO, Onset), a turbidity sensor (RBRsolo, RBR)  
161 and two light intensity loggers (HOBO Pendant MX, Onset) were located on the frame recording at 1 min  
162 intervals.

163 We deployed the EC at the center of the transplanted plots, resulting in a distance of 20 m between the 3  
164 yr and the 7 yr site. In order to maintain the same water depth, the bare site was located 46 m from the 7 yr and  
165 29 m from the 3 yr site with the natural site 57 m away from the 3 yr site, 47 m from the 7 yr site and 58 m from  
166 the bare site (Table S1). EC deployments lasted between 44 and 49 hours (Table S1). In between each deployment  
167 data was offloaded, sensors and frame cleaned, and batteries exchanged as necessary.

### 168 **2.2.2 Benthic chambers (BC)**

169 Simultaneously with EC, we deployed benthic chambers (n=6 per site) within five meters of the EC and randomly  
170 emplaced within 1 m of each other (Fig. S1). We assured that chambers were positioned downstream of the EC  
171 with respect to the dominant current direction as to not influence the footprint of the EC. Benthic incubation  
172 chambers consisted of acrylic cylinders (inner diameter = 12.45 cm, length = 65 cm) with a custom-made motor  
173 running a propeller to mix the water within the chamber and avoid build-up of vertical concentration gradients.  
174 We employed pilot tests with dye injection in the laboratory and field to ensure sufficient mixing and during  
175 incubations, chambers were inserted approximately 20 cm into the sediment. We used transparent (n=3) and  
176 opaque (n=3) chambers to simulate day (photosynthesis and respiration) and night (respiration only), respectively.  
177 Upon deployment, chambers were left with lids off for about 30 mins to allow for suspended sediment to settle.

178 We drew discrete samples of seawater at onset and termination of each incubation using two 50 mL  
179 syringes attached to 30 cm Tygon® tubing, inserted through a closable sampling port in the chamber lid. We

180 immediately analyzed seawater in the syringes for pH and dissolved oxygen (DO). pH was measured using an  
181 InLab Micro pH electrode with a FiveGo handheld pH meter (Mettler Toledo). The electrode was calibrated both  
182 using a two-point calibration with standard buffers (pH 7 and 10, Mettler Toledo) at the onset and termination of  
183 the field campaign and calibrated to certified Tris buffer in synthetic seawater (Dr. A. Dickson, SIO) in the  
184 beginning and end of each sampling day. This was done to account for the effect of salinity and to yield values  
185 on the total hydrogen ion scale (pH<sub>T</sub>). We measured salinity using a conductivity probe connected to a pH/cond  
186 340i multimeter (WTW).

187 We measured DO using a fiberoptic oxygen sensor coupled to a FireSting® GO2 oxygen meter  
188 (PyroScience). A temperature probe was also connected to the FireSting® to record temperature during each  
189 measurement. Seawater from the syringes was then filtered through 0.45 µm Minisart® sterile syringe filters  
190 (Sartorius) and stored in 50 mL Falcon tubes on ice. Upon return to the laboratory, we placed samples for TA in  
191 a dark container at 4 °C whereas samples for inorganic nutrients and DOC were frozen (-20 °C) immediately until  
192 subsequent laboratory analyses.

193 We determined TA by open-cell potentiometric titration using an 888 Titrando system with an Ecotrode  
194 plus pH electrode (Metrohm). Samples (40–50 g) were titrated with prepared 0.05 M HCl in ~0.6 mol kg<sup>-1</sup> NaCl,  
195 corresponding to the ionic strength obtained from the mean salinity of the samples. Accuracy and precision (-  
196 1.65±3.76 µmol kg<sup>-1</sup>) were determined using certified reference material (CRM, batch 200, n=8) provided by Dr.  
197 Andrew Dickson at Scripps Institution of Oceanography, San Diego.

198 We analyzed dissolved inorganic nitrogen (NH<sub>4</sub>-N and NO<sub>3</sub>-N) using Flow Injection Analysis on a FIA  
199 Star 5000 analyzer (FOSS) and phosphate (PO<sub>4</sub>-P) using ion chromatography on an 861 Advanced Compact IC  
200 (Metrohm). We analyzed dissolved organic carbon (DOC) and total nitrogen (TN) using a V-CPH Total Organic  
201 Carbon analyzer (Shimadzu).

202 We calculated DIC using the package *seacarb* in R (Gattuso et al., 2022) with measured values of pH<sub>T</sub>  
203 and TA in conjunction with *in situ* temperature, salinity, pressure and NH<sub>4</sub><sup>+</sup> as input parameters. We used  
204 dissociation constants K<sub>1</sub><sup>\*</sup> and K<sub>2</sub><sup>\*</sup> from Lueker et al. (2000). We also calculated the saturation state of CaCO<sub>3</sub>  
205 mineral form aragonite ( $\Omega_{Ar}=[Ca^{2+}][CO_3^{2-}]/K_{sp}^*$ ) from each sample using *seacarb*. All solute concentrations were  
206 calculated to µmol kg<sup>-1</sup>, using *in situ* pressure, temperature and salinity data.

207 Using incubations with discrete measurements to assess flux rates assumes that concentrations change  
208 linearly with time. We verified this assumption *ex situ* by bringing an intact chamber core from the natural  
209 meadow into the laboratory. The chamber was placed in a large water bath with running seawater and prior to  
210 each incubation, the chamber was saturated with oxygen by bubbling compressed air. We ran multiple dark  
211 incubations with continuous logging of dissolved oxygen and temperature (FireSting® GO2) combined with  
212 multiple discrete measurements of pH (n=4) and TA (n=2).

213 We used the abovementioned measurements at the onset of incubations to infer mean ambient seawater  
214 chemistry at each site (Table S3).

## 215 **2.3 Community components**

### 216 **2.3.1 Macrophytes and microphytobenthos**

217 We evaluated seagrass shoot density by placing a 0.25 m x 0.25 m frame randomly in ten areas of each site and  
218 counting seagrass shoots in subareas of 0.016 m<sup>2</sup> (n=10 per site). In addition, we collected seagrass shoots using

219 a mesh net bag attached to a closable aluminum frame (opening area = 0.1156 m<sup>2</sup>, n=3 per site). From these  
220 samples, we measured aboveground biomass, shoot density, number of reproductive shoots, leaf length, and  
221 number of leaves per shoot. We also assessed the taxa and biomass of macrophytes other than seagrass (e.g. red  
222 and brown macroalgae). Seagrass belowground biomass including live and dead roots and rhizomes were  
223 collected using sediment cores (see below). We dried biomass samples at 60 °C for 72 hours and values are  
224 reported as dry mass (g m<sup>-2</sup>).

225 We collected sediment samples to estimate microphytobenthos abundance, using sediment surface  
226 chlorophyll *a* as a proxy. From each sediment core, we used a cutoff 5-mL syringe (Ø=12 mm) to collect 2 mL  
227 sediment from the surface layer. This was repeated three times for each core and we pooled the three samples into  
228 one 6 mL sample per core and put in a 50 mL centrifuge tube covered in aluminum foil to avoid light penetration.  
229 The samples were immediately frozen (-20 °C) until subsequent extraction and analysis. After thawing at 4 °C  
230 overnight, we drew a subsample of 2 mL sediment from each sample, weighed and dried it at 60 °C for 72 hours  
231 to obtain wet weight (g) dry weight (g), dry bulk density (DBD, g cm<sup>-3</sup>) and water content (%). We extracted the  
232 chlorophyll using ethanol (99.5 %) and, after diluting and incubating overnight, measured fluorescence using a  
233 Turner TD-700 fluorometer (Turner Designs). We calculated chlorophyll *a* content (g m<sup>-2</sup>) using a modified  
234 equation from Hannides et al. (2014).

### 235 **2.3.2 Benthic fauna**

236 We targeted infauna and epifauna separately where we collected seagrass epifauna from the mesh net bag samples  
237 described above (mesh size ~ 0.2 mm, n=3 per site). This approach allows for capturing the entire community by  
238 which cores captures infauna and slow-moving epifauna and the mesh net approach captures fast-moving and  
239 larger epifauna present in the seagrass canopy. For infauna, we collected sediment cores using polycarbonate  
240 cylinders (inner diameter: 7.4 cm, length: 33 cm, 20 cm depth, n=6 per site) for determination of infauna and  
241 seagrass belowground biomass. Upon return to the laboratory, samples were sieved (0.5 mm) and fixed in 95 %  
242 ethanol for subsequent counting and species identification. Fauna was identified to lowest taxonomic level  
243 possible.

### 244 **2.3.3 Sediment properties**

245 In addition to the sediment cores used for infauna, we collected three additional sediment cores from each site to  
246 determine sediment properties. These cores were stored upright and immediately brought back to the lab and  
247 sliced into sections at 2, 4, 6, 8, 12, 16 cm depth. We used the top 0–2 cm section for determination of water  
248 content, DBD and porosity (refer to section 2.3.1). After removing all visible rhizomes, roots and shells, we dried  
249 all sections at 60 °C for 72 hours, homogenized with a pestle and mortar and analyzed subsamples (5 mL) for  
250 organic matter content using loss on ignition (4 hours at 520 °C). Subsamples from the top 0–2 cm sediment layer  
251 (n=12) were also analyzed for particulate organic carbon (POC), particulate inorganic carbon (PIC) and total  
252 nitrogen (TN) using a Vario MAX TN elemental analyzer (Elementar). We pre-treated samples with HCl to  
253 remove carbonates and PIC was obtained by subtracting POC from total carbon (TC). We obtained a linear  
254 relationship between OM and POC (POC=0.47\*OM-0.88; R<sup>2</sup>=0.84, p<0.001) which we used as a conversion  
255 factor to convert remaining OM values to POC and thereby obtain POC values for all core slices. This conversion  
256 is based on the assumption that the relationship persists with sediment depth and this introduces uncertainty in the

257 POC values at depth. We calculated carbon density for each slice between 0–12 cm by multiplying POC with  
 258 surface DBD and integrated across 0–12 cm to obtain the organic carbon stock ( $POC_{stock}$ ,  $g\ m^{-2}$ ) in the upper 12  
 259 cm of sediment. Using only DBD values for the top 0–2 cm introduces uncertainty in our depth-integrated  $POC_{stock}$   
 260 estimates but a previous study by Dahl et al. (2023) from the same area showed similar DBD values from 0–11  
 261 cm (mean  $0.43 \pm 0.15\ g\ cm^{-3}$ ) that were consistent with sediment depth.

## 262 2.4 Data analyses

### 263 2.4.1 Flux calculations

264 We calculated oxygen fluxes in the benthic chambers (BC) as the difference in solute concentration between the  
 265 onset and termination of each incubation as

$$F_{O_2} \text{ (mmol } O_2\ m^{-2}\ h^{-1}) = \frac{\Delta O_2}{\Delta t} \rho h \quad (1)$$

266 where  $\Delta O_2$  is the change in  $O_2$  concentration in  $mmol\ kg^{-1}$  between start and end of incubation,  $dt$  is the duration  
 267 of the incubation in hours,  $\rho$  is the density of the seawater in  $kg\ m^{-3}$  and  $h$  is the height of the chambers from the  
 268 top to the sediment surface in meters. We calculated the flux of salinity-normalized TA ( $nTA = TA/S_{in\ situ} \times S_{mean}$ ;  
 269 Table S2) in the same way:

$$F_{TA} \text{ (mmol TA } m^{-2}\ h^{-1}) = \frac{\Delta nTA}{\Delta t} \rho h \quad (2)$$

270 Similarly, we used DIC measurements to obtain fluxes as

$$F_{DIC} \text{ (mmol C } m^{-2}\ h^{-1}) = \frac{\Delta nDIC}{\Delta t} \rho h - 0.5F_{TA} \quad (3)$$

271 where  $\Delta nDIC$  is the change in salinity-normalized DIC in  $mmol\ kg^{-1}$ . The subtraction of  $0.5F_{TA}$  is to account for  
 272 the effect of inorganic processes (i.e. calcification/ $CaCO_3$  dissolution) on DIC according to the assumptions that  
 273 net community calcification affects TA and DIC in a ratio of 2:1 and NCP only modifies DIC (Smith and Key,  
 274 1975).  $F_{DIC}$  thus represents the DIC flux stemming from primary production and respiration only.

275 We calculated the photosynthetic (PQ) and respiratory (RQ) quotients from the average absolute fluxes  
 276 (i.e. the magnitude of the flux, excluding the direction) in transparent and dark chambers, respectively, as

$$PQ = \frac{|F_{O_2,light} - F_{O_2,dark}|}{|F_{DIC,light} - F_{DIC,dark}|} \quad (4)$$

277 and

$$RQ = \frac{|F_{DIC,dark}|}{|F_{O_2,dark}|} \quad (5)$$

278 Due to issues with the dark incubations in the natural meadow, RQ from this site was instead calculated as the  
 279 average of the three other sites.

280 We computed EC fluxes from the high frequency time series following a multiple-step protocol described  
 281 in Attard et al. (2019). In short, we bin-averaged the time series to 8 Hz, extracted fluxes for consecutive 15 min  
 282 time windows using linear detrending (McGinnis et al., 2014) and corrected fluxes for oxygen storage within the  
 283 canopy (Rheuban et al., 2014b). Subsequently, we bin-averaged 15 min fluxes to 1 hr for interpretation. We  
 284 defined  $F_{light}$  and  $F_{dark}$  based on when incident PAR was above or below  $1\ \mu mol\ m^{-2}\ s^{-1}$ , respectively. All sites  
 285 experienced 19 light hours and 5 dark hours on average. We calculated daily metabolic parameters gross primary  
 286 productivity (GPP) as

287

$$GPP \text{ (mmol } m^{-2}d^{-1}) = (F_{light} + |F_{dark}|) \times t_{day} \quad (6)$$

288 where  $t_{day}$  is the number light hours. We calculated community respiration (CR) as

$$CR \text{ (mmol } m^{-2}d^{-1}) = F_{dark} \times 24 \quad (7)$$

289 and net community productivity (NCP) as

$$NCP \text{ (mmol } m^{-2}d^{-1}) = GPP - |CR| \quad (8)$$

290 We converted oxygen-based daily metabolic fluxes to DIC fluxes by multiplying  $F_{light}$  and  $F_{dark}$  with our  
291 empirically derived PQ and RQ, respectively:

$$F_{light\_DIC} \text{ (mmol DIC } m^{-2}h^{-1}) = F_{light} \times \frac{1}{PQ} \quad (9)$$

292

$$F_{dark\_DIC} \text{ (mmol DIC } m^{-2}h^{-1}) = F_{dark} \times -\overline{RQ} \quad (10)$$

293 We then recalculated daily metabolic DIC fluxes  $GPP_{DIC}$ ,  $CR_{DIC}$  and  $NCP_{DIC}$  (mmol DIC  $m^{-2} d^{-1}$ ) using Eq. (6)–  
294 (8). Due to lack of information on the temporal variability in PQ and RQ, we only interpret DIC fluxes on a daily  
295 basis.

#### 296 **2.4.2 Biodiversity**

297 We evaluated biodiversity both from a taxonomic and a functional perspective. For taxonomic diversity, we used  
298 the *vegan* package in R (Oksanen et al., 2019) to compute Shannon diversity ( $H'$ ) and Pielou's evenness  
299 component ( $J'$ ).  $H'$  was converted to effective numbers ( $H_{eff} = \exp(H')$ ) to make it linear and scale to species  
300 richness (Jost, 2006). For functional diversity, we first assigned functional traits to each species based on existing  
301 literature (Österling and Pihl, 2001; Törnroos and Bonsdorff, 2012; Queirós et al., 2013; Riera et al., 2020; Remy  
302 et al., 2021; Kindeberg et al., 2022) and the databases Biological Traits Information Catalogue (Marlin, 2023) and  
303 Polytraits (Faulwetter et al., 2014). The selection of functional traits was based on direct connections to carbon  
304 cycling including feeding mode, bioturbation mode and whether the species is calcifying. Indirect, general traits  
305 included movement mode, living habit and environmental position. This selection process resulted in 25 trait  
306 modalities from which we constructed a traits-by-species matrix assigning each species to specific trait modalities  
307 (refer to Table S4). Species can exhibit multiple trait modalities, depending on life history and environmental  
308 conditions. To address this, and to avoid a disproportionally large influence by generalist species on functional  
309 diversity, we used fuzzy coding (Chevenet et al., 1994) whereby species comprising multiple trait modalities were  
310 assigned a score between 0 (no association) and 3 (full association), with the total sum of each trait always being  
311 3. Based on this matrix, we calculated community-weighted means of trait values (CWM) and several multivariate  
312 components of functional diversity including functional richness (FRic), functional evenness (FEve) and Rao's  
313 quadratic entropy (RaoQ). These calculations were performed using the *FD* package in R (Laliberté and Legendre,  
314 2010) and further detailed information on these multivariate components and their taxonomic analogs can be  
315 found in Mason et al. (2005) and Villéger et al. (2008). As with  $H'$ , the functional diversity index RaoQ was  
316 transformed to effective numbers as  $FD_{eff} = 1/(1-RaoQ)$ .

317 We measured biomass divided into classes. We obtained wet weight (g) after blotting each specimen on  
318 a tissue for two seconds and dry weight (g) after drying at 60 °C for 24 hours. Regrettably, due to a computer  
319 malfunction the class division per sample was lost for infauna samples and only total, pooled biomass per site is

320 available for this group. We combusted pooled samples at 520 °C for 4 hours to obtain ash-free dry weight  
321 (AFDW, g m<sup>-2</sup>).

### 322 **2.4.3 Light-use efficiency**

323 We evaluated the relationship between irradiance (PAR) and gross primary productivity (GPP) using a hyperbolic  
324 tangent function (Jassby and Platt, 1976; Platt et al., 1980):

$$GPP = P_m \times \tanh\left(\frac{\alpha PAR}{P_m}\right) \quad (11)$$

325 where P<sub>m</sub> is maximum oxygen flux of gross primary productivity (mmol O<sub>2</sub> m<sup>-2</sup> h<sup>-1</sup>), α is the quasi-linear initial  
326 slope of the curve and PAR is seabed irradiance as photosynthetic active radiation (μmol photons m<sup>-2</sup> s<sup>-1</sup>). We  
327 performed curve-fitting in OriginPro 2022 using a Levenberg–Marquardt iteration algorithm, and we scaled the  
328 standard error of the fitting parameters with the square root of the reduced chi squared statistic (Attard & Glud  
329 2020).

330 To examine these relationships further, we calculated the light-use efficiency (LUE) at each site, which  
331 indicates the efficiency with which absorbed PAR is converted to primary production, as:

$$LUE = \frac{GPP}{PAR \times fAPAR} \quad (12)$$

332 where fAPAR is the fraction of absorbed irradiance calculated from the difference between incident and reflected  
333 PAR as measured by the upward and downward facing PAR sensors (see above). Including fAPAR in the  
334 calculation of LUE thereby accounts for any differences owing to meadow characteristics such as the higher three-  
335 dimensional meadow complexity (higher fAPAR) relative to bare sediment (lower fAPAR) and captures the diel  
336 differences in seabed reflectance and absorption (Attard and Glud, 2020).

### 337 **2.4.4 Statistical models**

338 To test the effect of differences in abiotic factors between deployments, and thereby validate the use of the  
339 chronosequence approach, we employed linear mixed-effects models (package *lme4* in R (Bates et al., 2015),  
340 testing the effect and interaction of abiotic variables on absolute values of hourly oxygen fluxes ([F<sub>O2</sub>]). We used  
341 model selection (based on Akaike information criterion, AIC) to select the best model, which included sea surface  
342 temperature, flow velocity, PAR and turbidity as fixed effects and site as a random factor. We used type III  
343 ANOVA for significance testing of fixed effects and likelihood-ratio tests (LRT) for the random effect.  
344 Assumptions of models were tested using the *performance* package in R (Lüdecke et al., 2020). We assessed  
345 differences in oxygen fluxes calculated by the EC and BC using a two-sample t-test and compared oxygen and  
346 DIC fluxes in the benthic chambers using linear regression analyses. We tested site differences in biodiversity and  
347 sediment parameters using multiple one-way ANOVAs and visually reviewed multivariate community  
348 composition using non-metric multidimensional scaling (NMDS) and principal components analyses (PCA). We  
349 set significance level to α=0.05 for all statistical tests and performed all analyses in R, version 4.2.3 (Rcoreteam,  
350 2023).

### 351 **2.4.5 Carbon budget**

352 We constructed a carbon budget of daily inorganic carbon fluxes and pools of organic carbon. We based the  
353 sediment carbon pool on the POC stock of the top 12 cm of sediment whereas we inferred seagrass aboveground

354 and belowground carbon from dry weight (DW) and a global average carbon content for *Z. marina* of 34 % DW  
355 (Duarte, 1990). We estimated macroalgal carbon content based on DW and species-specific carbon content of the  
356 dominant red and brown algae reported from the area, which ranged from 29.1–39.9 % DW (Olsson et al., 2020).  
357 For benthic fauna, we converted ash-free dry weight (AFDW) to carbon, assuming a 50 % carbon content  
358 (Wijsman et al., 1999; Rodil et al., 2021). We converted organic carbon pools to moles and they are reported as  
359 mol C m<sup>-2</sup>. Lastly, we calculated the total pool of organic carbon for each site as the sum of all pool means. We  
360 calculated the total propagated uncertainty ( $SE_{total}$ ) as:  
361

$$SE_{total} = \sqrt{\sigma_{sediment}^2 + \sigma_{AG}^2 + \sigma_{BG}^2 + \sigma_{algae}^2 + \sigma_{fauna}^2} / \sqrt{n} \quad (13)$$

362 where  $\sigma$  is the standard deviation of each pool mean and  $n$  is the number of pools. AG and BG is eelgrass  
363 aboveground and belowground biomass, respectively.

### 364 3. Results

#### 365 3.1 Environmental conditions

366 The weather was sunny and dry during all field deployments with only two minor rain events in between (Fig.  
367 S2). Sea surface temperature ranged from 17.10–19.98 °C, driven mainly by the diel light cycle. Salinity ranged  
368 from 24.7 to 28.9 but remained constant ( $\pm 0.1$ ) during each individual deployment. Photosynthetic active radiation  
369 (PAR) at the seabed was similar between sites and deployments and reached a highest value of  $728 \mu\text{mol m}^{-2} \text{s}^{-1}$   
370 (Fig. 2; Fig. S2). Flow velocities ranged from 0.9 to  $21 \text{ cm s}^{-1}$ , averaging  $5.6 \pm 3.4 \text{ cm s}^{-1}$  across all sites (Fig. 2;  
371 Fig. S2).

372 Ambient seawater chemistry was largely similar between sites, although there was a higher background  
373 salinity, TA, DIC and DIN at the 3 yr and Nat site, which were sampled after a weather front passed by likely  
374 exchanging some of the bay water with off-shore fjord water (Table S3; Fig. S2). Average DO during EC  
375 deployments was highest in Bare and lowest in 3 yr, averaging (mean $\pm$ sd)  $302.9 \pm 21.8$  and  $260 \pm 37.3 \mu\text{M}$ ,  
376 respectively. Turbidity was generally low but increased markedly at the Nat site, following a minor rain event  
377 prior to deployment (Fig. S2; Table S2). Yet, differences in turbidity did not have any detectable effects on seabed  
378 PAR (Fig. S2; Table S2).

#### 379 3.2 Hourly oxygen fluxes

380 Hourly  $\text{O}_2$  fluxes followed the diel light cycle and increased both in magnitude and variability going from bare  
381 sediments to increasing age of the restored seagrass (Fig. 2).

382

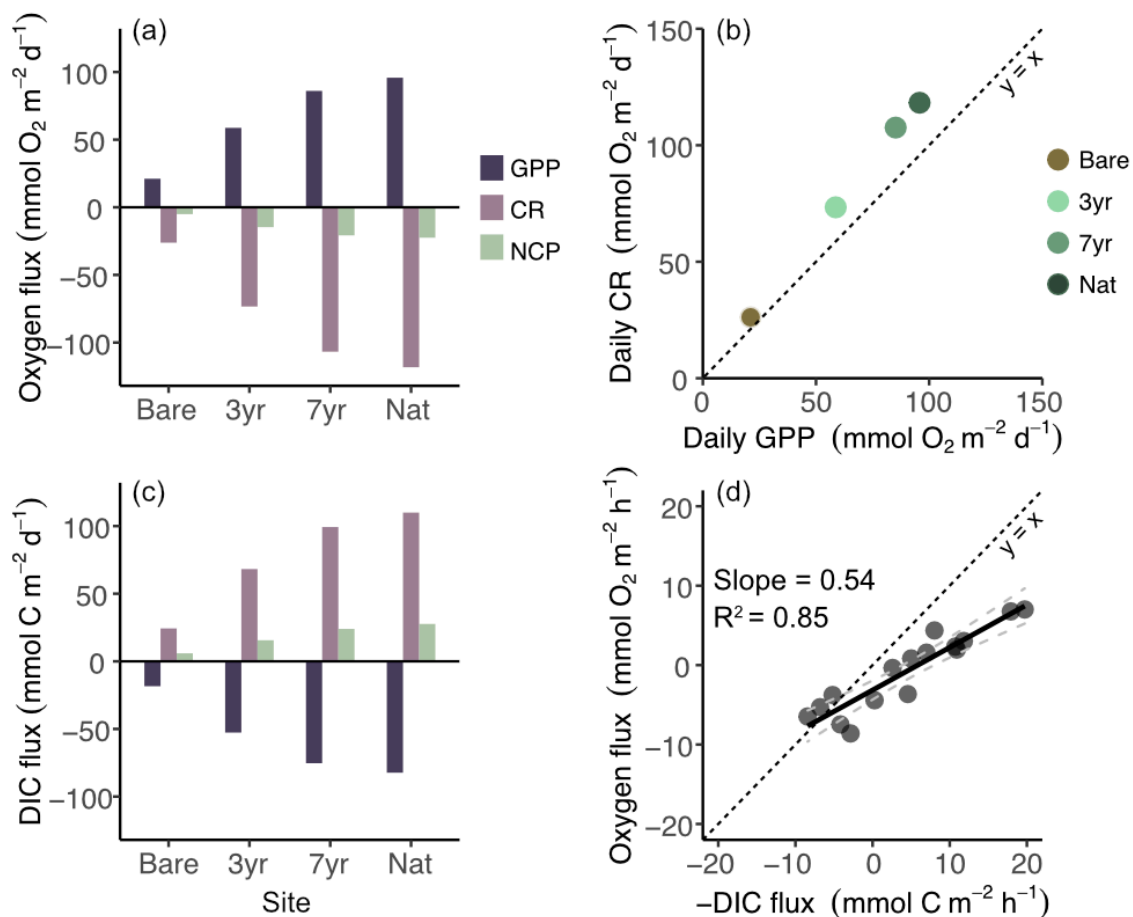

383 **Figure 2 Time series of flow, oxygen and light. Time series of (a) flow velocity, (b) ambient dissolved oxygen and (c)**  
384 **hourly oxygen flux overlaid on photosynthetic active radiation (PAR) in yellow.**

385 The largest hourly oxygen fluxes typically occurred in the afternoon, with highest recorded between 14:30–15:30  
386 in the 3 yr site ( $8.96 \pm 1.44 \text{ mmol m}^{-2} \text{ hr}^{-1}$ ). The largest oxygen uptake rates were generally observed during hours  
387 following midnight, with the most negative hourly flux recorded between 23:30–00:30 in Nat ( $-9.08 \pm 5.62 \text{ mmol}$   
388  $\text{m}^{-2} \text{ hr}^{-1}$ ).

389 Flow velocity was on average significantly higher in the 3 yr compared to Bare and significantly higher  
 390 in the 7 yr and Nat meadow compared to the 3 yr (Table S2). Although there was a general positive linear  
 391 relationship between flow velocity and absolute oxygen flux across all deployments, the higher flow velocities in  
 392 7 yr and Nat generally occurred during short time periods at night and did not correspond to consistent increases  
 393 in absolute oxygen fluxes for those sites (Fig. S3). Consequently, site  $R^2$  values were low ranging from  $<0.001$  –  
 394 0.20 (Fig. S3). Further analysis through linear mixed effects modelling indicated that while temperature, PAR,  
 395 turbidity and flow velocity explained 20% of the variation in hourly  $|F_{O_2}|$  across all sites, the random effect Site  
 396 was highly significant (LRT = 20.9,  $p < 0.001$ ) suggesting that some other feature, not included in the model,  
 397 contributed to the observed differences in oxygen fluxes between sites (Table S5).

### 398 3.3 Daily integrated metabolism

399 Daily metabolic oxygen fluxes (GPP, CR) as measured by the EC were lowest in the bare sediments and increased  
 400 with meadow age (Fig. 3a). GPP and CR were tightly coupled but  $|CR|$  was always higher than GPP, amounting  
 401 to an average GPP:CR ratio of 0.81 (Fig. 3b). Accordingly, we observed net heterotrophy at all sites (NCP  $< 0$ ;

402 **Figure 3 Fluxes and relationships of oxygen, carbon and productivity dynamics.** a) Daily oxygen fluxes as gross  
 403 primary productivity (GPP), community respiration (CR) and net community productivity (NCP). b) Linear  
 regression of daily oxygen-based GPP and CR; c) Daily dissolved inorganic carbon (DIC) fluxes based on eddy  
 covariance fluxes converted using photosynthetic (PQ) and respiratory (RQ) quotients d) Linear regression of oxygen  
 and dissolved inorganic carbon (DIC) hourly flux measured in the benthic chambers used to calculate PQ and RQ.  
 Dashed black line indicates slope=1 and dashed grey lines are 95 % confidence interval of the fitted slope.

404 Fig. 3a–b). Oxygen-based NCP decreased three-fold between the bare and the youngest restored meadow ( $-5$  to  $-$   
 405  $15 \text{ mmol m}^{-2} \text{ d}^{-1}$ ) with a further 40 percent decrease in the seven-year-old meadow ( $-21 \text{ mmol m}^{-2} \text{ d}^{-1}$ ).

404 Oxygen fluxes measured by the EC and BC were not significantly different from each other (two-sample  
 405 t test:  $p = 0.69$ ), although there was a tendency to overestimate oxygen fluxes in BC relative to EC by 0.7–4.0  
 406  $\text{mmol m}^{-2} \text{hr}^{-1}$ . Oxygen and DIC fluxes in the benthic chambers were highly correlated across all incubations (Fig.  
 407 3d), irrespective of differences in light conditions. The photosynthetic quotient (PQ) was always less than unity,  
 408 averaging  $0.46 \pm 0.10$  across the four sites, whereas the respiratory quotient (RQ) averaged  $0.93 \pm 0.25$ . Site-specific  
 409 RQ revealed high variability between sites ranging from 0.65–1.13.

410 Estimated DIC fluxes mirrored those of  $\text{O}_2$  and the benthic DIC net efflux ( $\text{NCP}_{\text{DIC}}$ ) increased as a  
 411 function of meadow age from 6  $\text{mmol m}^{-2} \text{d}^{-1}$  in the bare sediments to 28  $\text{mmol m}^{-2} \text{d}^{-1}$  in the natural meadow,  
 412 thus confirming the net heterotrophic status of the meadows as determined using oxygen fluxes (Fig. 3b, 3c).

### 413 3.4 Structural and functional diversity

#### 414 3.4.1 Meadow properties

415 All three eelgrass sites were characterized by high spatial heterogeneity within each meadow (Table 1). No  
 416 significant differences were observed in seagrass morphometry such as shoot density, canopy height or below- or  
 417 aboveground biomass. The only seagrass parameter that differed between the meadows was the number of  
 418 reproductive shoots containing seeds, which was significantly higher in the natural meadow ( $p = 0.004$ ). However,  
 419 the abundance and biomass of other macrophyte species such as brown and red macroalgae increased markedly  
 420 with meadow age. In the 3 yr meadow, only a small specimen of the brown algae *Spermatochnus paradoxus* was  
 421 found in one sample whereas in the natural meadow large quantities of up to five different macroalgal species  
 422 were found. However, due to large variability in biomass between samples within each site (Table 1), the between-  
 423 site differences in number of species were not statistically significant (ANOVA,  $p > 0.05$ ). The composition of  
 424 macrophyte species became more even with meadow age such that while the 3 yr meadow was dominated by *Z.*  
 425 *marina* (~99 % of total macrophyte biomass), the 7 yr and the natural meadow had a more heterogenous and  
 426 evenly distributed macrophyte community, where *Z. marina* on average contributed  $90 \pm 15$  % and  $64 \pm 32$  %,   
 427 respectively, to total macrophyte biomass (Table 1). As a result, the three-dimensional complexity of the canopy  
 428 increased with meadow age, driven mainly by large-bodied drifting furoid species (*F. serratus* and *F. vesiculosus*)  
 429 and red algae *Furcellaria lumbricalis* residing, unattached, within the canopies.

430 Benthic microalgae, as inferred from chlorophyll *a* on the sediment surface, showed the opposite trend  
 431 and decreased with meadow age and chlorophyll *a* was significantly lower in sediments underlying 7 yr  
 432 ( $0.28 \pm 0.03 \text{ g m}^{-2}$ ) and Nat ( $0.26 \pm 0.01 \text{ g m}^{-2}$ ) compared to Bare ( $0.56 \pm 0.07 \text{ g m}^{-2}$ ).

433 **Table 1 Eelgrass and macroalgal structural diversity. Morphometrics, biomass and diversity across the sites**  
 434 **(mean $\pm$ SE). ‘Rep. shoots’ represents reproductive shoots with seed spathes present. AG and BG are aboveground and**  
 435 **belowground eelgrass biomass, respectively, as captured by sediment cores. Macroalgal biomass represents macroalgae**  
 436 **collected from eelgrass canopy samples. Maximum number of species refers to the count of macroalgal species found**  
 437 **in a sample. Relative proportion indicates macroalgal biomass relative to total macrophyte biomass. Species richness,**  
 438 **diversity ( $H_{\text{eff}}$ ) and evenness ( $J'$ ) refer to macrophytes including macroalgae and eelgrass. An asterisk indicates**  
 439 **statistical significance ( $p < 0.05$ ).**

### 441 3.4.2 Benthic fauna

442 We collected a total of 1927 individuals representing 43 taxa. Taxonomic diversity parameters (abundance,  
443 number of species, Shannon diversity, evenness) exhibited large within-site variability, highlighting the small  
444 scale (<10 m) heterogeneity of fauna community structure. These parameters consistently showed higher values  
445 in vegetated compared to bare sediments but exhibited variable, but generally non-significant, differences between  
446 the eelgrass sites (Fig. 4; Table S6). Abundance of infauna was highest in the 3 yr site, primarily dominated by  
447 opportunistic polychaetes (e.g. *Capitella capitata*). Yet, despite the high abundance in the 3 yr site, this site did  
448 not show a corresponding spike in infaunal species richness but was reflected by the lowest evenness among all  
449 sites ( $J' = 0.47 \pm 0.08$ ). By contrast, in the 7 yr, the abundance had decreased by a third while species diversity (H<sub>eff</sub>)  
450 and evenness (J') nearly doubled, exhibiting similar values as the natural reference meadow (Table S6). Functional  
451 trait metrics revealed that both the functional group richness (FGR) and functional diversity (FD<sub>eff</sub>) were  
452 significantly higher in the 7 yr and Nat compared to the 3 yr and Bare sites which exhibited similar values (Table  
453 S6). Functional richness (FRic) was notably low in the bare sediments ( $0.06 \pm 0.05$ ) and tended to increase with  
454 meadow age peaking with the highest mean value in the natural meadow ( $0.53 \pm 0.11$ ). However, due to high  
455 within-site variability, FRic did not show statistically differences between sites (Fig. 4c).

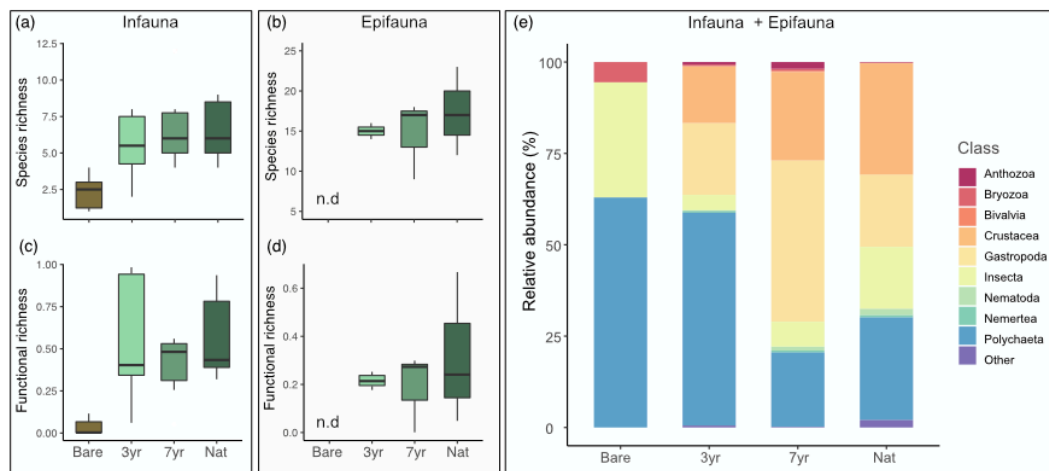

456 When separately targeting the meadows for epifauna, we found that they were species rich and highly  
457 diverse, ranging from 15–18 species and H<sub>eff</sub> from 7.4–10.9. However, neither taxonomic nor functional diversity  
458 metrics exhibited any significant differences between the meadows, although there were some increasing trends  
459 particularly in functional evenness (FEve), which was highest in Nat and lowest in 3 yr (Table S6). Epifaunal  
460 biomass increased on average three-fold in Nat compared to the two restored meadows, displaying the highest  
461 within-site variability ( $15.89 \pm 10.48$  g m<sup>-2</sup>), primarily driven by gastropods.

462 Community composition partly shifted as the meadow grew whereby bare sediments and the youngest  
463 restored meadow were dominated by polychaetes whereas more epifaunal species such as bivalves and  
464 crustaceans were found in older meadows (Fig. 4d). Absolute abundances and biomass supported these  
465 observations, with bryozoans and gastropods contributing to higher biomass in Nat relative to Bare. However,  
466 multivariate analysis of the different communities indicated an overlap in community composition (Fig. S4).

467 Our analysis of functional traits highlighted the prevalence of certain bioturbation modes in relation to  
468 meadow age. For instance, community-weighted means (CWM) of biodiffusors displayed a linear increase with  
469 meadow age and was significantly higher in the natural meadow and 7 yr compared to the 3 yr ( $F_{3,20} = 8.4$ ;  $p <$

470 0.001). Surficial modifiers among infauna were higher in eelgrass compared to bare sediment, peaking in the  
 471 oldest restored meadow at a CWM of  $0.29 \pm 0.10$ .

472

473 **Figure 4 Biodiversity patterns in benthic fauna.** Panels to the left show species richness (a–b) and functional richness  
 474 (c–d) of infauna samples (a & c) and epifauna samples (b & d). Large panel to the right (e) shows relative abundance  
 475 of different classes of all fauna combined (infauna + epifauna).

### 476 3.5 Sediment carbon stocks

477 The sediment within Gåsö bay eelgrass meadows has previously been reported as silty sand, with a median grain  
 478 size ( $D_{50}$ ) of the surface sediment between 140–170  $\mu\text{m}$  and a silt-clay content of 26–35% (Infantes et al., 2022;  
 479 Dr. Martin Dahl, pers. comm.). Concentrations of sediment OM, POC and TN were not significantly different  
 480 between sites ( $p < 0.05$ ) and did not display any consistent increases or decreases with meadow age (Table 2).  
 481 However, when integrating the POC density across the top 12 cm, the highest POC stock was found in one natural  
 482 meadow core ( $1529 \text{ g m}^{-2}$ ) and the lowest in a bare sediment core ( $209 \text{ g m}^{-2}$ ). Yet, due to large within-site  
 483 variability, the sites were not significantly different from each other ( $F_{3,8}=1.52$ ;  $p=0.28$ ; Table 2). Meadow age  
 484 did not show a clear trend, as demonstrated by the 3 yr site, which had an average carbon stock 32 % larger than  
 485 the 7 yr, while the 7 yr site was more similar to the bare sediments site (Table 2). Depth profiles of POC  
 486 concentration and density down to 20 cm revealed near-constant values down to between 12–16 cm, where  
 487 increase was observed (Fig. S5). Natural eelgrass had the highest average POC profile, but average values were  
 488 highly skewed by one core replicate displaying POC density four times higher than the other two replicates within  
 489 the site.

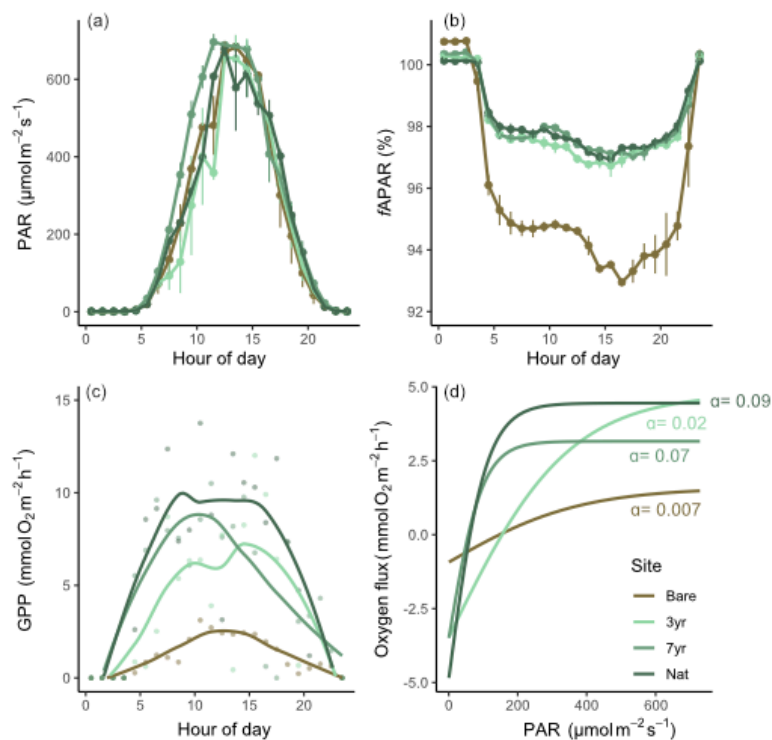

490 **Table 2 Sediment properties across sites. Organic matter (OM), particulate organic carbon (POC), particulate**  
 491 **inorganic carbon (PIC), total nitrogen (TN) and dry bulk density (DBD) of the top 2 cm of sediment. POC stock is the**

### 494 3.6 Light-use efficiency

495 All meadows experienced similar incident light conditions (Fig. 5a). The fraction of absorbed light ( $fAPAR$ ) was  
 496 always higher in eelgrass (~97 %) compared to bare sediments (~94 %) but did not differ between eelgrass sites  
 497 on a daily basis (Fig. 5b). Hourly GPP tracked PAR with a clear hysteresis effect evident in the 7 yr and natural  
 498 meadow but to a lesser extent in the bare site (Fig. 5c; Fig. S6). P-I relationships were best explained by the  
 499 hyperbolic tangent function yielding  $R^2$  between 0.45–0.74. The irradiance needed for photosynthesis to balance  
 500 respiration ( $I_k$ ) was almost four times higher in the bare site compared to the 7 yr site, equaling 380 and 97  $\mu\text{mol}$   
 501  $\text{photons m}^{-2} \text{s}^{-1}$ , respectively (Table S7; Fig. 5d). Estimated light-use efficiency (LUE) was lowest in Bare (0.001  
 502  $\text{O}_2 \text{ photon}^{-1}$ ) and increased with meadow age to 0.004 and 0.005  $\text{O}_2 \text{ photon}^{-1}$  in 3 yr and 7 yr, respectively. The  
 503 highest daily LUE was observed in Nat (0.007  $\text{O}_2 \text{ photon}^{-1}$ ) coincident with the highest number of macrophyte  
 504 species and the most diverse community structure (Fig. 6).

505

506 **Figure 5 Light-use efficiency and productivity relationships.** Panels a–c show different components of light-use  
 507 efficiency (LUE) as a function of hour of the day: a) incident photosynthetic active radiation (PAR); b) fraction of  
 508 absorbed PAR ( $fAPAR$ ); c) shows gross primary productivity (GPP) as a function of time of day and; d) shows the  
 509 relationship between oxygen flux and PAR as hyperbolic tangent curves estimated for each site.

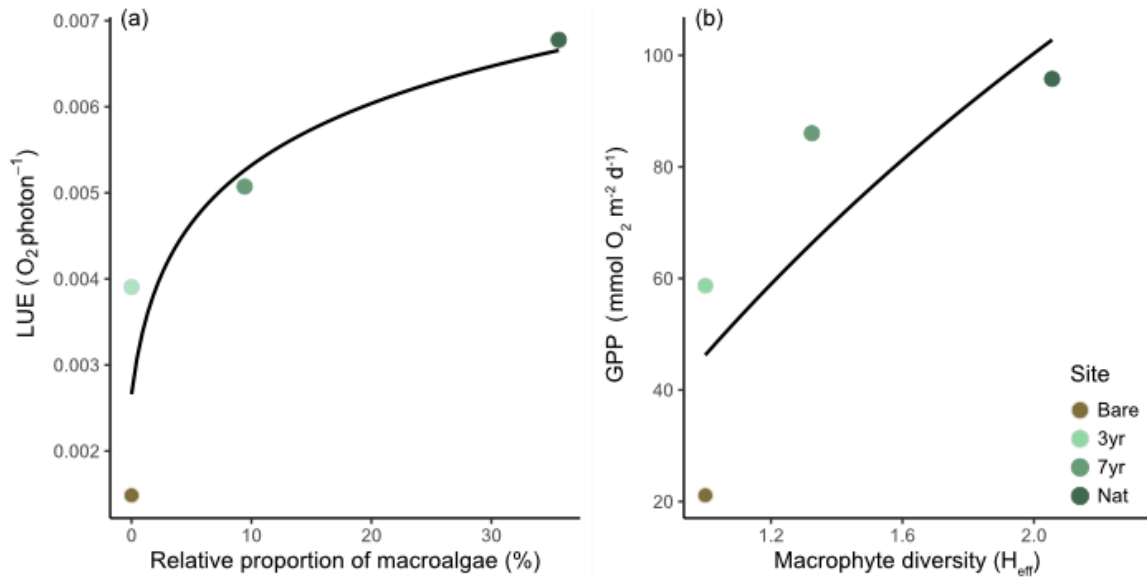

510 Similar to LUE, GPP and  $|CR|$  displayed a positive linear relationship with number of macrophyte  
 511 species. There was also a positive trend between these parameters and macrophyte Shannon diversity ( $H_{eff}$ ) and  
 512 the proportion of macroalgal biomass relative to eelgrass biomass, respectively (Fig. 6). As such, the model that  
 513 best explained changes in daily benthic metabolism across the four different stages of seagrass development was  
 514 a logarithmic model (Table 3).

515 **Table 3 Daily metabolism as a function of meadow age.** Curve fitting of daily metabolism parameters GPP, CR and  
 516 NCP to meadow age (SiteAge) converted to logarithmic scale ( $\log_{10}(x+1)$ ). SiteAge for the site Bare was defined as 0  
 517 and 13 years for the natural meadow.

Metabolic parameter	Function	p	R <sup>2</sup>
---------------------	----------	---	----------------

GPP	$GPP = 67.29 \pm 4.63 \times \log_{10}(\text{SiteAge} + 1) - 20.80 \pm 3.65$	0.005	0.99
CR	$CR = -83.08 \pm 5.77 \times \log_{10}(\text{SiteAge} + 1) - 26.06 \pm 4.56$	0.005	0.99
NCP	$NCP = -15.79 \pm 1.26 \times \log_{10}(\text{SiteAge} + 1) - 5.26 \pm 0.99$	0.006	0.98

518

519

520 **Figure 6 Biodiversity and productivity relationship.** (a) Light-use efficiency (LUE) as a function of the relative biomass  
521 of macroalgae to eelgrass ( $R^2_{\text{adj}} = 0.70$ ). (b) Gross primary productivity (GPP) as a function of macrophyte Shannon  
522 diversity index ( $R^2_{\text{adj}} = 0.46$ ); Black lines represent best fit ( $\log_e(x+1)$ ). Note that the bare site was not quantitatively  
523 sampled for macroalgal proportions or macrophyte diversity and was *a posteriori* set to 0 % and 1, respectively, for  
524 curve fitting.

### 525 3.7 Carbon pools

526 Converting seagrass community components to carbon illustrates the pools of carbon available for export,  
527 remineralization or burial. Notably, total carbon pools were higher in eelgrass relative to bare sediment but were  
528 similar between restored and natural seagrass (Table 4). Sediment POC stocks were the largest carbon pools  
529 followed by eelgrass biomass which contributed on average 11, 21 and 7 percent to the total carbon pool in the 3  
530 yr, 7 yr and natural meadow, respectively (Table 4).

531 **Table 4. Carbon pools.** Pools of particulate organic carbon (mean $\pm$ SE,  $\text{mol C m}^{-2}$ ) in the different components of the  
532 benthic habitats. AG and BG are above- and belowground eelgrass biomass, respectively. Fauna is total fauna  
533 (infauna+epifauna).

Site	Sediment	Eelgrass AG	Eelgrass BG	Macroalgae	Fauna	Total pool
Bare	28.54 $\pm$ 7.71	0	0	n.d.	0.03	28.57 $\pm$ 13.35

Nat	73.53 $\pm$ 27.65	3.08 $\pm$ 1.39	2.95 $\pm$ 0.69	3.78 $\pm$ 2.76	0.56	83.91 $\pm$ 24.14

534

#### 535 4. Discussion

536 We present a comprehensive dataset documenting post-restoration seagrass development that captures several  
537 aspects of seagrass metabolism. This dataset enables investigating the role of biodiversity and different  
538 components of a seagrass ecosystem in carbon cycling. We show that i) community-integrated photosynthetic  
539 (GPP) and respiratory (CR) fluxes increase as a function of meadow age (Fig. 3); ii) daily |CR| increased more  
540 relative to GPP resulting in net heterotrophy (NCP<0) on diel timescales during summer; iii) diversity and biomass  
541 of macrophytes other than the restored seagrass could be driving higher primary productivity through increased  
542 light-use efficiency (Fig. 5); iv) faunal communities recover rapidly and attain species- and functional richness  
543 comparable to natural meadows within seven years since restoration (Fig. 4); v) surficial (0–12 cm) sediment  
544 carbon stocks are large but are not significantly affected by the presence of seagrass in this sheltered bay.

545 Based on the above results, we postulate that while increased macrophyte diversity enhances both GPP  
546 and CR, the additional CR stemming from benthic fauna communities together with labile organic matter input  
547 push diverse seagrass meadows toward net heterotrophy during summer. This highlights potential tradeoffs  
548 between climate change mitigation and biodiversity conservation as incentives for seagrass restoration. Below we  
549 discuss four primary lines of evidence to support this postulation.

550

#### 551 4.1 Metabolic fluxes scale to meadow development

552 We found large daily fluxes of GPP- and CR derived O<sub>2</sub> and DIC that increased as the system developed from  
553 bare sediments to a mature meadow (Table 3; Fig. 3). Our values (mean±SE) of GPP, CR and NCP across the  
554 three seagrass sites were 80±11, -99±13 and -19±2 mmol O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, respectively, which is relatively low when  
555 comparing to global average GPP, CR and NCP estimated for temperate seagrasses of 166±14, -130±11 and 34±8  
556 mmol O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, respectively (Duarte et al., 2010). Yet, it should be noted that discrepancies owing to  
557 methodological differences are difficult to account for. An updated assessment of seagrass NCP in temperate areas  
558 reported an average of 29±79 mmol O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, although the study which covered 187 seagrass metabolism studies  
559 found that merely 68 % reported net autotrophy (Ward et al., 2022). Accordingly, the notion that seagrass habitats  
560 are strongly net autotrophic is being increasingly contested as methods continue to improve. In all our sampled  
561 sites, GPP was lower than |CR| resulting in net heterotrophy (negative NCP), independently established both by  
562 EC oxygen fluxes and benthic chamber DIC and oxygen fluxes. Several recent studies have reported instances of  
563 sustained net heterotrophy across multiple seagrass species and environments (e.g. Barron et al., 2006; Rheuban  
564 et al., 2014a,b; van Dam et al., 2019; Berger et al., 2020; Attard et al., 2019; Berg et al., 2022, Ward et al., 2022).  
565 For instance, a recent study of *Z. marina* using EC reported GPP and CR values similar to our natural meadow  
566 (95 and 94 mmol O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, respectively) resulting in a near balanced metabolic state across 11 years of  
567 monitoring (Berger et al., 2020). The authors reported a generally balanced metabolic state on monthly timescales  
568 but following a temperature-driven dieback event that diminished seagrass shoot density, GPP and |CR| decreased  
569 by 55 % and 48 %, respectively. This shifted the meadow to net heterotrophy during summer (NCP = -26±15  
570 mmol O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>). In the following years, the gradual increase in seagrass shoot density increased primarily GPP,  
571 showing clear signs of seagrass recovery (Berger et al., 2020).

572 Although GPP often substantially increases during summer in temperate seagrass meadows, so does CR  
573 to a similar extent (Ward et al., 2022). Consequently, despite large seasonal variability in photosynthesis and

574 respiration, the metabolic state is often relatively stable on an annual basis, granted there are no major ecosystem  
575 regime shifts. While interannual variability of NCP has been related to seagrass die-off and recovery episodes  
576 (Berger et al., 2020), seagrass phenology linked to abiotic factors such as temperature and light regimes typically  
577 dictates the metabolic state on intra-annual timescales (e.g. Champenois and Borges, 2012; Rheuban et al., 2014a,  
578 b). Here, we show that biotic components other than the seagrass itself can contribute to both the magnitude and  
579 variability in metabolic fluxes. Irrespective of traditional seagrass metrics such as seagrass shoot density and  
580 biomass, GPP and  $|CR|$  consistently increased in magnitude with meadow age which in turn corresponded to  
581 higher autotrophic diversity and macroalgal biomass. Further research should address whether these relationships  
582 are consistent across seasons and what role differing macrophyte phenologies play.

583         The chronosequence approach employed in this study utilizes the unique opportunity of assessing  
584 contrasting restored seagrass habitats of different ages that exist within a close distance from each other (Fig. 1).  
585 This enables comparisons between near-identical geomorphology, bathymetry, hydrodynamics and seawater  
586 characteristics. However, due to logistical limitations we were unable to measure all four sites simultaneously  
587 leading to a temporal mismatch of these comparisons. Consequently, this introduces the risk of potential  
588 environmental changes between deployments. Importantly, if the change in environmental conditions is conducive  
589 to altered benthic metabolism it can influence the comparison along the chronosequence (i.e between sites). The  
590 combined effect of abiotic variables, including PAR, flow velocity, seawater temperature and turbidity accounted  
591 for 20 % of the variation in  $O_2$  fluxes, as measured by the eddy covariance. Noticeably, PAR reaching the seabed  
592 did not differ between sites, despite varying levels of turbidity (Fig. 2; Fig. S2). Salinity was higher in the 3 yr  
593 and Nat site compared to 7 yr and Bare (Table S2; Fig. S2). However, due to missing data, we could not evaluate  
594 its impacts on oxygen fluxes within the model. However, we found no discernable effects on either oxygen or  
595 carbon fluxes during our incubations, suggesting that variability in salinity was not a driving factor of metabolism.  
596 Flow velocity peaked in Nat and 7 yr sites but while there was a positive relationship between  $|F_{O_2}|$  and flow in  
597 Nat and 3 yr site, no such relationship was evident in the 7yr or Bare site (Fig. S3). Nonetheless, we cannot  
598 decisively rule out the potential role of varying flow velocities in the observed differences in benthic metabolism  
599 between sites.

600

#### 601 **4.2 Carbon and oxygen balance**

602 As part of this study, we present a methodological approach that estimates *in situ* DIC fluxes under natural  
603 hydrodynamic and light conditions. This is obtained by combining the advantages of aquatic eddy covariance  
604 with the ability to constrain the marine carbonate system and oxygen dynamics using benthic chambers.  
605 Concurrent deployment of these two methods have been utilized in previous coastal studies (Long et al., 2019;  
606 Camillini et al., 2021; Polsenaere et al., 2021), but only for comparing oxygen fluxes.

607         Assessing the *in situ* relationship between oxygen ( $F_{O_2}$ ) and DIC fluxes ( $F_{DIC}$ ) can provide insights into  
608 biogeochemical processes and renders reliable estimates of photosynthetic (PQ) and respiratory quotients (RQ).  
609 All else equal, photosynthetic and respiratory quotients are governed by the C:N:P ratio of the fixed and respired  
610 organic matter present in the system (Champenois and Borges, 2021). However, considering the various sinks and  
611 sources of organic matter present in a seagrass meadow and the multitude of processes affecting  $F_{O_2}$  and  $F_{DIC}$   
612 differently, this is not very useful. Deviations from the theoretical 1:1 relationship between  $F_{O_2}$  and  $F_{DIC}$  (Fig. 3d)

613 are thus ubiquitous in the literature (e.g. Barron et al., 2006; Turk et al., 2015; Trentman et al., 2023). In fact, the  
614 slope we observed is identical to what Pinardi et al. (2009) observed in sediments vegetated with the freshwater  
615 macrophyte *Vallisneria spiralis* using sediment cores. Moreover, our relatively low PQ's (0.34–0.52) were similar  
616 to what Ribaudo et al. (2011) observed in *V. spiralis* (0.30–0.68) in microcosms. The authors attributed the low  
617 PQ to oxygen transport to roots and subsequent radial oxygen loss (ROL) which fuels aerobic respiration, a  
618 process well-documented in *Z. marina* as well (e.g. Jensen et al., 2005; Frederiksen and Glud, 2006; Borum et al.,  
619 2007; Jovanovic et al., 2015). Turk et al. (2015) observed PQs ranging from 0.5–2.6 in seagrass (*Thalassia*  
620 *testudinum*) and found a temporal component to the variability of PQ with lower values in the morning and higher  
621 in the evening (Turk et al., 2015). Similar to our study, Ouisse et al. (2014) obtained a PQ and RQ of  $0.42 \pm 0.27$   
622 and  $0.95 \pm 0.22$ , respectively, using *in situ* benthic chambers in dwarf eelgrass (*Z. noltei*) meadows across several  
623 seasons. The authors hypothesized that the low PQ could also be due to photorespiration in epiphytic algae on the  
624 seagrass leaves which can consume more than three moles of O<sub>2</sub> for every mole DIC used (Ouisse et al., 2014).  
625 We observed large quantities of epiphytic microalgae and biofilm on seagrass leaves across all our studied  
626 meadows, albeit only as qualitative observations (Kindeberg, T., *pers. obs.*). However, seagrass epiphytes are  
627 abundant in the area where it can exert detrimental effects on seagrass metabolic performance and positive effects  
628 on epifauna distribution (Baden et al., 2010; Gullström et al., 2012; Brodersen et al., 2015). It is important to note  
629 that inorganic processes (i.e. CaCO<sub>3</sub> production and dissolution), which can have a large influence on PQ and RQ  
630 (Champenois and Borges, 2021), are implicitly accounted for in our  $F_{DIC}$  by subtraction of the  $0.5F_{TA}$  term in Eq.  
631 (3).

632 While we obtained an average RQ close to unity, it was based on a relatively small sample size compared  
633 to PQ due to issues with dark incubations especially in the natural meadow. It is possible that our acclimation  
634 (~30 mins) or incubation times ( $3.0 \pm 0.1$  hours) were too short for accurately capturing dark DIC fluxes, as seen  
635 in the temporal lag in DIC fluxes relative to O<sub>2</sub> fluxes in a study by Fenchel and Glud (2000) and a lag in O<sub>2</sub>  
636 consumption due to the primary producer cellular machinery (Tang and Kristensen, 2007). Nonetheless, without  
637 any ancillary data on other biogeochemical processes we cannot reconcile the sources of our observed PQ and  
638 RQ.

639

#### 640 **4.3 Macrophyte diversity driving light-use efficiency and higher metabolism**

641 Despite the large research field on the relationship between biodiversity and primary productivity (Tilman et al.,  
642 2014), light-use efficiency (LUE) is largely understudied in benthic metabolism studies (Attard and Glud, 2020).  
643 Studies have hitherto focused mainly on smaller-scale LUE, such as microalgae in microbial mats and corals (Al-  
644 Najjar et al., 2010; Al-Najjar et al., 2012; Brodersen et al., 2014). We observed a positive relationship between  
645 macrophyte diversity and LUE when controlling for biomass, indicating that mixed meadows consisting of both  
646 seagrass and macroalgae utilize light resources more efficiently and are more productive compared to  
647 monospecific meadows. Importantly, the restored seagrass meadows became more mixed over time as drifting  
648 macroalgae inhabited the meadow. These unattached algae are a common feature in the area, often considered a  
649 nuisance that can prevent seagrass recovery (Moksnes et al., 2018). Here it seems they also improve overall LUE  
650 of the meadow and contributes to larger metabolic fluxes.

651 Whether higher LUE is driven by certain species remains unclear, but the change in canopy structure and  
652 increasing three-dimensional complexity can positively influence LUE (Zimmerman, 2003; Binzer et al., 2006).  
653 Niche complementarity is common in ecological systems (Loreau and Hector, 2001; Hooper et al., 2005) and it  
654 is reasonable to believe that with increased diversity of autotrophs, pigment complementarity can facilitate optimal  
655 resource-use, especially as brown and red macroalgae are known to have a wide range of photosynthetic pigments  
656 (Enríquez et al., 1994). Additionally, the mere presence of multiple growth morphologies may induce self-shading  
657 that further increases LUE (Tait et al., 2014). An increase in photosynthetic pathways (e.g. C3 and C4) with higher  
658 macrophyte diversity and differing affinity for forms of inorganic nutrients (e.g.  $\text{NH}_4^+$  and  $\text{NO}_3^-$ ) is also expected.  
659 Moreover, both *Z. marina* and furoid species are known to utilize both  $\text{CO}_2$  and  $\text{HCO}_3^-$  for photosynthesis (Binzer  
660 et al., 2006). However, the efficiency differs between species (e.g. Larsson and Axelsson, 1999; Invers et al.,  
661 2001) and considering the large spatiotemporal variability in pH and  $[\text{HCO}_3^-]$  relative to  $[\text{CO}_2]$  we observed, this  
662 could be another reason for the higher LUE at higher species diversity. Studies from macroalgal canopies have  
663 found similar relationships between macrophyte canopy complexity and LUE, attributed to niche complementarity  
664 where intact assemblages are more efficient and productive than the sum of its parts (Tait and Schiel, 2011; Tait  
665 et al., 2014). For instance, a study by Tait and Schiel (2011) using *ex situ* incubation chambers found that an intact  
666 assemblage of seven species had higher net photosynthesis than the sum of all individual species. The authors  
667 observed that different species played different roles at different irradiances. For instance, the furoid species  
668 *Cystophora torulosa* was exceptionally efficient at photosynthesizing at high irradiance and did not show signs  
669 of photoinhibition even at  $\text{PAR} > 2000 \mu\text{mol m}^{-2} \text{s}^{-1}$  (Tait and Schiel, 2011). Tait et al. (2014) studied P-I  
670 relationships in macroalgal assemblages and found that when more sub-canopy species were included (up to  
671 four) respiration and photosynthesis increased, thus corroborating our observed trends. However, they found that  
672 production did not saturate at incident irradiance of  $2000 \mu\text{mol m}^{-2} \text{s}^{-1}$  as opposed to less speciose assemblages (2  
673 sub-canopy species) that reached light saturation of net primary production (NPP) already at about  $600 \mu\text{mol m}^{-2}$   
674  $\text{s}^{-1}$  (Tait et al., 2014). This is somewhat contrary to what we found for GPP, where P-I curves saturated at lower  
675 irradiance with higher macrophyte diversity (Fig. 5d; Fig. S6). Albeit not specifically addressing canopy structure  
676 or diversity, Rheuban et al. (2014a) found that a younger, five-year-old, restored *Z. marina* meadow was light-  
677 saturated while an older, 11-year-old meadow did not show any signs of light saturation, and this was consistent  
678 across seasons.

679 Whereas it is rather intuitive that a diverse community of primary producers are better at  
680 photosynthesizing (i.e. higher GPP), the relationship is as strong with CR. This is likely explained by the tight  
681 coupling between GPP and CR stemming from respiration of labile photosynthates (Penhale and Smith, 1977).  
682 However, detritus of macroalgae such as *Fucus* spp. is also more labile than *Z. marina*, partly due to a lower C:N  
683 ratio and a more bioavailable polysaccharide composition (e.g. Kristensen, 1994; Thomson et al., 2020).

#### 684 **4.4 The role of benthic diversity in seagrass metabolism**

685 The fact that most fauna diversity metrics were not significantly different between the natural meadow and the  
686 youngest (3 yr) meadow implies that benthic diversity recovers quickly. Similar findings have recently been  
687 reported from *Z. marina* restoration projects in Denmark (Steinfurth et al., 2022) and from the very same sites as  
688 in this study (Gagnon et al., 2023). In fact, Gagnon et al. (2023) found that both taxonomic and functional diversity  
689 recovered within 15 months after restoration but already after 3 months the abundance was similar to documented

690 abundances in comparable seagrass meadows in the area. The authors partly attributed this to efficient larval  
691 dispersal from the adjacent natural meadow within the bay (Gagnon et al., 2023).

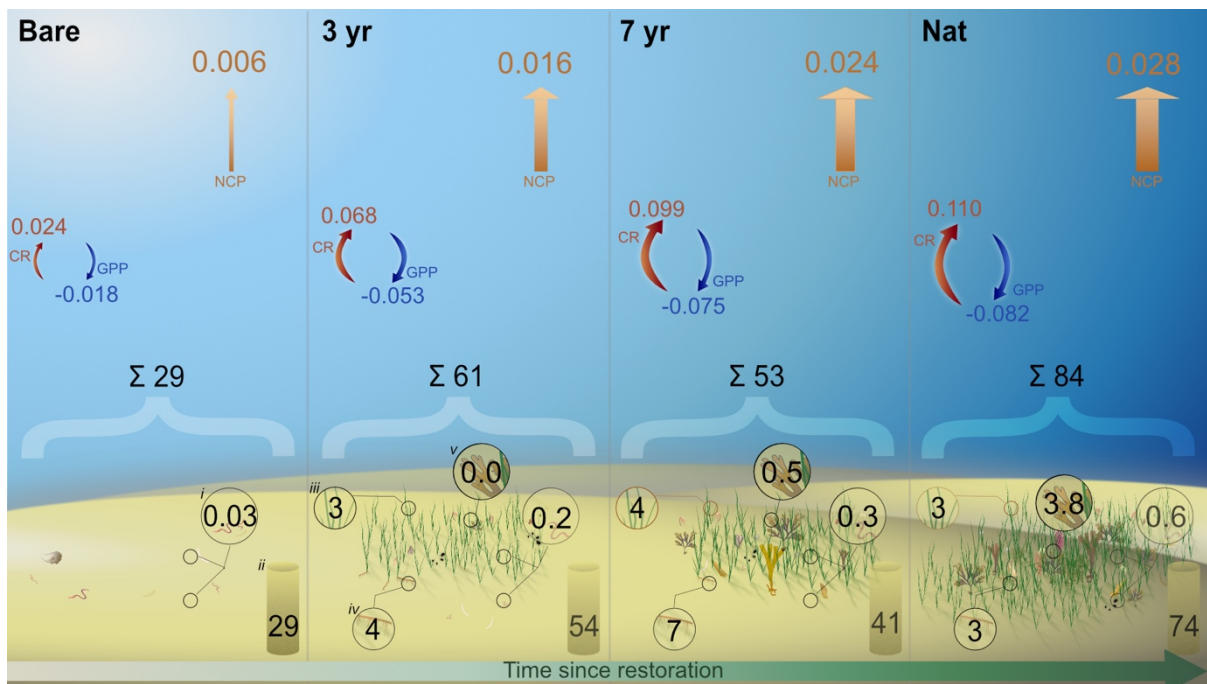

692 It is generally established that higher diversity yields higher productivity in seagrass meadows (Duffy et  
693 al., 2017), although the mechanisms behind the relationship are debated (Hooper et al., 2005; Gamfeldt et al.,  
694 2015). Based on our results, it seems that high macrophyte and macrofauna diversity positively influence GPP  
695 and CR, respectively, although the relationships with fauna are less clear. Aside from direct cellular respiration,  
696 many infauna species indirectly modify metabolic fluxes across the sediment-water interface through bioturbation  
697 and sediment reworking (Aller and Aller, 1998; Kristensen et al., 2012). A scrutiny of bioturbation and reworking  
698 modes revealed that especially biodiffusers and surficial modifiers increased with meadow age, despite highest  
699 total abundance of infauna in the youngest meadow (Table S4 & S6). It is possible that these functional modes  
700 benefited from larger quantities of macroalgal detritus building up on the sediment surface over the years.  
701 Thomson et al. (2020) found the lugworm *Arenicola marina*, an upward conveyor, contributed to a 37 % higher  
702 efflux of DIC in sediments containing *F. vesiculosus* compared to *Z. marina*. Macroalgal detritus was to a much  
703 higher extent respired or consumed compared to seagrass, which instead was buried in anoxic sediment layers by  
704 the lugworm (Thomson et al., 2020). Moreover, the role of bioturbation in oxygenating otherwise anoxic sediment  
705 can have large ramifications for sediment-water fluxes of DIC and could hence contribute to our observed CR.  
706

#### 707 **4.5 Implications of seagrass restoration on the carbon budget**

708 The observed net heterotrophy during the productive season implies the system relies on either historic production  
709 of autochthonous carbon or on trophic subsidies to sustain metabolism. Albeit only covering a brief period within  
710 the summer season, our results suggest that the seagrass in this area receives large amounts of allochthonous  
711 carbon that is partly turned over and released as DIC. A large influx and sedimentation of allochthonous carbon  
712 was shown in a recent study by Dahl et al. (2023) from the same bay. They reported relatively high carbon  
713 accumulation rates ( $0.91 \pm 0.06 \text{ mol m}^{-2} \text{ yr}^{-1}$ ) of which 51 % of sediment carbon originated from eelgrass  
714 productivity and 38 % from macroalgae (Dahl et al., 2023). Assuming this rate is constant throughout the year  
715 ( $0.0025 \text{ mol m}^{-2} \text{ d}^{-1}$ ), this accumulation rate is about an order of magnitude lower than our measured summer  
716  $\text{NCP}_{\text{DIC}}$ , implying that the majority of imported carbon is rapidly remineralized or assimilated by secondary  
717 producers (Fig. 7).

718 Our estimated budget of all carbon pools illustrates that whereas sediment stocks are the dominant pools,  
719 organic carbon is built up in living biomass following restoration (Table 4; Fig 7). Eelgrass and macroalgal  
720 biomass in the natural meadow made up 58 and 27 % of all biomass, respectively, which is on the same order as  
721 the relative proportion of sediment POC sources found in Dahl et al. (2023). Accumulation of sediment carbon  
722 and production of living biomass can be decoupled on longer time scales although trophic subsidies (i.e. external  
723 inputs) may be required to sustain both (Cebrian et al., 1997; Duarte et al., 2010; Huang et al., 2015). Notably,  
724 total fauna biomass also increased with meadow age, despite varying differences in abundance (Fig. 4; Fig. 7;  
725 Table S6).

726

727 **Figure 7 Pools and fluxes of carbon. Schematic illustration of a carbon budget including different benthic pools (mol**  
 728 **C m<sup>-2</sup>) of particulate organic carbon in i) fauna biomass, ii) sediment iii) eelgrass aboveground biomass, iv) eelgrass**  
 729 **belowground biomass and v) macroalgal biomass. Arrows indicate the daily metabolic fluxes of dissolved inorganic**  
 730 **carbon (mol m<sup>-2</sup> d<sup>-1</sup>) where blue arrows are gross primary productivity (GPP<sub>DIC</sub>), red arrows are community**  
 731 **respiration (CR<sub>DIC</sub>) and orange arrows are net community productivity (NCP<sub>DIC</sub>).**

732 While we are able to resolve the dominant carbon pools and metabolic fluxes, the import and export of organic  
 733 carbon over seasonal timescales is required to reconcile the annual carbon cycling at this site. Nevertheless, it is  
 734 reasonable to infer that NCP and carbon sequestration in these seagrass systems are sustained by lateral import of  
 735 allochthonous organic carbon.

## 736 5. Conclusion

737 Planting seagrass initiates a profound transformation of the benthic environment that influences biodiversity and  
 738 carbon cycling. Throughout our field study, we found that while fauna diversity developed in an anticipated  
 739 successional pattern, the metabolic fluxes and net release of DIC were always higher in seagrass. These fluxes  
 740 increased with meadow age and we observed increasing gross primary productivity and respiration as the seagrass  
 741 grew and drifting algae and benthic fauna colonized. Collectively, our findings suggest a scenario where higher  
 742 macrophyte and fauna diversity drives high primary productivity and respiration, respectively. Together with  
 743 ample input of sestonic organic matter to this sheltered bay, these productive meadows act as effective bioreactors  
 744 of organic carbon on diel timescales during summer, as evidenced by the net heterotrophic state and net efflux of  
 745 DIC. These results highlight the intricate connections between carbon cycling and biodiversity that should be  
 746 taken into consideration when restoring seagrass, especially in sheltered environments with large input of external  
 747 organic matter. Yet, identifying the individual mechanisms and constraining the relative importance of fauna and  
 748 flora diversity for benthic carbon fluxes remains a challenging task and should be a focal point in future research.

749 **Data availability**

750 The dataset is freely available in the Zenodo repository (<https://doi.org/10.5281/zenodo.8363551>).

751 **Author contributions**

752 TK conceived the study with input from KMA, COQ and EI. TK, KMA, COQ and EI designed the field study.  
753 TK, KMA, JH, JM and EI conducted the field work. TK and KMA analyzed data. TK wrote the manuscript with  
754 input from all co-authors. All authors approved the submitted version of the article.

755 **Conflict of interest statement**

756 The authors declare that the research was conducted in the absence of any financial or commercial relationships  
757 that could be construed as potential conflicts of interest.

758 **Acknowledgements**

759 TK acknowledges funding from the Gyllenstiernska Krapperup Foundation (grant number KR2020-0066), the  
760 European Union LIFE programme (grant number LIFE17 CCA/SE/000048) and the Royal Physiographic Society  
761 of Lund (grant number 42518). KMA received funding from the Danish Institute for Advanced Study and COQ  
762 received funding from SDU Climate Cluster. We extend our gratitude to Dr. Florian Cesbron, Dr. Pierre  
763 Polsenaere and Dr. Guillaume Bernard whose constructive reviews significantly improved an earlier version of  
764 this manuscript. We thank Dr. Mogens Flindt for lending of benthic chambers, Dr. Adam Ulfso for assistance  
765 with total alkalinity analyses, Dr. Susanne Pihl Baden and Dr. Per Carlsson for help with fauna identification and  
766 Dr. Mirjam Victorin for assistance with flux calculations. We are also grateful for the hospitality and assistance  
767 of the staff at Kristineberg Center. Symbols used in figures courtesy of the Integration and Application Network,  
768 University of Maryland Center for Environmental Science.
