26

27 **Abstract.** Microbial methane production is intimately linked to the biogeochemical cycling of iron, sulfur, and carbon in  
28 sedimentary environments. Sulfate-reducing microbes often outcompete methanogens for shared substrates. However, in a  
29 prior study at our field site, the Oak Ridge Reservation Field Research Center (ORR FRC) in Oak Ridge, TN, we observed  
30 co-occurring sulfate reduction and methanogenesis at 100-150 cm depth where iron (Fe) oxides of varying crystallinities were  
31 also detected. Fe oxides are known to act as electron conduits for direct interspecies electron transport (DIET) between  
32 syntrophic partners and can connect the metabolisms of methanogens with syntrophic Fe-reducing microbes in nature.  
33 However, whether the nature of Fe oxides can influence electron transfer reactions between sulfate-reducing microbes and  
34 methanogens is less understood. In this study, we utilized a microbial community enriched from ORR FRC vadose zone  
35 sediment to demonstrate the effects of Fe oxides of varying crystallinities on sulfate reduction and methanogenesis. We  
36 hypothesized that more crystalline Fe oxides facilitate the co-existence of sulfate-reducers and methanogens. Communities  
37 enriched from subsurface sediments produced methane when amended with crystalline hematite but not when amended with  
38 the amorphous, short range-ordered (SRO) ferrihydrite. Furthermore, Fe reduction occurred only in incubations amended with  
39 SRO ferrihydrite, indicating how poorly crystalline Fe oxides potentially contribute to the dynamic redox nature of the  
40 subsurface sediments. Microbial communities enriched during these incubations were composed of several taxa commonly  
41 associated with iron and sulfate reduction, fermentation, and methanogenesis, consistent with our geochemical data. Overall,  
42 the results from this work deepen our understanding of the role of Fe oxides in extracellular electron transfer, thereby mediating  
43 anaerobic metabolisms in the terrestrial subsurface environment.

44

## 45 **1 Introduction**

46 In subsurface sedimentary environments, carbon cycling and methane emissions are intimately linked to other  
47 biogeochemical processes, including those related to the cycling of sulfur and iron (Jørgensen et al., 2019; Jørgensen and  
48 Kasten, 2006). Subsurface biogeochemical cycling is a poorly understood component of global carbon cycle, particularly in  
49 respect to the processes that mediate methanogenesis. It is critical to constrain both the biotic and abiotic processes that govern  
50 these complex ecological processes. When sulfate is present in anoxic zones within sediments, sulfate-reducing bacteria (SRB)  
51 often outcompete methane-producing archaea (methanogens), resulting in distinct zones of sulfate reduction and  
52 methanogenesis (Claypool and Kaplan, 1974). This metabolic advantage of SRB is due to the higher affinity of their enzymes  
53 for shared substrates and to the thermodynamic favorability of sulfate reduction as compared to methanogenesis (Kristjansson  
54 et al., 1982; Schönheit et al., 1982). In addition, methanogens suffer from the toxicity effects of the reduced sulfur (S)  
55 compound, hydrogen sulfide, more acutely than SRB (Koster et al., 1986). Nonetheless, co-existence of the two groups has  
56 been observed in anaerobic environments and were explained by non-competitive substrate usage under high organic loading  
57 rates (Oremland and Polcin, 1982) or under low sulfate conditions (Ozuolmez et al., 2020). However, these specific conditions

58 do not fully account for the broadly observed co-existence of the two dominant anaerobic metabolisms, warranting further  
59 investigation into other factors that may also impact this phenomenon in the complex terrestrial subsurface.

60 A previous study at our field site, the Oak Ridge Reservation Field Research Center (ORR FRC) in Oak Ridge, TN,  
61 USA indicated the coincidence of methane production and sulfate reduction. Specifically, high methane production rates  
62 coinciding with sulfate reduction were reported in the vadose zone (100-150 cm depth) of the subsurface sediments (Moon et  
63 al., 2020). Both SRB and methanogens can participate in the syntrophic degradation of organic matter in sedimentary  
64 environments, where SRB catalyze the breakdown of volatile fatty acids and other more complex organic substrates into simple  
65 substrates, such as acetate, carbon dioxide, and hydrogen gas, which can then either be used for methanogenesis (Dworkin et  
66 al., 2006; Nozhevnikova et al., 2020) or further metabolized to continued sulfate reduction (Thauer et al., 2007). Given the  
67 kinetic and thermodynamic advantages that SRB have over methanogens, the coexistence of these two metabolisms is  
68 unexpected under the environmental conditions at our field site, possibly challenging what we know about subsurface  
69 biogeochemistry.

70 Notably, high concentrations of crystalline Fe oxides were also detected at our field site in the same zone as  
71 concomitant sulfate reduction and methanogenesis (Moon et al., 2020). The redox potential of the Fe(III)–Fe(II) redox couple  
72 lies between the redox potentials of the major C, N, O or S redox couples (Michael Madigan et al., 2019), and therefore, the  
73 presence of Fe oxides adds a new layer of complexity to C and S cycling. Moreover, Fe oxides show distinct electrochemical  
74 properties depending on their crystal structures; for example, crystalline hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) is semiconductive whereas  
75 amorphous ferrihydrite is insulating (Cornell and Schwertmann, 2003; Xu and Schoonen, 2000). Several laboratory-based  
76 studies have shown that these Fe oxides can connect syntrophic metabolisms between microbial partners by serving as conduits  
77 that mediate direct interspecies electron transport (DIET) (Kato et al., 2012; Park et al., 2018). Many Fe(II)-oxidizing and  
78 Fe(III)-reducing bacteria are metabolically flexible as well, which helps them adapt to the availability of electron donors and  
79 acceptors that mediate environmental redox reactions. Some of the studied mechanisms of electron transfer from  
80 microorganisms to Fe(III) minerals include direct contact between the bacterial cell and Fe(III) minerals, secretion of chelating  
81 agents to complex with Fe minerals, electrically conductive pili and multistep electron hopping via redox cofactors that are  
82 present in biofilms (Melton et al., 2014). While crystalline minerals such as hematite can promote microbially mediated  
83 electron transfer through conductive nanowires, short-range ordered (SRO) insulating Fe (oxy)hydroxides such as ferrihydrite  
84 are instrumental in interacting with chelating agents such as EDTA through reductive dissolution and co-precipitation (Mikutta  
85 et al., 2008; Weihe et al., 2019; Zhou et al., 2014). The provision of Fe oxides has additionally been shown to enhance rates  
86 of syntrophic methanogenesis in several studies using sediment-hosted microbial communities (Aromokeye et al., 2018, 2020;  
87 Rotaru et al., 2018; Zhang and Lu, 2016). However, these enrichments were performed using sulfate-free media, and as such  
88 the specific contributions of SRB were not investigated. Therefore, it remains unclear whether SRB participate in syntrophic  
89 methanogenesis via DIET using Fe oxide minerals as conduits for electron transfer.

90 We hypothesized that crystalline Fe oxides facilitate metabolic interactions between sulfate-reducers and  
91 methanogens in the ORR FRC vadose zone, allowing these microbes to coexist under conditions that typically result in

92 competition for substrates. In this study, we use a microbial community enriched from ORR FRC vadose zone sediment to  
93 demonstrate the effects of Fe oxides of varying crystallinities on sulfate reduction and methanogenesis. In addition to the  
94 microbially mediated processes, abiotic reaction mechanisms were also investigated to untangle the biotic and abiotic controls  
95 for the reaction. The interplay of microbially-mediated and abiotic reactions in the biogeochemical Fe and S cycles helps us  
96 develop a better understanding of the role of Fe oxides and electron transfer reactions in anoxic zones within the terrestrial  
97 subsurface.

98

## 99 **2 Materials and Methods**

### 100 **2.1 Sediment Collection**

101 Sediments were collected from borehole EB271 in March 2017 near the S-3 pond at the Oak Ridge Reservation Field  
102 Research Center (ORR FRC) located within the Y-12 National Security Complex in Oak Ridge Tennessee, USA (see Watson  
103 et al., 2004 for more information on this site and Moon et al., 2020 for detailed location information and geochemical analysis  
104 of borehole EB271). Our inoculum was collected at a depth of 100-150 cm, the same depth where methane production, sulfate  
105 reduction, and the presence of Fe oxide minerals were previously reported (Moon et al., 2020). Sediments were frozen and  
106 stored at -80 °C upon collection for microbial and biogeochemical analyses.

### 107 **2.2 Culture Conditions**

108 A novel, custom mineral growth medium that mimics the geochemical conditions of the sampling location (sediment  
109 core EB271) at the ORR FRC was developed to replicate the field conditions as closely as possible and create environmentally  
110 relevant experimental conditions, which is hereafter referred to as the EB271 medium. Briefly, the EB271 mineral medium  
111 contained mineral salts, a selenite/tungstate solution (1 mL), a trace element solution (1 mL), L-cysteine as the reducing agent  
112 (0.6 g), N-[Tris(hydroxymethyl)methyl]-2-aminoethanesulfonic acid (TES, 2.292) and NaHCO<sub>3</sub> (2.5 g) as buffers, and 0.25  
113 ml 0.1% w/v resazurin as an oxygenation indicator. The mineral salts were comprised of NH<sub>4</sub>Cl (0.3 g), KH<sub>2</sub>PO<sub>4</sub> (0.2 g),  
114 MgCl<sub>2</sub>·6H<sub>2</sub>O (0.5 g), and CaCl<sub>2</sub>·2H<sub>2</sub>O (0.015 g) per liter. The selenite/tungstate solution contained Na<sub>2</sub>SeO<sub>4</sub>·6H<sub>2</sub>O (0.0006 g)  
115 and Na<sub>2</sub>WO<sub>4</sub>·5H<sub>2</sub>O (0.0008 g) per liter. The trace elements solution contained HCl (0.01 ml 25% w/w), H<sub>3</sub>BO<sub>3</sub> (0.006 g),  
116 NaOH (0.5 g), MnCl<sub>2</sub>·4H<sub>2</sub>O (0.1 g), CoCl<sub>2</sub>·6H<sub>2</sub>O (0.19 g), ZnCl<sub>2</sub> (0.07 g), CuCl<sub>2</sub>·2H<sub>2</sub>O (2.0 mg), NiCl<sub>2</sub>·6H<sub>2</sub>O (2.4 mg)  
117 Na<sub>2</sub>MoO<sub>4</sub>·2H<sub>2</sub>O (0.036 g), FeSO<sub>4</sub>·7H<sub>2</sub>O (2 g) and AlKSO<sub>4</sub>·12H<sub>2</sub>O (0.1 g) per liter. The vitamin solution contained d-biotin  
118 (2.0 mg), folic acid (2.0 mg), pyridoxine-HCl (10.0 mg), thiamine-HCl (5.0 mg), riboflavin (5.0 mg), nicotinic acid (5.0 mg),  
119 pantothenic acid (5 mg), vitamin B12 (0.1 mg), p-aminobenzoic acid (5.0 mg), and lipoic acid (5.0 mg) per liter.

120 To obtain a sediment-free microbial inoculum for our experimental incubations, a preconditioning enrichment of  
121 EB271 sediment was conducted in anoxic EB271 medium amended with 5 mM sodium butyrate and 10 mM sodium sulfate  
122 for approximately 6 months under a N<sub>2</sub>:CO<sub>2</sub> (80:20) headspace. Butyrate was chosen as primary electron acceptor for this  
123 experiment as previous work showed that many simple carbon sources, including glucose or acetate, do not promote diverse

124 communities of microbes from our field site (Wu et al., 2020). In addition, butyrate is known to stimulate syntrophic  
125 metabolisms under sulfate-reducing and methanogenic conditions (Struchtemeyer et al., 2011). We transferred this enrichment  
126 three times (two-month incubation intervals) at 10 % v/v inoculum prior to the start of our experimental incubations described  
127 in this work. All later experimental incubations using this enriched inoculum were also conducted using 5 mM sodium butyrate  
128 and 10 mM sodium sulfate maintained under an N<sub>2</sub>:CO<sub>2</sub> (80:20) headspace and ran for ~ 3 months.

129 To test the influence of Fe(III) minerals in our incubations, hematite or ferrihydrite were added in concentrations of  
130 1% w/v. Hematite comprised a majority of conductive minerals in sediment bore EB271 (Moon et al., 2020) and was chosen  
131 to mimic field conditions whereas ferrihydrite was chosen because of its reduced crystallinity and increased reactivity  
132 compared to hematite.

133 To better understand the microbial influences in our system, several sets of biotic control incubations were conducted  
134 where we inhibited the metabolisms of specific groups of microbes. Incubations were performed in parallel using either 5 mM  
135 2-bromoethanesulfonate (BES) to inhibit methanogenesis (Goenrich et al., 2004) or 10 mM sodium molybdate to inhibit sulfate  
136 reduction (Taylor and Oremland, 1979). Incubations without the addition of minerals or metabolism inhibitors were conducted  
137 to serve as controls for the experimental treatments. Treatments with no added minerals or metabolism inhibitors served as  
138 controls for all incubation conditions (See Table 1 descriptions of experimental incubations and acronyms used to describe  
139 each treatment).

140 We also concurrently performed abiotic incubations containing no microbial inoculum with and without the presence  
141 of 10 mM sulfide to investigate abiotic influences on the geochemical dynamics of our systems (See Table 2 for descriptions  
142 of abiotic incubations and acronyms used to describe each treatment). All biotic and abiotic incubations were conducted in  
143 triplicate.

### 144 **2.3 Geochemical Analyses**

145 Samples for geochemical analyses were collected periodically throughout the incubation. Under sterile and anoxic  
146 conditions, 1 mL from the headspace was taken (while replacing headspace volume with 1 mL N<sub>2</sub>:CO<sub>2</sub> gas) to measure methane  
147 using gas chromatography with a thermal conductivity detector with helium as the carrier gas (6890N Network GC System;  
148 Agilent Technologies; Santa Clara, CA, USA). Methane concentrations were calculated to account for changes in headspace  
149 volume due to regular sampling of the cultures. To quantify sulfate, butyrate, acetate, Fe(II), and dissolved sulfide, 1 mL of  
150 the culture was taken and sterilized with 0.2 µm PES filters prior to analysis. Sulfate, butyrate, and acetate were measured  
151 using ion chromatography (Dionex ICS 2100; Thermo Fisher Scientific; Waltham, MA, USA). Samples for Fe(II)  
152 quantification were acidified using 0.5 N HCl and quantified using a modified version of the ferrozine assay (Stookey, 1970)  
153 using a microplate reader (BioteK Epoch2; Agilent; Santa Clara, CA, USA). Dissolved sulfide quantification immediately  
154 fixed in 91 mM zinc acetate was determined using colorimetric analysis within a day of sampling using a modified microplate  
155 version of the Cline assay (Cline, 1969).

## 156 2.4 X-ray Absorption Spectroscopy

157 Synchrotron-based X-ray absorption spectroscopy (XAS) was used to determine Fe and S speciation (oxidation state  
158 and chemical coordination environment). S and Fe K-edge X-ray absorption near-edge structure (XANES) and iron K-edge  
159 extended x-ray absorption fine structure (EXAFS) spectral analyses were conducted on beamline 4-3 at the Stanford  
160 Synchrotron Radiation Laboratory (SSRL), at Menlo Park, CA under ring operating conditions of 3 GeV with a current of 450  
161 mA. Experiments were performed in pure helium to minimize absorption and scattering from the atmosphere. Samples were  
162 sealed on Teflon holders with Kapton tape to preserve the oxidation state of Fe and S to prevent any potential beam damage  
163 which might occur during data collection. A double crystal Si (220) monochromator with an unfocused beam was detuned  
164 30% to reject harmonics affecting the primary beam. Pure elemental Fe foil was used for energy calibration for Fe at 7112 eV  
165 whereas thiosulfate ( $S_2O_3^{2-}$ ) was used for energy calibration of S at 2472 eV. The Lytle detector was used to record the  
166 fluorescence spectra of EXAFS and XANES scans. Between 7 and 10 individual spectra were averaged for each sample.  
167 Fluorescence spectra were background subtracted and the atomic absorption was normalized to unity using Athena (Ravel and  
168 Newville, 2005).

## 169 2.5 16S Microbial Community Analyses

170 To examine changes in microbial community composition over time, two 2 mL aliquots of culture were collected  
171 from days 0 (T0), 36 (T4), and 87 (T8) from each vial containing live microbes and were centrifuged. The supernatants were  
172 decanted, and the pellets were frozen at -80 °C until extraction. Samples were extracted using the Qiagen DNeasy PowerLyzer  
173 PowerSoil Kit following the manufacturer's suggested protocol. Negative control samples were generated during each round  
174 of extractions to be included in the sequencing run.

175 Extracted genomic DNA was sent to Novogene Corporation, Inc. for quality control and subsequent sequencing with  
176 the Illumina MiSeq. Microbial community composition was analyzed by targeting the V4 region of the 16S gene with the 515F  
177 (5'-GTGCCAGCMGCCGCGGTAA-3') and 806R (5'-GGACTACHVGGGTWTCTAAT-3') primer pair (Caporaso et al.,  
178 2011) to generate 300 bp paired-end reads. A subset of samples were also sequenced using the archaeal specific 519F (5'-  
179 CAGCCGCCGCGGTAA-3') and 915R (5'-GTGCTCCCCGCCAATTCCT-3') primer pair (Herfort et al., 2009; Casamayor  
180 et al., 2002). Sequences were analyzed via the Qiime2 paired-end read pipeline version 2022.2 (Bolyen et al., 2019).  
181 Representative sequences that were found in both the experimental and negative controls at a prevalence of 0.05 or higher  
182 were marked as contaminants and were removed from the experimental samples using the R package *decontam* (Davis et al.,  
183 2018). Sequences were taxonomically assigned using the Silva database release 138. Nonmetric multidimensional scaling  
184 (NMDS) indices and ordination ellipses drawn around the mean centroid (95% CI) were constructed using Bray Curtis  
185 dissimilarity metrics using the R package *vegan* (Dixon, 2003).

186

## 187 3 Results and Discussion

### 188 3.1 Geochemical Analyses

189 We examined changes in the concentrations of analytes relevant to the metabolisms of interest (butyrate, acetate,  
190 sulfate, sulfide, methane, and Fe(II)) to determine whether the addition of either hematite or ferrihydrite to our cultures  
191 influenced the physiologies of our enriched microbial communities. Conditions S, SH, and SF represent treatments where no  
192 mineral or inhibitor were added (see Table 1 for information on treatments and all corresponding acronyms). Throughout the  
193 87-day incubation period, we observed  $4.3 \pm 0.16$  mM,  $4.0 \pm 0.3$  mM, and  $3.8 \pm 0.5$  mM butyrate consumed and  $6.8 \pm 2.5$ ,  $9.0$   
194  $\pm 2.1$  mM, and  $7.6 \pm 6.4$  mM sulfate reduced by these cultures, respectively (Fig. 1). In conditions S and SH, net  $4.8 \pm 0.4$  mM  
195 and  $1.7 \pm 1.8$  mM acetate and  $3.7 \pm 1.8$  mM and  $0.15 \pm 0.023$  mM aqueous sulfide were respectively produced. In condition  
196 SF, net  $0.60 \pm 0.45$  mM acetate was consumed over 87 days with a peak aqueous acetate concentration of  $8.8 \pm 0.087$  mM on  
197 day 17. We only detected methane production in condition SH, representing cultures that contained uninhibited microbes  
198 amended with hematite. We observed  $3.3 \pm 5.8$  mM of methane produced over the duration of the incubation, suggesting that  
199 this more crystalline Fe oxide may be required for methanogenesis to occur in this system. We observed acid extractable Fe(II)  
200 accumulation in condition SF, peaking at  $2.0 \pm 2.4$  mM on day 42. We were unable to detect any accumulation in any hematite-  
201 amended or mineral-free cultures.

202 We performed incubations using BES to inhibit methanogenesis and in these cultures (SB, SHB, and SFB),  $4.6 \pm$   
203  $0.75$ ,  $4.0 \pm 0.41$ , and  $3.9 \pm 0.40$  mM butyrate was consumed and  $7.6 \pm 0.30$ ,  $7.3 \pm 3.2$ , and  $11 \pm 0.66$  mM sulfate was reduced,  
204 respectively, throughout the incubation period (Fig. 1). As expected, we did not observe methane accumulated in any BES  
205 treated culture. In conditions SB and SHB, net  $5.0 \pm 0.15$  and  $5.2 \pm 2.2$  mM acetate was produced, respectively. Cultures from  
206 SBF conditions produced net-zero acetate over the 87-day experiment with a maximum aqueous acetate concentration of  $8.9$   
207  $\pm 0.80$  mM on day 17. Fe(II) was only detected in condition SFB, peaking at  $1.3 \pm 0.90$  mM on day 36.

208 In cultures where molybdate was added to inhibit sulfate reduction (conditions SM, SHM, SFM), there was no notable  
209 consumption of butyrate or sulfate nor was there production of sulfide or methane (Fig. 1). Ferrous iron peaked at  $0.52 \pm 0.15$   
210 mM on day 52 in condition SFM but was not detected in SM and SHM. Small amounts of acetate were produced in all sulfate  
211 reduction inhibited cultures, peaking at  $2.9 \pm 0.47$  mM for condition SM,  $2.5 \pm 0.14$  mM for condition SHM, and  $2.9 \pm 0.10$   
212 mM for condition SFM by day 17.

213 It is interesting to note that while we did not observe Fe(II) accumulation in our hematite treated conditions, we did  
214 ferrihydrite-amended cultures showed Fe(II) accumulation. This was likely due to increased crystallinity of hematite compared  
215 to ferrihydrite, rendering it a more difficult electron acceptor for microbes to use (Schwertmann, 1991). This idea is supported  
216 by prior work showing decreased Fe reduction in the presence of hematite compared to less crystalline Fe oxides for both pure  
217 cultures (Li et al., 2006) and enrichments (Zhang et al., 2020) of Fe-reducing microbes. In addition, the rapid precipitation of  
218 new minerals upon reduction of hematite may have also occurred. For example, precipitation of crystalline spinels such as  
219 magnetite precipitated during incubation, may have underestimated Fe(II) production (Benner et al., 2002). We also observed

220 decreases in Fe(II) concentrations towards the end of these incubations, due to the potential coprecipitation of Fe  
221 (oxy)hydroxides and Fe sulfides that is typically observed following the reductive dissolution of Fe oxides, especially in  
222 association with organic matter (Cornell and Schwertmann, 2003; Li et al., 2006; Neal et al., 2001). Finally, the observed  
223 accumulation of ferrous iron in condition SF may have also been due to increased rates of fermentative iron reduction, which  
224 would also be supported by faster butyrate consumption concurrent with higher peak acetate production at earlier time points  
225 when compared to conditions S and SH.

226 Control incubations where no microbial inoculum was added were performed to examine any abiotic changes in  
227 analyte concentrations in the medium (See Table 2 for description of control conditions). The observed some decreases in both  
228 butyrate and sulfate concentrations throughout the incubation period for all treatments was smaller in magnitude than the  
229 respective biotic incubations (Fig. S1), indicating that active microbial metabolisms were the primary driving factor for the  
230 changes in analyte concentrations. In condition CS, where no mineral was added, we observed a decrease of  $6.36 \pm 0.98$  mM  
231 sulfide, which may be attributed to the introduction of oxygen during the sampling process. Sulfide depletion in conditions  
232 CHS and CFS was likely due to interactions between the added iron oxide minerals. Given the differences in reactivity versus  
233 hematite and ferrihydrite, it is not surprising that we observed total depletion of sulfide in condition CHS slowly over the first  
234 52 days while no sulfide was able to accumulate in cultures from condition CFS due to rapid oxidization by ferrihydrite. We  
235 did not observe accumulation of acetate, methane, or Fe(II) in any of our control incubations. Overall, these control incubations  
236 provided context for the changes in analyte concentrations caused by active microbial metabolisms.

237

### 238 **3.2 Iron and sulfur speciation under (a)biotic incubations during syntrophic butyrate degradation**

239 Synchrotron-based XAS data provided critical molecular-scale insights on the coupled Fe-S redox chemistry during  
240 incubations in the presence and absence of BES and molybdate inhibitors as a function of altered mineral crystallinity  
241 (ferrihydrite being the amorphous or poorly crystalline and hematite being the crystalline mineral). Overall, Fe K-edge XANES  
242 data indicates that bulk Fe was in +3 oxidation state across all the experimental incubations tested both under biotic and abiotic  
243 conditions (Fig 2A). Subtle changes in the relative peak positions (lower and higher values indicating reduced and oxidized  
244 Fe species, respectively) together with spectral shapes and intensities in the XANES region among the different samples  
245 indicated that the relative proportions of Fe(II) and Fe(III) varied as a function of mineral crystallinity across the samples  
246 incubated with specific inhibitors. In the absence of inhibitors (conditions SH and SF), the maximum peak intensities for SF  
247 and SH occurred at  $\sim 7129.5$  eV and  $\sim 7133$  eV respectively, indicating that bulk Fe is in +3 oxidation state (O'Day et al., 2004).  
248 A similar trend is observed in BES treated cultures (SFB and SHB). When comparing molybdate incubated samples (conditions  
249 SHM and SFM), the average oxidation state of Fe is similar between these treatments.

250 In general, samples incubated with ferrihydrite exhibited the maximum differences in uninhibited and BES treated  
251 cultures (conditions SF and SFB), hinting at potential biotic Fe reduction promoted by amorphous ferrihydrite. This is also  
252 supported by observed changes in the coordination environment of Fe atoms (determined via EXAFS analysis) in samples  
253 from SF and SFB when compared to pristine ferrihydrite (Fig. S2). Samples from hematite amended conditions (SH, SHB,

254 SHM) maintained similar EXAFS patterns when compared to pristine hematite, suggesting Fe atoms in hematite remained  
255 relatively untouched during incubation. For molybdate treated samples, the distinct pre-edge peak at  $\sim 7114.7$  eV in SFM when  
256 compared to that of SHM indicated that Fe from the ferrihydrite treatment has a well-defined stable molecular geometry,  
257 despite ferrihydrite being the amorphous mineral (Fig. 2A). This finding is in accordance with literature data which shows that  
258 short-range ordered ferrihydrite-like minerals often are the controlling factors for mineral-organic matter stabilization and  
259 subsequent preservation in terrestrial ecosystems (Kleber et al., 2015).

260 To explore abiotic versus biotic reduction mechanisms, Fe XANES data were also collected on the abiotic incubations  
261 (CS, CFS and CHS) (Fig. 2A). The similarities in peak positions between our abiotic control incubations indicate that the  
262 mechanisms of iron reduction were predominantly biotic in nature.

263 Upon analysis of the sulfur speciation in our samples by S K-edge XANES (Fig. 2B), peaks at  $\sim 2482.7$  eV in most  
264 of our samples indicated the presence of sulfate (S in +6 oxidation state, Prietzel et al., 2011). The absence of this peak in  
265 conditions SF, SHB, SFB indicate that sulfate was reduced into other sulfur species by SRB during these incubations. Peaks  
266 at  $\sim 2472.6$  eV in a few treatments (CHS, CFS, SFB) were indicative of the presence of elemental sulfur (Prietzel et al., 2011),  
267 likely a product of reaction between dissolved sulfide and Fe oxide minerals (Poulton, 2003; Pyzik and Sommer, 1981; Yao  
268 and Millero, 1996). Additionally, the presence of sulfonate (S in +5 oxidation state) at  $\sim 2481.3$  eV was observed across all  
269 treatments (Prietzel et al., 2011), likely due to the use of TES buffer in the incubation medium. No sulfide species indicative  
270 of Fe sulfide minerals ( $\sim 2470.7$  eV for FeS and  $\sim 2471.3$  eV for FeS<sub>2</sub> (Prietzel et al., 2011)) was observed, indicating that the  
271 bulk mineralogical speciation from hematite and ferrihydrite were retained during the incubations.

272

### 273 3.3 Microbial Community Composition

274 To examine how the addition of either hematite or ferrihydrite affected the composition of the microbial communities  
275 enriched in our experiment, the DNA from samples collected at day 0 (T0), day 36 (T4) and day 87 (T8) from all biotic  
276 incubations was extracted and the 16S rRNA gene was sequenced (Fig. 3).

277 A large proportion of the communities from our initial inoculum were strict or facultative anaerobic fermenters (Fig.  
278 3, samples labeled T0). Organisms from the class Clostridia were the most abundant members of these communities, with  
279 ASVs matching to the genus *Lachnoclostridium*, spore forming anaerobes that produce acetate as their major fermentation  
280 product (Yutin and Galperin, 2013). Microorganisms within the Bacteroidia families Dysgonomonadaceae, Paludibacteraceae,  
281 or Prevotellaceae were also enriched and are known to be strict or facultative anaerobes capable of fermenting complex  
282 polysaccharides (Owusu-Agyeman et al., 2022; Parte et al., 2011; Ueki, 2006). Members of the Paludibacteraceae have  
283 previously been enriched in both microbial electrolysis cells and microbial fuel cells under anoxic conditions, suggesting their  
284 potential for extracellular electron transfer reactions and possible involvement in similar interactions with conductive minerals  
285 in sedimentary environments (Kim et al., 2011; Satinover et al., 2020). The only cultured genus of the Paludibacteraceae  
286 known to date is Paludibacter, which is known to produce propionate and acetate as major fermentation products (Ueki, 2006).  
287 Other fermenters that were enriched include *Lactobacillus* of the class Bacilli which were only found in the second replicate

288 of this initial inoculum (sample T0S2). The high relative abundances of these fermentative organisms in our samples are not  
289 surprising given that our initial microbial communities were pre-conditioned for several subcultures anoxically using the  
290 fermentable substrate butyrate as a primary electron donor.

291 In addition to these fermenters, organisms from the classes Desulfotomaculia and Desulfitobacteria were also  
292 enriched in our T0 samples. ASVs from within the Desulfotomaculia matched to the genera *Desulfallus* and *Desulfurispora*,  
293 which are canonically known to engage in sulfate reduction, with the latter putatively thought to also engage in iron reduction  
294 (Kaksonen et al., 2007; Watanabe et al., 2020; Wen et al., 2018), as well the genus *Sporotomaculus*, another genus of anaerobic  
295 fermenters (Brauman et al., 1998). Within the Desulfitobacteria, members of the sulfate-reducing genus *Desulfosporosinus*  
296 (Hippe and Stackebrandt, 2015) were enriched, though some members of the genus are also known to engage in iron reduction  
297 (Hippe and Stackebrandt, 2015). The methanogenic archaeal class, Methanobacteria, was observed in T0S3. These ASVs  
298 matched to *Methanobacterium sp.*, organisms known to engage in hydrogenotrophic methanogenesis.

299 Overall, the microbial communities making up the starting inoculum contained higher total observed ASVs and  
300 Shannon diversity indices compared to our experimental conditions (Fig. S3), suggesting that our communities became  
301 selectively structured throughout our incubations through decreases in species richness. Inverse Simpson indices (which  
302 incorporates both species richness and evenness) were largely similar between the starting inoculum and most of the  
303 experimental conditions. Higher Inverse Simpson indices were observed for several communities which exhibited greater  
304 evenness among observed ASVs, including communities collected at day 87 and provided molybdate as an inhibitor (T8SM,  
305 T8SHM, and T8SFM), as well as in the communities collected at day 37 and provided hematite and molybdate (T4SHM),  
306 suggesting that the addition of molybdate lead to changes in the relative abundances of the organisms enriched under these  
307 conditions.

308 Communities from incubations where no minerals were added contained many of the same organisms found in our  
309 initial inoculum (Fig. 3). Interestingly, shifts in the relative abundances of putative sulfate- and iron-reducing microbes  
310 occurred over time, where we observed greater representation of Desulfitobacteria in T4 samples and observed higher relative  
311 abundances of Desulfotomaculia in T8 samples. Methanobacteria were observed in varying abundances in these sets of  
312 incubations, except in those where methanogenesis was inhibited using BES (condition SB).

313 Organisms from the class Coriobacteria were also detected in all 'No Mineral' conditions, with ASVs matching to  
314 Actinobacteria OPB41. While transcriptomics and enzyme assays performed on uncultured group OPB41 representatives from  
315 marine sediments suggested the capacity for anaerobic sugar hydrolysis (Bird et al., 2019), two organisms from this group that  
316 have been isolated recently for the first time are confirmed to be either sulfur- or Fe-reducers (Khomyakova et al., 2022).  
317 Organisms from the class Negativicutes were also enriched during these incubations, with the majority of ASVs within this  
318 class matching to the acetogenic genus *Sporomusa sp.* While acetogens in general are known for their wide substrate utilization  
319 (Drake et al., 1997), *Sporomusa* are typically known to use a variety of substrates ranging from CO<sub>2</sub> (Breznak and Blum, 1991;  
320 Tremblay and Zhang, 2015) to sugars, methanol, and N-methylated compounds (Visser et al., 2016). Since the data reported  
321 in our study are the result of subcultured communities (at 10% v/v inoculum), it is possible that a portion of the energy driving

322 the observed acetogenesis is from the subcultured incubation and the carbon may be derived from carryover organic carbon or  
323 CO<sub>2</sub>, which was present in the serum bottle headspace. *Sporomusa sp.* were detected in higher relative abundances in  
324 incubations where either methanogens or sulfate-reducers were inhibited. Since methanogens and sulfate-reducers both  
325 generally have thermodynamic advantages over acetogens for shared substrates (Lever, 2012), it is likely acetogens were able  
326 to persist in higher abundance in these inhibited conditions because of reduced competition. This likely also explains the  
327 production of acetate in molybdate treated samples observed in our geochemical analyses (Fig. 1, panels SM, SHM, and SFM).

328 We used Bray Curtis analyses to statically measure dissimilarities in community composition between our  
329 experimental treatments and constructed NMDS plots to observe these differences. We observed little overlap between the  
330 ordination ellipses highlighting the “Initial” and “No Mineral” treatment groups (Fig. S4), suggesting the microbial  
331 communities from treatment groups were significantly different from each other. These results were supported by a p-value of  
332 0.001 calculated from pairwise PERMANOVA analysis of Bray Curtis metrics between these two treatment groups (Table  
333 S1). The differences between these treatment groups are likely the result of selective structuring of the microbial communities  
334 during the incubation period, which is also corroborated by decreases in total observed ASVs and Shannon Diversity metrics  
335 between these groups as described earlier (Fig. S3).

336 The addition of Fe oxide minerals to the cultures also significantly impacted the composition of microbial  
337 communities. There was also little overlap in ordination ellipses between the “Initial” treatment and either the “Hematite” and  
338 “Ferrihydrite” treatments (Fig.S4), which was also supported by Pairwise PERMANOVA p-values of 0.001 between these  
339 treatment groups (Table S1). PERMANOVA analyses comparing the “No Mineral” treatment group with either the “Hematite”  
340 and “Ferrihydrite” treatments also resulted in p-values <0.05 (Table S1), despite visual overlap in ordination ellipses between  
341 these groups (Fig. S4). Interestingly, we did not detect significant differences between the “Hematite” and “Ferrihydrite”  
342 treatments, as the p-value for this pairwise PERMANOVA analysis was calculated to be 0.196. These data suggest that while  
343 the addition of an iron oxide to the incubation lead to distinct microbial communities, the type of iron oxide (whether it be  
344 hematite or ferrihydrite) did not seem to any specific differences in community composition.

345 Many of these mineral amended cultures, specifically those that were incubated with either BES or no added  
346 metabolism inhibitors (conditions SH, SHB, SF, and SFB), were largely dominated by Desulfitobacteriia (Fig. 3). The relative  
347 abundances of Desulfitobacteriia and Desulfotomaculia were greatly diminished in incubations where molybdate was added  
348 (conditions SHM and SFM). The inhibition of sulfate-reducing metabolisms through the addition of molybdate allowed for  
349 Clostridia to increase in relative abundance, making up the vast majority of these communities.

350 Organisms from the classes Bacterioidia and Anaerolineae were found in many of the samples collected from both  
351 hematite and ferrihydrite amended cultures at T8. ASVs within Anaerolineae matched to uncultured *Leptolinea*, *Pelolinea*,  
352 and *Levilinea*, organisms known to be anaerobic fermenters (Imachi et al., 2014; Yamada et al., 2006). Uncultured members  
353 of the Anaerolineae have also previously been enriched under iron reducing conditions. Organisms from the class Myxococcia  
354 were also observed in many of the ferrihydrite treated samples, with ASVs matching to the genus *Anaeromyxobacter*, members  
355 of which are known iron reducers (He and Sanford, 2003; Petrie et al., 2003). The higher reactivity of ferrihydrite likely

356 allowed *Anaeromyxobacter* (and likely other Fe reducers) to reduce Fe at greater rates during these incubations. This is  
357 supported by detection of Fe(II) in both ferrozine assays (Fig. 1) as well Fe K-edge XANES analyses (Fig. 2A) performed on  
358 samples collected from this set of incubations.

359 We detected *Methanobacterium sp.*, known for performing hydrogenotrophic methanogenesis (Boone, 2015), in  
360 varying abundances in a few cultures across many experimental conditions, despite only observing methane production in  
361 cultures amended with hematite and no metabolism inhibitors. Interestingly, we also only observed *Methanosarcina sp.* in low  
362 relative abundance in one hematite amended culture at one time point (T4SH1). *Methanosarcina* are known to engage in both  
363 DIET and in extracellular electron uptake reactions directly from cathodes (Rowe et al., 2019; Yee et al., 2019; Yee and Rotaru,  
364 2020) and likely contributed to DIET in our experimental system. The low representation of methanogens in our communities  
365 overall may be attributed to the poor specificity of the universal 515F/806R primers towards archaeal sequences in general  
366 (Raymann et al., 2017). Due to constraints resulting from low DNA extraction yields from many of our samples, we were only  
367 able to re-sequence a subset of our samples using archaeal specific 519F/915R primers. With this primer pair, we were able to  
368 detect a greater presence of Methanobacteria in a few of our “No Mineral” treatment samples (T4S1 and T8S2), which is  
369 interesting as we did not detect any accumulation of methane in any cultures in this treatment group, consistent with the  
370 hypothesis that crystalline iron oxides are needed to facilitate DIET-mediated methanogenesis in our system. We detected  
371 some *Methanosarcinia* at higher relative abundances in only a few of our only a few a few of our “Hematite” treatment samples  
372 (T4SH1 and T8SH3, Fig. S5).

373

### 374 **3.4 Effects of metabolism inhibitors on microbial communities**

375 Parallel experiments using either BES or molybdate to inhibit methanogenesis and sulfate reduction respectively were  
376 conducted to determine the contribution of each metabolism to the syntrophic interactions occurring in our incubations. BES  
377 is an analog of coenzyme M and is known to disrupt methanogenesis by irreversibly binding to the active site of methyl  
378 coenzyme M reductase (Mcr), preventing the enzyme from catalyzing the reduction of methyl coenzyme M to methane  
379 (Goenrich et al., 2004). Our results are consistent with this knowledge, as methane accumulation did not occur in the headspace  
380 of our BES amended incubations. Trends in the production or consumption of all other compounds measured are similar to  
381 what was observed in the inhibitor free conditions (Fig. 1, plots S, SH, SF, SB, SHB, SHF). While the composition of the  
382 microbial communities incubated with BES appear similar to the uninhibited control experiments (see Fig. S6 for microbial  
383 community composition data grouped by inhibitor used), the differences between the structure of the BES treated communities  
384 were significantly different than the original inoculum, communities treated with molybdate, and communities that were left  
385 uninhibited (Pairwise PERMANOVA p-values <0.05 for all pairwise comparisons, Table S2). This is likely due to decreases  
386 in relative abundances of the *Desulfitobacteriia* collected day 36 (T4) and Day 87 (T4) and increases in the abundances of the  
387 *Desulfomaculia* increased during this period.

388 Molybdate is canonically known to selectively inhibit sulfate reduction metabolisms by targeting sulfate  
389 adenylyltransferase (Sat), an enzyme that uses ATP to activate inert sulfate ions, forming adenosine 5' phosphosulfate (APS)

390 in the process. Upon binding to Sat's active site, molybdate converts to an unstable adenosine 5' molybdophosphate (APMo)  
391 product, also consuming ATP in the process. This depletion of ATP can rapidly decrease the cellular energy reserves, leading  
392 to overall inhibition in the organism (Taylor and Oremland, 1979). Given this, it is unsurprising that we observed little change  
393 in sulfate concentrations and no accumulation of sulfide over time in the molybdate treatments (Fig. 1, plots SM, SHM, SFM).  
394 We did, however, expect DIET between organisms with putative Fe reducing metabolisms and methanogens in the SHM  
395 incubations to still occur, as the addition of molybdate is not known to affect Fe reduction metabolic pathways. Methane was  
396 not produced in SHM incubations (Fig. 1).

397       Recent work revealed that a mutant strain of *Desulfovibrio vulgaris* Hildenborough lacking Sat was still inhibited by  
398 molybdate addition. Further investigation suggested that molybdate likely also targeted a protein containing a YcaO domain  
399 in this organism (Zane et al., 2020). While this YcaO-like protein has yet to be fully characterized in *D. vulgaris*, this protein  
400 superfamily is known for several critical functions, including azoline, macroamidine, and thioamide formation, catalysis of  
401 RimO-dependant methylthiolation, and biosynthesis of ribosomally synthesized and posttranslationally modified peptides  
402 (Burkhart et al., 2017). YcaO-like proteins can engage in phosphorylation reactions and contain an ATP binding motif that's  
403 highly conserved throughout the superfamily (Dunbar et al., 2014). Zane et al., posited in 2020 that molybdate is also a  
404 substrate for YcaO-like proteins, forming APMo upon phosphorylation, leading to a similar depletion of intracellular energy  
405 reserves as observed during Sat inhibition.

406       There are currently more than 17,000 proteins containing Ycao-like domains listed in the InterPro database  
407 (Accession no: IPR003776), spanning wide phylogenetic diversity within both bacteria and archaea. We searched this database  
408 and found Ycao-like domain containing proteins in several species representative of the genera enriched in our incubations  
409 that were either highly abundant or putatively have metabolisms that are relevant for our study. These genera include,  
410 *Lactobacillus*, *Lachnoclostridium*, *Desulfosporosinus*, *Anaeromyxobacter*, *Sporomusa*, *Syntrophomonas*, *Methanosarcina*,  
411 *Methanobacterium*, and several members of the Anaerolineae (see Table S3 for list of species and Interpro accession numbers).  
412 It is possible that molybdate amendment to our incubations not only specifically inhibited sulfate reduction, but also inhibited  
413 the general physiology of many of the other organisms. The absence of methane production in SHM cultures could possibly  
414 be attributed to general inhibition of the Fe reducers and/or the methanogens, reducing the organisms' capabilities to perform  
415 DIET. We detected much less acid-extractable Fe(II) in our ferrihydrite treatments when molybdate was provided compared  
416 to molybdate free incubations (Fig. 1 and S7, panel SFM) and the lack of peaks associated with reduced ferrous iron in XANES  
417 analyses for sample SFM (Fig. 3A), providing further support for the inhibition of Fe reducing microbes via molybdate. Very  
418 little butyrate was consumed and much less acetate was produced in the molybdate treatments compared to the other conditions  
419 (Fig. 1, panels SM, SHM, and SFM), suggesting that many of the fermenters were inhibited by molybdate as well.

420       It is also worth noting that the concentration of molybdate used (10 mM) may have been high enough to impart global  
421 toxicity on several of the organisms, regardless of whether they express YcaO domain containing proteins. Recently,  
422 molybdate's IC50 for sulfide production by both a sulfate-reducing enrichment culture and model SRB *Desulfovibrio*  
423 *alaskensis* G20 were calculated to be 0.0069 mM and 0.089 mM, respectively. In addition, the IC50s for overall growth (as

424 determined by OD 600 measurements) for this sulfidogenic enrichment culture and *D. alaskensis* G20 grown using pyruvate  
425 as an electron acceptor were 0.69 mM and 0.092 mM, respectively (Carlson et al., 2021). Since more than an order of  
426 magnitude more molybdate was used in our sediment incubations, it is possible that metabolic activity and growth of most  
427 organisms enriched in these cultures was arrested.

428 The composition of the microbial communities was also significantly affected by the addition of molybdate, as Bray-  
429 Curtis dissimilarity metrics indicated significant differences in composition of molybdate treated communities and the initial  
430 inoculum, communities where no inhibitors were added, and communities treated with BES (PERMANOVA p-values = 0.001  
431 for all pairwise comparisons, Table S2, Fig. S8). Molybdate incubations were largely dominated by Clostridia.  
432 Desulfitobacteria and Desulfotomaculia were still detected in samples collected at day 36 but decreased in abundance by day  
433 87. While Methanobacteria were observed in several of the molybdate incubations, we were unable to detect the presence of  
434 Methanosarcinia. These differences in community composition in response to molybdate addition may also partially explain  
435 the lack of methane production in our SHM incubations, as the organisms most likely to engage in DIET were found in much  
436 lower abundances in these communities than in the incubations where no inhibitors were added.

437

### 438 3.5 Investigation of microbe-mineral interactions mechanisms

439 Possible mechanisms of microbe-mineral interactions that may explain observations from our incubations are  
440 presented in Fig 4. In all inhibitor-free conditions (Fig. 4A), the consumption of butyrate coincided with the reduction of sulfate  
441 by sulfate reducing bacteria. We observed the production of methane in incubations amended with hematite, presumably  
442 through DIET mechanisms between sulfate/Fe reducing microbes and methanogens. We did not observe methane production  
443 in incubations amended with ferrihydrite. Fe reducers enriched during these incubations were likely able to use the more  
444 reactive ferrihydrite as an electron acceptor, resulting in its reductive dissolution and subsequent release of Fe(II) (Figs. 1,  
445 3A, and S2) previous studies (Tang et al., 2021).

446 Natural enrichment of several genera of Fe reducing microbes in our incubations made it challenging to specifically  
447 determine how much sulfate-reducing metabolisms contributed to DIET in the presence of hematite, a phenomenon that has  
448 already been well studied in sedimentary environments (Aromokeye et al., 2018, 2020; Rotaru et al., 2018; Zhang and Lu,  
449 2016). In addition, members of enriched genera, including *Desulfispora*, *Desulfosporosinus*, and potentially organisms from  
450 Actinobacteria group OPB41, are known to engage in both sulfate and Fe reduction, further obscuring microbe-mineral  
451 interactions occurring within these incubations.

452 Molybdate was used to specifically inhibit sulfate-reducers to assess their contribution to methane production and  
453 DIET processes occurring in our system (Fig. 4B). However, we may have also inadvertently inhibited the general physiologies  
454 of Fe-reducers and many other microbes that we enriched, likely due to molybdate also targeting the ubiquitous biosynthesis  
455 proteins of the YcaO superfamily, leading to subsequent ATP depletion. In addition to lack of methane production as a result  
456 of DIET in our SHM conditions, there was an overall decrease in Fe reduction capacities in these cultures, indicated by lower  
457 accumulation of acid-extractable Fe(II) in SFM incubations compared to SF and SFB conditions (Fig. 1 and S7).

458 Interactions at the biotic/abiotic interface are complex in terrestrial subsurface environments and this study further  
459 elucidates these intricately linked processes by emphasizing the role that both microbes and minerals play in facilitating  
460 biogeochemical cycles. Our results highlight the direct influences mineralogy has on microbial biogeochemistry. We showed  
461 that methanogenesis can occur under sulfate replete conditions when crystalline Fe oxides are present to mediate DIET  
462 interactions between microbial partners. This study helps to explain the co-occurrence of sulfate reduction and methane  
463 production in other terrestrial subsurface environments rich in semiconducting Fe minerals.

464

#### 465 **Data Availability**

466 The raw sequences analyzed for this study are available in the NCBI repository under BioProject PRJNA945499, BioSample  
467 Accession numbers SAMN33786795 through SAMN33786856.

468

#### 469 **Author Contributions**

470 MY, and RC designed experiments. MY and KCG performed the incubation experiments. BE, MY, KCG, AB performed  
471 analyses. BE, AB, and SGD contributed to initial manuscript draft. BE, RC, MY, KC, SGD, TH reviewed and edited the  
472 manuscript.

473

#### 474 **Competing Interests**

475 The authors declare that they have no conflict of interest.

**Figure 4. Proposed mechanism of microbe-mineral interactions in our system. A) Under uninhibited conditions, SRB and fermenters catalyze both the conversion of butyrate to acetate as well as the conversion of acetate to CO<sub>2</sub> and H<sub>2</sub>. Iron reducing bacteria can utilize acetate, H<sub>2</sub>, CO<sub>2</sub>, or other organic substrates produced in the cultures to either reduce ferrihydrite or engage in EET transfer electrons to hematite. Methanogens in hematite amended cultures likely use electrons transferred to hematite from iron reducers to fix CO<sub>2</sub> into methane.**
