11 **Abstract**

12 Atmospheric sulfur (S) deposition has been increasingly recognized as a major driver
13 of soil acidification. However, little is known on how soil acidification influences
14 above- and belowground biomass via altering leaf and root traits. We conducted a 3-
15 year S addition experiment to simulate soil acidification in a meadow. Grass (*Leymus*
16 *chinensis* (Trin.) Tzvelev) and sedge (*Carex duriuscula* C. A. Mey) species were chosen
17 to evaluate the linkage between plant traits and biomass. Sulfur addition led to soil
18 acidification and nutrient imbalance. Soil acidification decreased specific leaf area
19 (SLA) but increased leaf dry matter content (LDMC) in *L. chinensis*, showing a
20 conservative strategy and thus suppression of aboveground instead of belowground
21 biomass. Whereas in *C. duriuscula*, soil acidification increased plant height and root
22 nutrients (N, P, S, and Mn), favoring competition for natural resources by enhanced
23 above- and belowground biomass, *i.e.*, adoption of an acquisitive strategy. Increased
24 soil acidity resulted in an overall reduction in community aboveground biomass by 3-
25 33%, but increased the community root biomass by 11-22% due to upregulation through
26 higher soil nutrient availability. Our results demonstrate that plant above- and
27 belowground biomass is affected by S-induced acidification. Understanding the linkage
28 between plant biomass and functional traits contributes to better knowledge on plant-
29 soil feedback in grassland ecosystems.

31 plant biomass

32

33 **1 Introduction**

34 Acid deposition as a consequence of anthropogenic activities has significant impacts
35 on terrestrial biodiversity and ecosystem functions (Tian and Niu, 2015; Clark et al.,
36 2019; Yang et al., 2021). Atmospheric sulfur (S) deposition is one of the main causes
37 of soil acidification, with its effects equal to or exceeding that of nitrogen (N) deposition
38 in Asia (Duan et al., 2016; Zhang et al., 2022). Despite a large decrease in average S
39 deposition across China over the past decades, the problem is still very severe in
40 Northeast China and Inner Mongolia (Yu et al., 2017). The northern grasslands of China
41 as an integral part of the Eurasian grassland have experienced severe soil acidification
42 with a significant decline in mean soil pH from 7.84 to 7.21 during 1980s- 2000s, and
43 S deposition undoubtedly accelerates this process (Yang et al., 2012). Therefore, soil
44 acidification has become a major global concern; it not only leads to soil nutrient
45 imbalance but also decreases the productivity of terrestrial ecosystems (Chen et al.,
46 2013a; Tibbett et al., 2019; Duddigan et al., 2021).

47 In natural ecosystems, sulfur is an essential nutrient element in forming plant
48 proteins for being a constituent of certain amino acids (Vitousek and Howarth, 1991;
49 Garrison et al., 2000). Shifts in plant species and community associated with S
50 deposition are mainly a consequence of soil acidification rather than a S-fertilization
51 effect (Clark et al., 2019). This is because soil pH is a primary regulator of nutrient
52 availability that plant growth and species co-existence rely on (Bolan et al., 2003;
53 Tibbett et al., 2019). For instance, soil acidification inhibits nitrification (Kemmitt et
54 al., 2005), but facilitates the release of soil available phosphorus (P), micronutrients
55 and the leaching of soil base cations (Jaggi et al., 2005; Chen et al., 2015; Feng et al.,
56 2019). Evidence of a previous manipulative S addition experiment has shown that
57 aboveground biomass (AGB) generally decreases with soil acidification, except high
58 acid tolerance species sedges which displays a reversed pattern of responses in a
59 subalpine grassland (Leifeld et al., 2013). The acidification-mediated decreases in soil
60 cation concentrations (such as Ca^{2+} and NO_3^-) could increase the relative abundance of
61 acid-tolerant and oligotrophic species (van Dobben and de Vries, 2010; Clark et al.,

62 2019), as a result of decreasing abundance of other species (Jung et al., 2018).
63 Additionally, soil Mn toxicity caused by soil acidification in calcareous grassland
64 asymmetrically reduces aboveground biomass of different species and functional
65 groups through suppression of photosynthesis (Tian et al., 2016).

66 Findings from a global meta-analysis predominantly on forest ecosystems show
67 negative acidification effects on root biomass under sulfuric acid addition (Meng et al.,
68 2019), because forest soils with low initial pH ($\text{pH} < 5$) generally have greater level of
69 Al^{3+} and Fe^{3+} but less base cations, hence the inhibition of root growth (Li et al., 2018).
70 Different from findings with forests, in typical and alpine grasslands belowground
71 biomass increases with soil acidification mainly due to the compensatory growth
72 concomitant with the dominance of graminoids over forbs (Chen et al., 2015; Wang et
73 al., 2020). Plausibly, perennial rhizome grasses and sedges have higher ionic tolerance
74 (such as H^+ , Al^{3+} , NH_4^+ , and SO_4^{2-}) than perennial bunchgrasses and forbs, which allow
75 for the maintenance of high community biomass under soil acidification (Chen et al.,
76 2015; Cliquet and Lemauiel-Lavenant, 2019; Wang et al., 2020). Therefore, shifts in
77 grassland community are mainly regulated by soil nutrient fluctuations as induced by
78 soil acidification that eventually affect above- and belowground biomass (Mitchell et
79 al., 2018; Wang et al., 2020).

80 Functional traits are known to substantially influence plant survival, growth and
81 reproduction via closely association with plant capability for resource acquisition
82 (Violle et al., 2007). To cope with environmental stresses for persistence and
83 reproduction, plants often rely on a possessing a broad spectrum of functional traits
84 ranging from conservative to proactive strategies of resource acquisition (De Battisti et
85 al., 2020). For example, some plant species can upregulate tissue nutrients as a fast
86 resource acquisition strategy when soil environmental conditions become challenging
87 (Mueller et al., 2012). In contrast, some plant species under environmental stresses tend
88 to be more nutrient-conservative by having long-lasting leaves generally with a low
89 specific leaf area (SLA) but a high leaf dry matter content (LDMC) (Kandlikar et al.,
90 2022). Grass species may also increase root length to avoid acid and Al^{3+} stresses
91 (Göransson et al., 2011). In general, studies show that species with an acquisitive

92 strategy gain a greater biomass more rapidly, but those with a conservative strategy
93 have a slower pace of biomass growth to prolong their life span (Reich, 2014; Hao et
94 al., 2020).

95 Due to difficulties in measuring grassland root traits in situ, we still have very
96 limited knowledge on how root trait strategies are linked to the response of
97 belowground processes to soil acidification. It is known that some plants can cope with
98 nutrient deficiency in acidic soils via modifications of their root morphologies and
99 through their nutrient uptake capability and metabolic adjustment (Hammond et al.,
100 2004). Plants growing in resource-poor soils tend to have lower specific root length
101 (SRL) and lower root nutrient concentrations for the conservation of resources
102 (Delpiano et al., 2020). Findings from a pot experiment show that root length of
103 perennial grasses decreases with soil acidification, demonstrating the constraint of root
104 development under environmental stresses (Haling et al., 2010). However, in natural
105 ecosystems, it has been found that grasses develop densely branched root systems with
106 higher nutrient use efficiency and are more stress-tolerant to nutrient deficiency for
107 maintaining nutrient balance and growth (Tian et al., 2022). Moreover, aboveground
108 and belowground biomass might be strongly influenced by specific functional traits
109 (Clark et al., 2019; Wang et al., 2020), soil nutrient availability, and nutrient contents
110 in leaves and roots under soil acidification (Geng et al., 2014; Rabêlo et al., 2018; Tian
111 et al., 2021). To date, it still remains elusive on how the functional traits for both above-
112 and belowground components of different species respond to soil acidification.

113 To understand how soil acidification resulting from S deposition influences plant
114 traits, biomass and the linkage between the two in coping with S-induced stress, we
115 conducted a S addition experiment with eight loading rates (from 0 to 50 g S m⁻² yr⁻¹)
116 to simulate different levels of soil acidification in a meadow grassland. We assessed the
117 role of plant above- and belowground traits and soil abiotic variables in affecting the
118 biomass of two dominant and contrasting plant species (*Leymus chinensis* (Trin.)
119 Tzvelev and *Carex duriuscula* C. A. Mey) under soil acidification. Specifically, we aim
120 to examine how the relationships between biomass and plant functional traits are
121 modified by changes in soil conditions. As a perennial rhizome grass, *L. chinensis* is

122 widely distributed in arid and semi-arid areas of northern China. This species occurs in
123 the top layers of the local grassland communities, as such likely having an advantage
124 in resource acquisition, especially for light. Additionally, grasses generally exhibit
125 flexibility in absorbing various forms of soil N, thereby expanding their ecological
126 niche (Grassein et al., 2015). The perennial rhizomatous sedge *C. duriuscula* is a shorter
127 subordinate species and an indicator plant for soil degradation, and possesses cluster
128 roots and tends to consume more photosynthetic products for increased ability to
129 acquire nutrients (Zhang et al., 2021). Both species exhibit distinct rhizosheaths that
130 enable them to tightly adhere to the soil and show compensatory growth in response to
131 environmental disturbance (Tian et al., 2022). Our study addresses the following
132 questions: (i) how do soil properties (*i.e.* soil pH, Ca^{2+} , Al^{3+} , available N, available P),
133 above- and belowground plant traits (*i.e.* morphological and nutrient traits) and biomass
134 respond to different doses of S addition in a meadow grassland? (ii) What are the key
135 plant functional traits that regulate the biomass responses of two species to soil
136 acidification? We hypothesized that soil acidification caused by S addition would lead
137 to a nutrient imbalance in the meadow grassland soil. Grass *L. chinensis* may respond
138 to soil acidification by adjusting its aboveground light acquisition traits for biomass
139 growth; whereas the sedge *C. duriuscula* may adopt a strategy of the increased tissue
140 nutrient concentrations for enhancing its tolerance to soil acidification, consequently
141 leading to compensatory root growth (Fig. S1).

142 **2 Materials and methods**

143 **2.1 Experimental site and design**

144 This study was conducted at the Erguna Forest-Steppe Ecotone Research Station (50°
145 10' N, 119° 23' E) of Chinese Academy of Sciences in Inner Mongolia, China. The area
146 belongs to a transitional climate zone between mid-temperate to cold-temperate climate
147 with mean annual temperature and precipitation of -2.45 °C and 363 mm, respectively
148 (Feng et al., 2019). Soil at the experimental site is classified as a Haplic Chernozem
149 according to the Food and Agricultural Organization of the United Nations
150 classification (IUSS Working Group WRB, 2014), and was composed of $37 \pm 0.9\%$

151 sand, $40 \pm 1.0\%$ silt and $24 \pm 0.8\%$ clay (Li et al., 2019). Vegetation in this area is a
152 meadow steppe community predominantly comprised of *L. chinensis*, *Stipa baicalensis*
153 Roshev, *Cleistogenes squarrosa* (Trin.) Keng, *C. duriuscula*, *Pulsatilla turczaninovii*
154 Kryl. et Serg., and *Cymbaria dahurica* Linn.

155 The experimental field had been used for hay harvesting until 2013, and was fenced
156 to exclude livestock grazing since then. A field elemental S addition experiment was
157 established in 2017, to simulate soil acidification caused by atmospheric S deposition
158 in a homogeneous and flat field containing naturally assembled communities. The
159 vegetation in the experimental plots is composed of the dominant species (relative
160 abundance >40%) *L. chinensis*, subordinate species (relative abundance between 1%
161 and 30%), including *S. baicalensis*, *C. duriuscula*, *C. squarrosa*, *Achnatherum*
162 *sibiricum* (Linn.) keng, *C. dahurica*, *P. turczaninovii*, *Thermopsis lanceolala* R. Br and
163 *Achnatherum sibiricum* (Linn.) keng. The experimental setup adopted a randomized
164 block design with eight levels of S addition rate (0, 1, 2, 5, 10, 15, 20, and 50 g S m^{-2}
165 yr^{-1}) and five replicated $6 \text{ m} \times 6 \text{ m}$ plots (Fig. S2). The low dose S applications in our
166 study was to mimic the current atmospheric SO_4^{2-} deposition level ($2 - 4 \text{ g S m}^{-2} \text{ yr}^{-1}$)
167 in Northeast of China (Yu et al., 2017). Adjacent plots were separated by a 2-m wide
168 and mowed buffer strip. Purified sulfur fertilizer (elemental S > 99%), mixed with 200
169 g soil collected from the untreated areas nearby, was applied by hand spreading
170 annually in late May starting in 2017. Sulfur powder in soil can be oxidized by soil
171 microorganisms to form H^+ and SO_4^{2-} which simulate soil acidification well (Duddigan
172 et al., 2021). In the present study, we collected plant and soil samples from all the plots
173 from five out of eight levels of S addition treatments (0, 5, 10, 20, and $50 \text{ g S m}^{-2} \text{ yr}^{-1}$).

174 **2.2 Plant and soil sampling**

175 In early August 2019, the annual aboveground biomass of plant communities was
176 harvested at the peak growth. All living tissues were clipped within a randomly selected
177 $1 \text{ m} \times 1 \text{ m}$ quadrat in each plot, sorted by species and oven-dried at $65 \text{ }^\circ\text{C}$ for 48 h to
178 measurements of aboveground net primary productivity (ANPP) and leaf nutrient
179 concentrations.

180 We measured three aboveground morphological traits for the two dominant species
181 *L. chinensis* and *C. duriuscula*. Ten individual plants with complete shoot were
182 randomly selected for each species within each plot. They were measured for maximum
183 height and then clipped at the ground level. All the samples were immediately placed
184 in a portable refrigerator and later detached to measure leaf area in laboratory. To ensure
185 water saturation of the leaves, the samples were submerged in purified water and
186 rehydrated for a minimum period of 6 hours. Then the water-saturated leaves were
187 carefully wiped off the surface water with filter paper and weighed. The leaf samples
188 were all scanned using an electronic scanner (Eption Perfection V39, Seiko Epson
189 Corporation, Japan) for measurements of leaf area and then dried to constant weight at
190 60 °C for 72 h for measurements of dry mass. Specific leaf area (SLA, cm² g⁻¹) was
191 calculated as the ratio of projected leaf area to dry mass. Leaf dry matter content was
192 calculated as the ratio of dry mass to saturated mass (LDMC, g g⁻¹).

193 Plant roots were sampled using the soil block method in late August 2019.
194 Specifically, a 30 × 30 × 30 cm soil block was collected using a steel plate and a shovel
195 from each plot, resulting in a total of 25 soil blocks. All soil blocks were immediately
196 transported to the processing area upon collection and then gently loosened by hands to
197 separate roots from soils. The separated plant roots were carefully washed to remove
198 the adhering soil and placed in iceboxes for transportation to laboratory. Before
199 determining root morphological and chemical traits, all root samples were frozen at -
200 20 °C. At least 10 intact individual plants for each of *L. chinensis* and *C. duriuscula*
201 within each plot were used for determination of root nutrient traits (root [N], [P], [S],
202 [Ca], [Fe], and [Mn]) and morphological traits. The total root length, surface area and
203 volume were determined using the scanned images by the WinRHIZO software (Regent
204 Instruments Inc., Quebec City, QC, Canada). Specific root length (SRL, m g⁻¹) was
205 calculated as total root length divided by its dry mass. Specific root surface area (SRA,
206 cm² g⁻¹) was defined as total surface area divided by its dry mass. Root tissue density
207 (RTD, g cm⁻³) was obtained as the ratio of root dry mass to its volume. All the above
208 samples were dried at 65 °C to constant mass for measurements of root biomass at
209 species and community levels, respectively. Root and leaf N concentrations were

210 determined using an elemental analyzer (Vario EL III, Elementar, Hanau, Germany).
211 Both root and leaf samples were digested with 8 mL HNO₃ + 4 mL HClO₄ for
212 measurements of P, S, Ca, Fe and Mn concentrations by inductively coupled plasma
213 optical emission spectrometry (5100 ICP-OES; Perkin Elmer, America).

214 Fresh soil sampling (0 - 10 cm depth) was performed using a soil auger (5 cm inner
215 diameter). In each plot, three cores were collected and mixed into one composite sample.
216 After removing the visible plant detritus and rocks, we sieved the fresh soils through a
217 2-mm screen and divided each soil sample into two portions. For each sample, 10 g of
218 fresh soil was immediately extracted with 2 mol L⁻¹ KCl solution. The extracted
219 solution was analyzed for nitrate (NO₃⁻) and ammonium (NH₄⁺) concentrations using
220 an autoAnalyser III continuous Flow Analyzer (Bran and Luebbe, Norderstedt,
221 Germany). The other subsamples were air-dried for measurements of physicochemical
222 properties. Soil pH was determined in 2.5: 1 (v/w) water/soil ratio with a digital pH
223 meter (Precision and Scientific Instrument Co. Ltd., Shanghai, China). Soil available P
224 concentration was measured using extractions in 0.5 mol L⁻¹ NaHCO₃ solution and soil
225 available S concentration in 0.1 mol L⁻¹ Ca(H₂PO₄)₂ solution (Tabatabai and Bremner,
226 1972) with a UV-VIS spectrophotometer (UV-1700, Shimadzu, Japan) at 880 nm and
227 440 nm, respectively. Soil exchangeable aluminum (Al³⁺) concentration was measured
228 using titration by 0.25 M NaOH to pH 7.0 after extraction with 1 M KCl solution from
229 air-dried soil samples. Soil exchangeable calcium (Ca²⁺) was extracted by 1 M NH₄OAc
230 (pH = 7.0) at a 1:10 ratio (w/v) for 30 min. Diethylene triamine pentaacetic acid
231 (DTPA)-Fe and Mn were extracted from 10 g of air-dried soil sample with 20 ml of
232 0.005 M diethylenetriamine pentaacetic acid (DTPA), 0.01 M CaCl₂, and 0.1 M
233 triethanolamine (TEA) at pH 7.3 and determined using an atomic absorption
234 spectrophotometer (AAS, Shimadzu, Japan) (Feng et al., 2019; Li et al., 2021).

235 **2.3 Statistical analyses**

236 The effects of S addition on soil properties, plant traits and biomass were analyzed using
237 one-way analysis of variance (ANOVA) with Duncan test for comparison of multiple
238 means. Pearson's correlation analysis was performed to determine the relationships

239 among plant traits, plant biomass and soil abiotic variables across the S addition levels.
240 All the statistical analyses were performed using SPSS16.0 (SPSS Inc., Chicago, USA)
241 with significance level at $p < 0.05$.

242 We used structural equation modelling (SEM) to determine the indirect effects of
243 S addition in mediating the aboveground and root biomass from the perspective of
244 plant traits and soil factors. Prior to SEM analysis, the number of variables were
245 reduced by conducting principal component analysis (PCA) on all the variables for soil
246 (pH, $\text{NH}_4^+\text{-N}$, $\text{NO}_3^-\text{-N}$, available P, available S, exchangeable cations Ca^{2+} and Al^{3+} ,
247 DTPA-Fe and DTPA-Mn), aboveground morphological traits (Height, SLA, LDMC),
248 leaf nutrient traits (Ca, Fe, Mn), root morphological traits (SRL, SRA, RTD) and root
249 nutrient traits (N, P, S, Ca, Fe, Mn). We then used the first principal components (PC1)
250 for the subsequent SEM analysis to represent soil acidification (PC1 explained 94.8%
251 of the variation), soil nutrients (PC1 explained 62.3% of the variation), root nutrient
252 traits in *C. duriuscula* (PC1 explained 45.7% of the variation), aboveground
253 morphological traits in *L. chinensis* (PC1 explained 54.7% of the variation) (Table S1).
254 A conceptual model of the hypothetical relationships was constructed (Fig. S1),
255 assuming that S addition would directly impact soil physicochemical properties, and
256 indirectly influence aboveground and belowground biomass through altering soil pH,
257 soil nutrient availability and plant traits. The SEM analyses were performed using
258 AMOS 24.0 (Amos Development Co., Maine, USA) and the PCA analyses were
259 performed using the vegan package in R 4.2.2.

260

261 **3 Results**

262 **3.1 Effects of S addition on soil properties**

263 Sulfur addition significantly decreased soil pH from 6.95 to 5.19, but increased soil
264 exchangeable Al concentration only in the highest S-addition level of $50 \text{ g S m}^{-2} \text{ yr}^{-1}$
265 (Table 1). Similarly, S addition increased soil ammonium concentration but decreased
266 nitrate concentration in the highest S addition treatment (Table 1). Soil available P,
267 available S, DTPA-Fe and DTPA-Mn concentration increased with increasing S

268 addition rate, while soil exchangeable Ca concentration decreased (Table 1).

269 **3.2 Effects of S addition on above- and belowground biomass**

270 In the third year of the treatment, S addition suppressed the aboveground biomass of
271 plant community (Fig. 1). Aboveground biomass of the two dominant species showed
272 contrasting responses to S addition; it increased in *C. duriuscula* but decreased in *L.*
273 *chinensis* (Fig. 1). Moreover, S addition significantly increased the belowground
274 biomass of plant community owing to the increase in *C. duriuscula*, but had no impact
275 on the belowground biomass in *L. chinensis* (Fig. 1).

276 **3.3 Effects of S addition on above- and belowground traits in *L.*** 277 ***chinensis* and *C. duriuscula***

278 Sulfur addition resulted in increased plant height growth in *C. duriuscula*, but had no
279 impact in *L. chinensis* (Fig. 2a). The values of SLA were decreased, and the values of
280 LDMC increased in *L. chinensis* by the S addition treatment, but were not affected in
281 *C. duriuscula* (Fig. 2b and c). For the belowground tissues, S addition treatment
282 increased SRL in both species, but decreased SRA only in *C. duriuscula* (Fig. 2d and
283 e). However, RTD did not respond to the S addition treatment in either of the two
284 species (Fig. 2f).

285 For the nutrient traits, S addition had no significant impact on any of leaf [N], [P],
286 and [Ca], but increased leaf [S] and [Mn] in both species, and decreased leaf [Fe] in *C.*
287 *duriuscula* and increased leaf [Fe] in *L. chinensis* (Fig. 3). Root [N], root [P], root [S]
288 increased in *C. duriuscula* under the S addition treatment, but were not affected in *L.*
289 *chinensis* (Fig. 3h, i and j). Sulfur addition decreased root [Ca] in *C. duriuscula*, but did
290 not affect the root [Ca] in *L. chinensis* (Fig. 3k). Root [Fe] showed similar patterns of
291 responses to S addition treatments that of leaf [Fe]; it decreased in *C. duriuscula* and
292 increased in *L. chinensis* (Fig. 3l). Root [Mn] in both species were enhanced by S
293 addition (Fig. 3m).

294 **3.4 Correlations and pathways of S-induced soil acidification effects** 295 **on plant traits and biomass**

296 Correlation analysis revealed species-specific responses to S addition in the
297 aboveground morphological traits and the root nutrient traits (Figs. S3 and S4). This
298 was mainly due to an increase in soil acidity, and occurrence of Al^{3+} toxicity and
299 nutrient imbalance (*i.e.*, the deficient or excessive level of certain nutrients in the soil)
300 induced by S addition, as demonstrated by the well fitted structural equation modelling
301 (SEM) ($\chi^2 = 51.83$, $P = 0.10$, $df = 40$, $AIC = 103.83$, $n = 25$) (Fig. 4). The indirect
302 positive effect of S addition on community belowground biomass was mainly imposed
303 through a decreased soil pH in combination with an imbalance of soil available nutrients,
304 alteration of leaf and root nutrient traits, and increased belowground biomass in *C.*
305 *duriuscula*, collectively accounting for 69% of the variation in community
306 belowground biomass (Fig. 4). The indirect negative effect of S addition on community
307 aboveground biomass was mainly operated through soil acidification, changes in the
308 aboveground morphological traits and increased aboveground biomass in *L. chinensis*,
309 altogether accounting for 59% of the variation in community aboveground biomass (Fig.
310 4).

311 **4. Discussion**

312 **4.1 Species-specific trait responses to S addition**

313 The patterns of trait response to S addition differed between *L. chinensis* and *C.*
314 *duriuscula*. Specifically, the nutrient traits in *L. chinensis* were less plastic, as evidenced
315 by unchanged concentrations of N, P, S, and Ca, compared with *C. duriuscula*. *Leymus*
316 *chinensis* was suggested to be a highly homeostatic species with greater stability in
317 elemental composition in a temperate steppe (Yu et al., 2010). Higher macroelement
318 homeostasis helps plant maintain the functional and growth stability to resist changes
319 in soil environment (Yu et al., 2010; Feng et al., 2019).

320 It is intriguing that increases in both leaf and root [Fe] in *L. chinensis* caused by S
321 addition were not associated with soil available [Fe] (Figs. 3 and S3). Iron uptake and
322 assimilation has been shown to be dependent on sulfate availability (Zuchi et al., 2012).
323 Previous research demonstrated close relationships between Fe and S nutrition,
324 suggesting common regulatory mechanisms for the homeostasis of the two elements

325 (Fioreri et al., 2013). For grasses, S addition could enhance assimilation of plant S,
326 which is subsequently incorporated into methionine in order to accelerate the secretion
327 of phytosiderophore (Zuchi et al., 2012; Courbet et al., 2019). However, Fe absorption
328 in *C. duriuscula* was inhibited by soil acidification, consistent with Fe (III)-reduction-
329 based mechanism (Tian et al., 2016). Namely, acquisition of Fe by non-graminaceous
330 monocotyledonous species is mediated by the reduction of Fe³⁺ to Fe²⁺ catalyzed by the
331 ferric chelate reductase in root cells; Fe²⁺ absorption can be further interfered by
332 competition with Mn²⁺ for the same metal transporter (Curie and Briat, 2003; Pittman,
333 2005). Acidification-induced higher soil DTPA-Mn concentration in the calcareous soil
334 contributed to Mn accumulation in plant tissues of the two species (Figs. 3 and 5).
335 Sulfur addition increased tissue [Mn] greater in *C. duriuscula* than in *L. chinensis*.

336 *Leymus chinensis* responded to soil acidification stress by decreasing SLA and
337 increasing LDMC to reduce the loss of water and nutrients, adopting a conservative
338 resource-uptake strategy. The SLA and LDMC in *L. chinensis* were significantly
339 correlated with soil exchangeable Al, implying that conservative traits might also be
340 linked with Al-resistant strategy (Poozesh et al., 2007). We found that with decreasing
341 soil pH, soil nitrate was reduced and was positively correlated with SLA but negatively
342 with LDMC in *L. chinensis* (Table 1 and Fig. S3). Soil nitrification has been shown to
343 be positively related to leaf traits (such as leaf [N] and SLA; Laughlin et al., 2011). This
344 suggests that a decrease in soil nitrate under soil acidification could be an important
345 driver of plant trait variations. For *L. chinensis*, the belowground traits were
346 unsusceptible to S addition compared with *C. duriuscula*. One plausible explanation for
347 this insensitivity is that deep-rooted plants are more resilient to changing soil
348 environment than the shallow-rooted plants (such as sedge *C. duriuscula*) (Zhang et al.,
349 2019). We found both species responded to S-induced soil acidification by enhancing
350 SRL, in agreement with findings by Göransson et al. (2011) that grass species increases
351 root length to avoid acid stress. These results indicate that variation of root
352 morphological traits has the potential to mitigate the negative effects of soil acidity and
353 should be considered as part of stress-avoidance or tolerance strategies (Thomaes et al.,
354 2013).

355 **4.2 Species-specific and community biomass responses to S addition**

356 To clarify the underlying mechanisms of the regulation of plant biomass by functional
357 traits, we explored the role of morphological and nutrient traits in mediating
358 aboveground and belowground biomass changes under S addition. We found that the
359 aboveground and root traits in *L. chinensis* and *C. duriuscula* exhibited contrasting
360 adaptive strategies for acquiring aboveground and belowground resources (Figs. 4 and
361 5). SEM illustrated that a decrease in aboveground biomass in *L. chinensis* was related
362 to increased soil acidification and the conservative responses in aboveground
363 morphological traits under S addition (Figs. 4 and 5). *Leymus chinensis* is found to be
364 a nitrophilic and resource-acquisitive species under N-rich environment (Feng et al.,
365 2019; Yang et al., 2019), but is disadvantaged under S-induced soil acidification. For
366 example, we found SLA and LDMC in *L. chinensis* were positively correlated with the
367 aboveground biomass of both *L. chinensis* and plant community (Fig. S3). Soil
368 acidification has been found to result in enhanced toxic effects of proton and
369 exchangeable Al (Roem and Berndse, 2000). In view of environmental stress
370 hypothesis, plant species could adopt different strategies in term of trait responses to
371 mitigate such environmental stress (Encinas-Valero et al., 2022). SLA and LDMC are
372 often believed to be prominent indicators of plant strategy for maintaining productivity
373 in response to environmental stress and disturbance regimes. Stress tolerant species
374 normally have lower growth rates, photosynthetic rates, and SLA but higher LDMC
375 (Pérez-Harguindeguy et al., 2013). Sulfur addition causes acidic stress to plants, leading
376 to reduced SLA accompanied with lower photosynthesis and decreased plant
377 aboveground productivity. Damages to photosynthetic capacity associated with
378 oxidative stress has been found to occur in tree species under acid rain (Chen et al.,
379 2013b), yet it is still less understood how plants in grassland ecosystems respond
380 physiologically and biochemically to soil acidification. The future research needs to
381 test the photosynthetic and antioxidant responses of plants to soil acidification.

382 We found that plant community aboveground biomass exhibited a trend of decline
383 from 22% to 11% under soil acidification, although the overall effect was rather weak

384 between pH 6.7 and 5.19 (Fig. 1, Table 1). In this study, *Leymus Chinensis* was found
385 to play a dominant role contributing to aboveground productivity, consistent with the
386 findings by Tibbett et al. (2019) that grasses make up about 60% of plant coverage in
387 acid grassland and Heathland. Therefore, the decreased aboveground biomass in *L.*
388 *chinensis* was one of the reasons for the decline of community aboveground
389 productivity (Fig. 4). Another explanation for the decline of aboveground biomass may
390 be competitive exclusion of bunchgrasses and forbs under soil acidification (Stevens et
391 al., 2010; Chen et al., 2015). Together, findings from this study help advance our
392 knowledge on the importance of leaf morphological traits in regulating grassland
393 productivity in response to soil acidification.

394 In contrast to the role of *L. Chinensis*, *C. duriuscula* was found to dominate the
395 influence on belowground biomass of plant community under soil acidification; the
396 belowground biomass in both *C. duriuscula* and plant community significantly
397 increased from 19 to 52% by S addition (Fig. 1). The sedge species (e.g. *C. duriuscula*)
398 appears to be more tolerant to S-induced soil acidification than the perennial rhizome
399 grass species (e.g. *L. chinensis*). This finding is partly supported by results for alpine
400 grasslands and typical steppe ecosystems (Chen et al., 2015; Wang et al., 2020).
401 Previous studies suggested that the sedge had a greater competitive advantage in
402 nutrient-poor environments than other functional groups (Gusewell, 2004). An increase
403 in root biomass under soil acidification suggested that sedge invested more resources
404 in favor of nutrient acquisition. SEM provided further evidence that for *C. duriuscula*,
405 the higher nutrient demand (such as root [N], [P], [S], [Mn]) was matched by greater
406 root biomass under S addition treatment (Fig. 4). An increased root biomass in *C.*
407 *duriuscula* contributed to increased belowground biomass of plant community as a
408 result of shifts in soil available nutrients under S addition. Our study provides direct
409 evidence that *C. duriuscula* is highly efficient in nutrient acquisition and thereby
410 responds to soil acidification stress with increased biomass production (Figs. 4 and 5).
411 Our short-term findings suggest that sedges play an important role in preventing the
412 decline of grassland productivity in acidified soils. Consistent with results from a long-
413 term acidification experiment (Tibbett et al., 2019), compensatory growth of acid-

414 tolerant species is probably key to maintaining grassland productivity over the longer
415 term, particularly for ecosystems that experience acidification by chronic N and S
416 deposition.

417 For grassland ecosystems, most of the carbon is allocated belowground (Bontti et
418 al., 2009). Accumulation of roots may benefit competition for nutrient and water
419 resources in a short term (Wang et al., 2020). In the longer term, however, asymmetric
420 light competitive advantage of larger individuals (*L. chinensis*) rather than competition
421 for soil resources (DeMalach and Kadmon, 2017) would likely have a decisive effect
422 on grassland plant community productivity and diversity under soil acidification.
423 Findings in this study are in contrary to previous findings by Wang et al. (2020), who
424 reported that diameter of 3rd-order roots contributed to the increased community
425 belowground biomass under soil acidification in an alpine grassland. Our study clearly
426 demonstrates that leaf and root nutrients as a whole jointly mediate the community
427 belowground biomass in response to soil acidification induced by S addition.

428 **5 Conclusion**

429 Our results highlighted that the aboveground and root traits played important roles in
430 mediating grassland plant competition for environment resources under soil
431 acidification. Sulfur addition resulted in soil acidification, and leads to nutrient
432 imbalance (i.e. higher ammonium, available P, Fe, Mn and exchangeable Al³⁺, but lower
433 nitrate and exchangeable Ca²⁺). The dominant species *L. chinensis* showed a
434 conservative trait response strategy, with decreased SLA and increased LDMC under S
435 addition. Moreover, the conservative traits were linked with stable root biomass but
436 lower aboveground biomass as a direct impact from soil acidification. In contrast, *C.*
437 *duriuscula* displayed an efficient nutrient acquisitive strategy, with increased plant
438 height and more efficient root traits ([N], [P], [S], [Mn], SRL) in favor of aboveground
439 and root productivity under S addition, as mediated via altered soil acidity and nutrient
440 availability. Such divergent and species-specific responses were strongly driven by soil
441 environmental conditions which resulted in inconsistent changes in grassland
442 community aboveground and belowground biomass under S addition. Our results

443 highlight the important roles of both aboveground and root traits in regulating species
444 and community biomass under soil acidification.

708

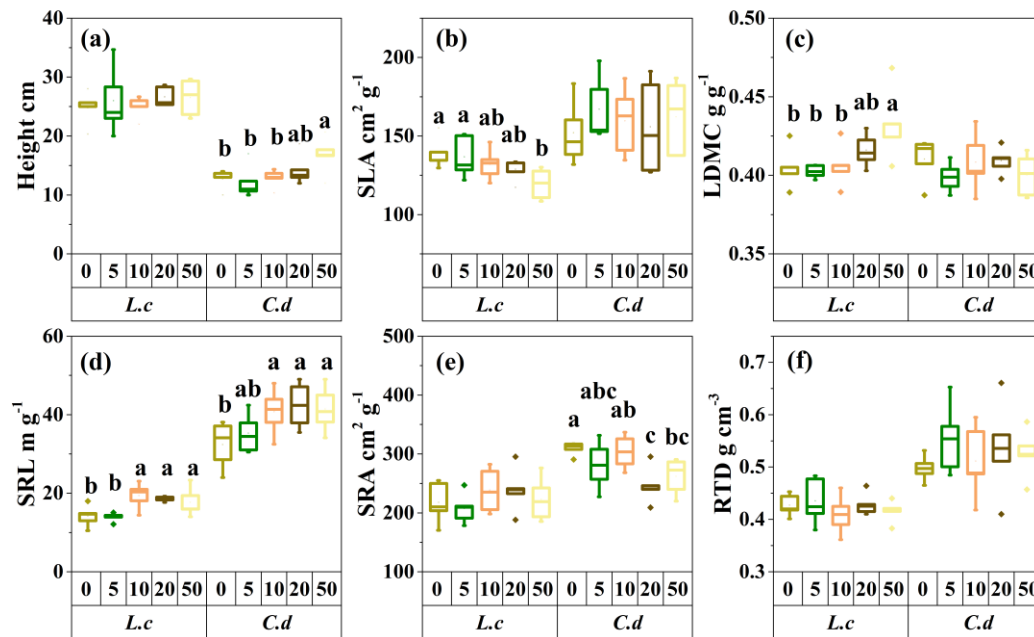

709 **Figures**

710

711 **Fig. 1** Effects of S addition on community and species aboveground and belowground
 712 biomass. Bars are means \pm the standard error. Lower case letters indicate significant
 713 difference among treatments ($P < 0.05$).

714

716

717 **Fig. 2** The response of the morphological traits to S addition for the two dominant
 718 species in a meadow steppe. Abbreviations: SLA, Specific leaf area; LDMC, Leaf dry
 719 matter content; SRL, specific root length; SRA, specific root area; RTD, root tissue
 720 density; *L.c.*, *L. chinensis*; *C.d.*, *C. duriuscula*. Different letters above the bars indicate
 721 significant influence among the S-addition level by one-way ANOVA at $P < 0.05$.

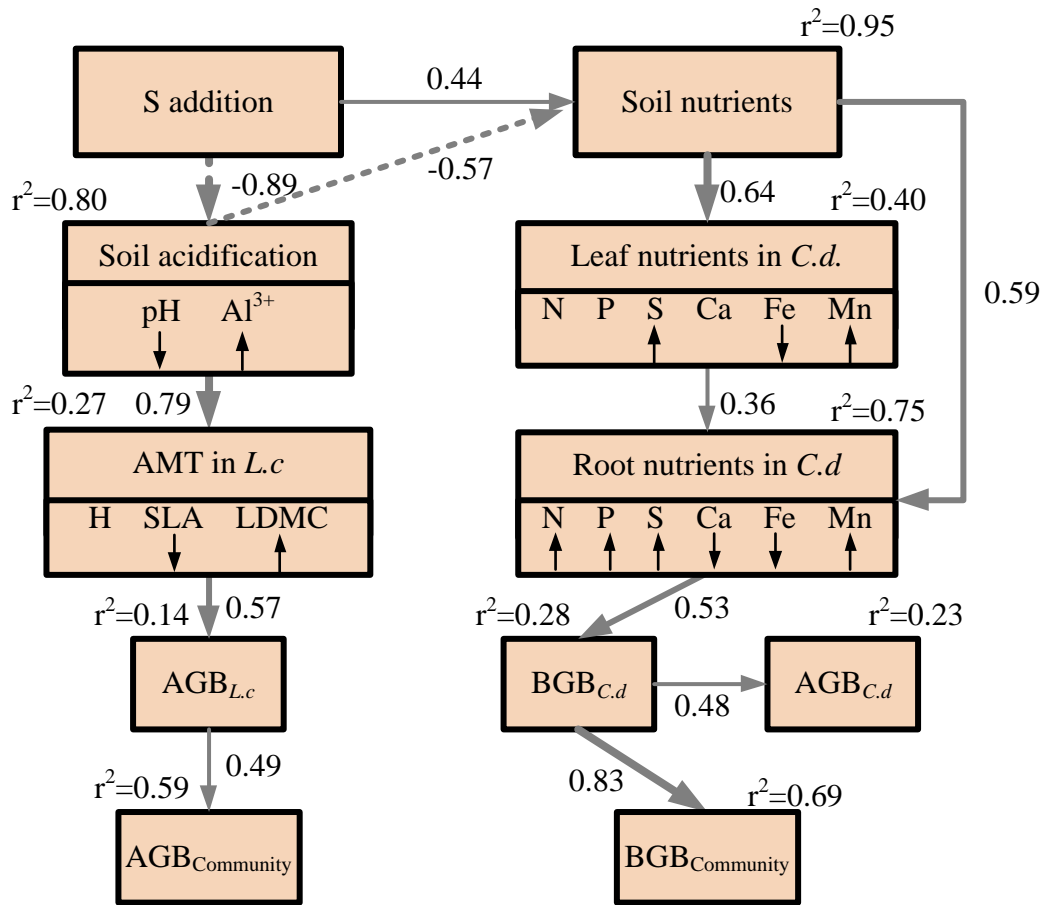

722

724

725 **Fig. 3** The response of the chemical traits to S addition for the two dominant species in
 726 a meadow steppe. Abbreviations: Leaf [N], leaf N concentration; Leaf [P], leaf P
 727 concentration; Leaf [S], leaf S concentration; Leaf [Ca], leaf Ca concentration; Leaf
 728 [Fe], leaf Fe concentration; Leaf [Mn], leaf Mn concentration; Root [Ca], root Ca
 729 concentration; Root [Fe], root Fe concentration; Root [Mn], root Mn concentration;
 730 Root [N], root nitrogen concentration; Root [P], root phosphorus concentration; Root
 731 [S], root sulfur concentration; *L.c.*, *L. chinensis*; *C.d.*, *C. duriuscula*. Different letters
 732 above the bars indicate significant influence among the S-addition level by one-way
 733 ANOVA at $P < 0.05$.

734

736

737 **Fig. 4** Structural equation model of S addition on plant community biomass through
 738 the plausible pathways. Square boxes indicate the included variables in the analysis: S
 739 addition; Soil nutrients include soil $\text{NH}_4^+\text{-N}$ and $\text{NO}_3^-\text{-N}$ concentrations, soil available
 740 phosphorus, soil available sulfur; soil exchangeable cations Ca^{2+} , Fe^{2+} and Mn^{2+} ; soil
 741 acidification includes soil pH and exchangeable Al^{3+} ; Aboveground morphological
 742 traits (AMT) includes plant height, specific leaf area, leaf dry matter content in *L.*
 743 *duriuscula*; Leaf nutrients include leaf N, P, S, Ca, Fe, Mg concentrations in *C.*
 744 *duriuscula*; Root nutrients include root N, P, S, Ca, Fe, Mg concentrations in *C.*
 745 *duriuscula*; *C. duriuscula* aboveground biomass; *C. duriuscula* belowground biomass;
 746 *L. chinensis* aboveground biomass; Community aboveground biomass and
 747 belowground biomass. The symbols \downarrow and \uparrow indicate significant decrease or increase,
 748 respectively, with increasing S addition. The final SEM adequately fitted the data: $\chi^2 =$
 749 51.83, DF = 40, $P = 0.10$, AIC = 103.83, $n=25$. R^2 values next to each response variable
 750 indicate the proportion of variation explained by relationships with other variables.

751 Solid and dashed arrows represent significant positive and negative pathways ($P < 0.05$),
 752 respectively. Nonsignificant ($P > 0.05$) pathways are not shown. Values at each arrow
 753 indicate the standard path coefficient, which is equivalent to the correlation coefficient.
 754
 755

756
 757 **Fig. 5** Schematic diagram illustrating the ecological effects of S-induced soil
 758 acidification on above- and belowground biomass and traits of two dominant species in
 759 a meadow steppe. ↑ = increase in response to S addition; ↓ = decrease in response to S
 760 addition; Com. = Community; AVP = Soil available phosphorus; AVS = Soil available
 761 sulfur.
 762

763 **Table**

764 **Table 1** Effects of S addition on soil abiotic variables. All numbers refer to the mean
 765 (the standard error). Lower case letters indicate significant difference among treatments
 766 ($P < 0.05$).

Soil parameters	S addition				
	0	5	10	20	50
Soil pH	6.95(0.06) a	6.70(0.07) ab	6.77(0.17) a	6.17(0.31) b	5.19 (0.20) c
