11 **Abstract.** In the last decade, there have been several research articles on the methane paradox (aerobic CH₄ production) first
12 described in the 1960s. In this study, we present observations of CH₄ supersaturation in the surface layer in the central Chile
13 upwelling zone (36° S, 73° W) throughout two seasonal cycles (2018-2021). Additionally, CH₄ cycling experiments were
14 performed using plankton fractions (natural planktonic community, <150, <3 and <0.2 μm) in a seasonal phytoplankton
15 succession. Our findings highlight the significant role of picoplankton (<3 μm) in CH₄ production on the ocean surface,
16 contrasting with the limited involvement of larger organisms (<150 μm). Incubations with methylated substrates such as
17 methylphosphonic acid (MPn) and trimethylamine (TMA) stimulated CH₄ production in the picoplankton fraction during both
18 upwelling (austral spring-summer) and non-upwelling (winter) seasons, being particularly relevant in the later period when
19 *Synechococcus* contributed with high relative abundance. Long-term microcosm experiments underscore the importance of
20 heterotrophic bacteria and cyanobacteria in methylotrophic methanogenesis, enhancing CH₄ regeneration, mediated by
21 dissolved organic matter (DOM) recycling. In conclusion, picoplankton emerges as a key factor in both production and
22 metabolization of methylated substrates, being responsible for maintaining CH₄ supersaturation. These findings provide
23 valuable insights into the biogeochemical processes driving CH₄ dynamics in highly productive upwelling waters.

24 **Key words:** dissolved methane, oxic methane production, surface layer, picoplankton, coastal upwelling.

25 **Key points:**

26 1. Picoplankton (<3 μm) are identified as key players in CH₄ production in the ocean surface layer, in light and dark conditions,
27 while larger organisms (<150 μm) do not significantly contribute to this process.

28 2. Methylated substrates, such as methylphosphonic acid (MPn) and trimethylamine (TMA), stimulate CH₄ production in the
29 picoplankton fraction.

30 3. *Synechococcus* and MPn substrate could be important components for CH₄ generation during the non-upwelling season,
31 while picoeucaryotes and TMA substrate are important during the onset of upwelling for CH₄ generation.

32 4. Picoplankton's role in methylotrophic methanogenesis is crucial in maintaining CH₄ supersaturation in the surface layer and
33 contributing in part to CH₄ exchange with the atmosphere.

34
35

36 1 Introduction

37 Methane (CH₄) is the most abundant organic molecule on Earth and acts as a potent greenhouse gas, with a radiative power
38 thirty times greater than CO₂ over 100 years, positively affecting the global heat balance (IPCC, 2021). Its short lifetime, about
39 10 years, makes it possible to take actions to mitigate climate change (Harmsen et al., 2020). In the ocean, physical and
40 biogeochemical processes modulate CH₄ distribution in a complex manner, especially in the surface layer (Weber et al., 2019).
41 Biogeochemically, CH₄ regeneration is governed by methanogenesis; conducted by methanogenic archaea in sediments and
42 oxygen-deficient zones (Reeburgh, 2007), whereas methanotrophy, performed by methanotroph bacteria, consuming CH₄,
43 slows its exchange with the atmosphere (Bates et al., 1996; Saunio et al., 2020).

44 Paradoxically, non-methanogenic processes produce CH₄ in oxygenated surface environments (Liu et al., 2022; Karl et al.,
45 2008). These processes could be important sources of biogenic CH₄, maintaining well observed CH₄ supersaturations in the
46 ocean surface (Lamontagne et al., 1973; Karl et al., 2008; Repeta et al., 2016), but not-well documented in global balances
47 (Saunio et al., 2020). In the last decade, phytoplankton has been identified as an important nexus in CH₄ production in different
48 marine ecosystems, linked to pathways such as demethylation via methylated compounds, which serve as substrates for aerobic
49 CH₄ regeneration (Damm et al., 2010; Florez-Leiva et al., 2013; Lenhart et al., 2016; Karl et al., 2008; Sun et al., 2011).

50 Some of these compounds are produced/synthesized or exudated/degraded by diverse microbes such as *Nitrosopumilus*
51 *maritimus*, which produces phosphonates like methylphosphonic acid (MPn) (Metcalf et al., 2012); while different
52 phytoplanktonic size fractions contribute to sulphur derivatives like methionine (Lenhart et al., 2016),
53 dimethylsulfoniopropionate (DMSP), and dimethyl sulfide (DMS) (Belviso et al., 1990; Stefels and Van Boekel,
54 1993) as well as trimethylamines (TMA) (Sun et al., 2019). These substrates serve as potential carbon sources for
55 microorganisms generating CH₄, a process denominated methylotrophic methanogenesis.

56 Picoplankton (< 0.2 μm), the smallest plankton size excluding viruses, are abundant in the ocean surface (Johnson and
57 Sieburth, 1979) and key to dissolved organic carbon (DOM) recycling (Pomeroy et al., 2007). The coupling between
58 autotrophic (e.g., *Prochlorococcus sp.*, *Synechococcus sp.*) and heterotrophic picoplankton (e.g., Pelagibacter, SAR 11) could
59 lead to CH₄ production from various C-1 compounds (Carpenter et al., 2012; Repeta et al., 2016; Sun et al., 2019). Furthermore,
60 Cyanobacteria serve as a CH₄ source through H₂ production during N₂ fixation (Berg et al., 2014).

61 The concentration and composition (quality) of DOC play a crucial role in marine CH₄ biogeochemistry, as DOC is released,
62 consumed, and transformed (Azam and Malfatti, 2007). Specifically, heterotrophic prokaryotes degrade up to 50% of the
63 carbon fixed by primary producers (Azam et al., 1983), reintroducing it into higher trophic levels through the microbial loop
64 (Azam et al., 1983; Pomeroy et al., 2007). Additionally, they remineralize nutrients and generate greenhouse gases, such as
65 CH₄ (Dinasquet et al., 2018; Sun et al., 2011). This highlights the intricate pathways involved in the biological origin of CH₄.
66 Several studies have indicated empirical correlations between pico- and microplankton (haptophytes, cryptophytes, and
67 diatoms) biomass and CH₄ supersaturation (Bizic, 2021; Klintzsch et al., 2020; Lamontagne et al., 1973), suggesting a not

68 well-known mechanism linking photosynthesis with a methylated precursor (Bižić et al., 2020; Hartmann et al., 2020; Lenhart
69 et al., 2016; León-Palmero et al., 2020); however, since picoplankton are small in size and biomass, it is difficult to observe
70 this relationship. Understanding the interaction between plankton fractions and organic substrates is essential for
71 comprehending the biogeochemical dynamics of CH₄ in the upwelling waters of central Chile, and has broader implications
72 for marine ecosystems in general.

73 2 Material and methods

74 2.1 Water collection

75 Seawater was collected from the upwelling zone of central Chile (36° 0.802' S 73° 07.750' W) at the University of Concepcion
76 (Chile) time series station, ST18. Monthly samplings have been conducted aboard the RV Kay Kay II since 2002. Continuous
77 sampling with a CTD-O (SBE-19) instrument was performed to obtain temperature, salinity, and dissolved oxygen (DO)
78 profiles, whereas seawater samples using 10 L Niskin bottles at various depths (0, 5, 10, 20, 30, 50, 65, 80 m) were obtained
79 in triplicate for dissolved gas (oxygen and methane), nutrient and chlorophyll-a (Chl-a) analysis. Detailed methodologies can
80 be found in Farías et al. (2021). From March 2019 to June 2020, Dissolved Organic Carbon (DOC) samples were specifically
81 procured from depths of 5, 20, 50 and 80 m.

82 Furthermore, to investigate the role of different sized planktonic communities in CH₄ cycling, seawater was gathered at a depth
83 of 10 m, commonly associated with the Chl-a peak, as observed in studies such as Testa et al. (2018). These samples were
84 earmarked for experiments with size-fractionated planktonic communities. Large zooplankton (150 µm mesh sieve) were
85 excluded using the methodologies outlined by Sieburth et al. (1978), and the experiment included enrichment with organic
86 substrates like MPn and TMA. The experimental setup is outlined in Table 1 and includes two variations of negative controls:
87 1) sterile filtration using a 0.2 µm filter, a widely employed technique for microorganism removal (Hahn, 2004), and 2) HgCl₂
88 addition, ensuring complete biological inactivation. The positive control was considered to be the natural community (NC),
89 with the entire community present naturally. To maintain the integrity of the samples, the seawater was transported in light-
90 restricted black drums under controlled temperature conditions to the Marine Station Biology laboratory at Dichato (Fig. 1),
91 minimizing the potential for biological activity. This is a time series study, from 2018 until 2021, encompassing CH₄ cycling
92 experiments in different productivity phases.

93

94 **Table 1. Summary of the experimental setup of short-term (GC vials) and long-term (microcosms) experiments with different**
95 **treatments: NC: seawater with the natural plankton (control); <3 µm: picoplankton; <0.2 µm: femtoplankton (control +); <0.2 µm**
96 **+ HgCl₂: femtoplankton with HgCl₂ (control +) and CC: picoplankton concentrate; and the addition of methylated substrates (MPN:**
97 **methyl phosphonic acid and TMA: trimethylamines). Different phases of the productivity period are: PI: Phase I; PII: Phase II;**
98 **and PIII: Phase III.**

Date	Type of experiment	Setup	Plankton size (μm)	Place	Time (h)	Productivity period
December 2018	GC vials	Plankton fractionation	CN, <3 and <0.2	Incubator	24	High (PI)
January 2019	GC vials	Plankton fractionation	CN, <3 and <0.2	Incubator	24	High (PI)
March 2019	GC vials	Add: MPn	<3	Incubator	24	Intermediate (PII)
May 2019	GC vials	Add: MPn and TMA	<3	Incubator	24	Basal (PIII)
April 2019	Microcosms	Add: MPn and TMA	CN, <3, and CC	Cold room	60	Intermediate (PII)
September 2019	Microcosms	Add: MPn and TMA	CN, <3, and CC	Cold room	60	High (PI)

Figure 1. Assembly of the microcosm for long-term experiments (10 L). Capillary 1 is connected directly to the spectrometer. Capillary 2 is connected to a TEDLAR bag filled with N₂ (3L). Capillary 3 is removable and connected to the outlet of the spectrometer. Capillary 4 is connected to a loose hose for water sampling and hose 5 is connected to zero air.

104

105 **2.2 Short-term experiments of CH₄ cycling by size-fractionated planktonic communities enriched with organic**
106 **substrates.**

107 The fractionation of planktonic communities based on size was conducted through a careful sequential filtration process, where
108 5 L of seawater was gently passed through a pre-filter of 150 µm nylon, followed by 3 µm Isopore, and 0.22 µm Millipore
109 membranes, yielding two fractions: picoplankton (<3 µm), and femtoplankton (<0.2 µm) communities. NC was obtained
110 directly without filtering, as is detailed in Table 1.

111 Prior to incubation, initial seawater sampling was taken for each treatment group, wherein triplicate measurements were taken
112 of oxygen (125 mL), COD (60 mL), Chl-a (100 mL), and nutrients (15 mL). Subsequently, each size-fractionated sample was
113 homogenized and swiftly transferred into 20 mL vials (108 in total, twenty-seven per treatment). These vials were immediately
114 sealed using rubber and aluminium caps to prevent any potential atmospheric gas contamination. The incubation of these
115 sample vials took place within an FOC 225E incubator, maintained at a temperature of 13 °C, and under a 12-hour photoperiod
116 (24 hours). The illumination was calibrated to fall in a range of 11-11.5 µmol m⁻² s⁻¹ using blue and neutral density blank
117 filters. At intervals of four hours, three vials from each treatment (Table 1) were withdrawn, and immediately poisoned with
118 50 µL of HgCl₂ and then, the vials were gently agitated to ensure homogenization. Gas chromatography was employed to
119 analyze the CH₄ content of the vials.

120 In another set of experiments (Table 1), the picoplankton fraction was singled out to ascertain its capacity for metabolizing
121 methylated substrates and subsequently cycling CH₄. This involved adding MPn and TMA to the samples. The final
122 concentration of both substrates in these treatments was maintained at 1 µM, assuming that natural concentrations in the
123 seawater were at trace levels. Thus, these could be considered as potential experiments (highly enriched). The experimental
124 conditions remained consistent with those employed in the earlier experiment.

125 **2.3 Long-term experiments of CH₄ cycling by size-fractionated planktonic communities enriched with organic**
126 **substrates.**

127 Nine microcosms were developed using a system of gas-tight polycarbonate bottles (13 L). Each microcosm contained 10L of
128 seawater for treatment and 3L of headspace. They were equipped with a closed gas circuit and connected to a gas spectrometer
129 analyzer capable of simultaneously and continuously measuring various gases, including CO₂, CH₄, N₂O, and humidity
130 percentage. Each bottle featured a rubber cap equipped with four holes (as depicted in Fig. 1), housing a 5mm glass capillary
131 within each hole. These capillaries were connected to gas-tight Teflon hoses. Specifically, the first capillary extended to the
132 middle of the headspace (1) and was linked to an accessory (16-Port Distribution Manifold A0311) of the Picarro G-2308
133 spectrometer for Cavity Ring Spectroscopy System (CRDS), designed for the measurement of gases in equilibrium with the
134 aqueous phase. The second capillary was suspended within the headspace (2) and connected to a Tedlar bag (3 L) filled with
135 N₂. This arrangement aimed to prevent imbalance when drawing water samples from the microcosm. The third capillary, also

136 suspended in the headspace (3), was equipped with a 3-way cannula, and was connected to the air outlet of the Picarro G-2308
137 spectrometer, to facilitate the recirculation of air within the headspace. This system optimization aimed to mitigate excessive
138 headspace during spectrometer air sampling, preventing a gas-seawater phase imbalance. This hose (3) was adjustable and
139 replaced upon measuring gas concentrations in each microcosm. The fourth glass capillary was submerged in the seawater, 3
140 cm from the bottom (4). It was attached to a 3-way cannula, streamlining the sample extraction process.

141 In both April and September of 2019, a series of long-term microcosm experiments were conducted. These months were
142 strategically chosen: the first coinciding with the transition of phytoplankton composition to nano-picoplankton (the basal
143 productivity period), and the second with diatom blooms (larger phytoplankton dominance) (high productivity period), as
144 highlighted in studies by Anabalón et al. (2007), Cuevas et al. (2004), and González et al. (2007). The experiment encompassed
145 three distinct treatments, 1) Control without any methylated substrates added to natural communities (NC), picoplankton
146 community ($< 3 \mu\text{m}$) and concentrated picoplanktonic community (CC) 2) all treatments enriched with MPn 3) and all
147 treatments enriched with TMA (see Table 1).

148 The concentrated fraction of picoplankton (CC) was procured through tangential flow filtration via a $0.2 \mu\text{m}$ filter, following
149 a procedure developed by Giovannoni et al. (1990) for harvesting greater quantities of microbial biomass and using pre-
150 filtering steps as discussed earlier to concentrate only picoplankton ($< 3 \mu\text{m}$). To discern whether the tangential flow filtering
151 was effective, the abundance of cyanobacteria, picoeukaryotes and heterotrophic bacteria was measured with flow cytometry.
152 The incubations were carried out within a controlled cold room environment, maintaining a temperature range of 12 to $13 \text{ }^\circ\text{C}$,
153 with same illumination used in short periods over 60 hours. In the initial stages, each bottle was sealed and allowed to acclimate
154 for six hours in darkness. Following this stage, 1 mL of MPn (10 mM stock solution) and TMA (10 mM stock solution) were
155 introduced to each bottle, yielding a final concentration of $1 \mu\text{M}$, matching the conditions established in prior experiments.

156 To prevent CH_4 residue contamination, a purge with Zero air was performed (as shown in Fig. 1, line 5), ensuring accurate
157 CH_4 concentration measurement within each microcosm, and establishing a baseline. Every four hours a cycle of CH_4
158 measurements was conducted continuously over 3 minutes, followed by a 6-minute hose cleaning (used for recirculation) with
159 Zero air before connecting to capillary 3 for subsequent measurement. It is important to note that the equipment absorbed 240
160 mL of air per minute of reading. Therefore, air recirculation within the microcosm, as previously mentioned, was essential.
161 Preceding the actual experiment, the concentrations of gases measured by the spectrometer were closely monitored for 30
162 minutes, confirming that the recirculation process did not impact the measured gas concentrations.

163 2.4 Analytical analysis

164 Once the CH_4 samples were taken, they were stored upside down, at room temperature and protected from light, and then
165 analyzed in the GC. CH_4 (discrete samples) was determined using the phase equilibrium method (McAuliffe, 1963). In this
166 procedure, each vial was carefully treated, with the addition of 5 mL of inert gas (helium), creating a headspace to facilitate
167 equilibrium between the aqueous and gas phases. Subsequently, the gas phase was measured in a gas chromatography
168 Shimadzu 17 equipped with a flame ionization detector (FID). A Restek RT QS-Bond column (30 m length, 0.53 mm inner

169 diameter, 20 μm film thickness) was employed, maintained at a temperature of 30 $^{\circ}\text{C}$ with a flow of 2.6 ml min^{-1} , using He as
170 an ultrapure gas carrier.

171 Five-point calibration curves (linear response of the detector) were made for each monthly sample set (treatment), using a gas
172 with a composition and concentration equivalent to that of the current atmosphere from NOAA (1863.4 ± 0.3 ppbv for CH_4)
173 (Bullister et al., 2016) as the primary standard, as well as three standard gas mixtures (Air Liquide, USA) and zero air (synthetic
174 air without CH_4 tracers). In each CH_4 sample set (every treatment), standards were added at the beginning, middle and end of
175 the measurements to corroborate the correct functioning of the detector. CH_4 measurements (triplicate) with a variation
176 coefficient greater than 10% were not considered.

177 To assess DO content, 125 mL glass flasks were used for sample collection in triplicate. These samples were immediately
178 fixed and analyzed within 6 hours of collection through the Winkler method (Carpenter, 1965). The analysis was conducted
179 using a Dosimat 665 instrument featuring an automatic photometric endpoint detector. The detection limit for this method
180 stood at 2 $\mu\text{mol L}^{-1}$. Nutrient samples were collected in triplicate using a 60 mL syringe and filtered through a 0.45 μm cellulose
181 acetate filter. The filtered content was held in 15 mL Falcon polyethylene bottles and stored at -20°C . Analysis of these nutrient
182 samples followed standard colorimetric techniques (Grasshoff et al. 1983) and was conducted using a SealAA3 segmented
183 flow auto-analyzer. This analyzer featured four distinct channels, each equipped with specific modules tailored for individual
184 nutrients.

185 To quantify Chl-a content, triplicate samples of 100 mL seawater were filtered using a GF/F filter and immediately stored at -
186 20°C . Analysis was performed according to the method outlined by Holm-Hansen et al. (1965). A Turner Designs 10AU
187 fluorometer was employed for measurement, and a standard pigment served as a reference (Sigma-Aldrich C6144-1MG). For
188 DOC assessment, samples were collected in triplicate using polyethylene bottles. Each 60 mL seawater sample was filtered
189 through a GF/F filter that had been pre-treated by heating at 450 $^{\circ}\text{C}$ for 4 hours. After filtration, the samples were acidified to
190 achieve a pH range of 2-3 and stored at -20°C . These samples were analyzed via the infrared combustion method using a
191 Shimadzu Organic Carbon Analyzer (TOC-LCPH).

192 For picoplankton abundance, 3mL of water was fixed with a glutaraldehyde solution (1%) and promptly frozen (-80°C) in
193 liquid nitrogen for storage. Samples were analyzed with flow cytometry using an INFLUX, Cytopeia, equipped with five lasers
194 (355-457-488-532-638 nm). Sort gates were optimized based on the autofluorescence of each group. *Synechococcus sp.* were
195 identified based on their orange fluorescence (530/40 nm) using 488 nm blue and 532 nm green lasers, picoeukaryotes were
196 identified by their red fluorescence (692/40 nm) using 488 nm blue laser, and bacterioplankton were detected using a
197 combination of side scatter light (SSC) (related to cell size) versus green fluorescence (530/40 nm).

198 2.5 Data analysis

199 Dissolved CH_4 concentration was calculated using the solubility coefficient from Wiesenburg & Guinasso (1979). The
200 water column was divided into two layers according to density gradients: (1) surface layer (0 - 20 m) well mixed and (2)

201 subsurface layer (20 – 90m) from the base of the mixed layer to the bottom, around ~ 90 m (Farías et al., 2015), this was to
202 interpret the vertical and temporal variability of CH₄ variation.

203 Inventories of CH₄, Chl-a, nutrients, and nutrient ratios at the surface and subsurface layers were calculated through the
204 trapezoidal integration of concentrations of each variable at each layer, using a minimum of three depths per layer. The averages
205 were taken for DOC, because there were only two measurements taken per layer. The net CH₄ recycling rate (CH₄ accumulation
206 minus CH₄ consumption) in different fractions of the phytoplankton community was calculated through a linear regression of
207 CH₄ concentrations (Farías et al., 2009) during the incubation time (24 hours), separating the light cycles (12 hours of light
208 and 12 hours of darkness).

209 CH₄ saturation was calculated following Eq. (1):

$$210 \text{ Sat}(\%) = \frac{[CH_4]_{in\ situ}}{[CH_4]_{eq}} \quad (1)$$

211 Where [CH₄]_{eq} was calculated using the solubility coefficient from Wiesenburg & Guinasso (1979).

212 Monthly anomalies of CH₄, were estimated only in the surface layer, using the following Eq. (2)

$$213 \text{ Anomaly} = \frac{xCH_4 - \bar{x}CH_4}{\sigma_{CH_4}} \quad (2)$$

214 Where: xCH₄ is the discrete value at a certain depth (surface) and time (month), and $\bar{x}CH_4$ is the median value for the whole
215 (2018-2021) period at surface and σ_{CH_4} is the standard deviation of this dataset.

216 CH₄ hot moments were defined as a ΔCH_4 three times higher than the average monthly disequilibrium anomaly ($\bar{x} \Delta CH_4$) at
217 each depth within the surface layer as Eq. (3).

$$218 \frac{\Delta CH_4}{\bar{x} \Delta CH_4} > 3 \quad (3)$$

219 Where: ΔCH_4 is the disequilibrium of the gas at each depth and was estimated as Eq. (4):

$$220 \Delta CH_4 = [CH_4]_{in\ situ} - [CH_4]_{eq} \quad (4)$$

221 The daily CH₄ flux ($F = \mu\text{mol m}^{-2} \text{d}^{-1}$) across the air-sea interface was determined using the equation from Broecker and
222 Peng (1974), modified by Wanninkhof (1992) as follows Eq. (5):

$$223 F = K_w * (C_w - C^*) \quad (5)$$

224 Where: K_w (cm h^{-1}) is the transfer velocity from the surface water to the atmosphere, as a function of wind speed, temperature,
225 and salinity from the mixed layer depth (MLD), where wind speed were obtained from a meteorological station located at
226 Carriel Sur (<http://www.meteochile.gob.cl/>) and MLD was calculated using a potential density-based criterion of Kara et al.
227 (2003). C_w (nmol L^{-1}) is the mean CH₄ concentration in the mixed layer and C^* is the gas concentration in the mixed layer
228 expected to be in equilibrium with the atmosphere according to Wiesenburg & Guinasso (1979). Historical atmospheric
229 values were obtained from registers of gas hemispheric and global monthly means from the NOAA/ESRL program at NOAA
230 (<http://www.esrl.noaa.gov>). More details about the calculation of CH₄ fluxes are described in Farías et al. (2021).

231 2.6 Statistical analysis

232 To determine significant differences between the upwelling and non-upwelling periods in both surface and subsurface layers,
233 the non-parametric Mann-Whitney U test was used. To analyze the degree of relationship between oceanographic variables
234 and the variability of CH₄ in the surface layer, Spearman correlations were used. In addition, the Kruskal-Wallis non-
235 parametric statistical test was used to define significant differences between the concentrations produced by the different
236 treatments. The statistically significant value was considered to be $p < 0.05$.

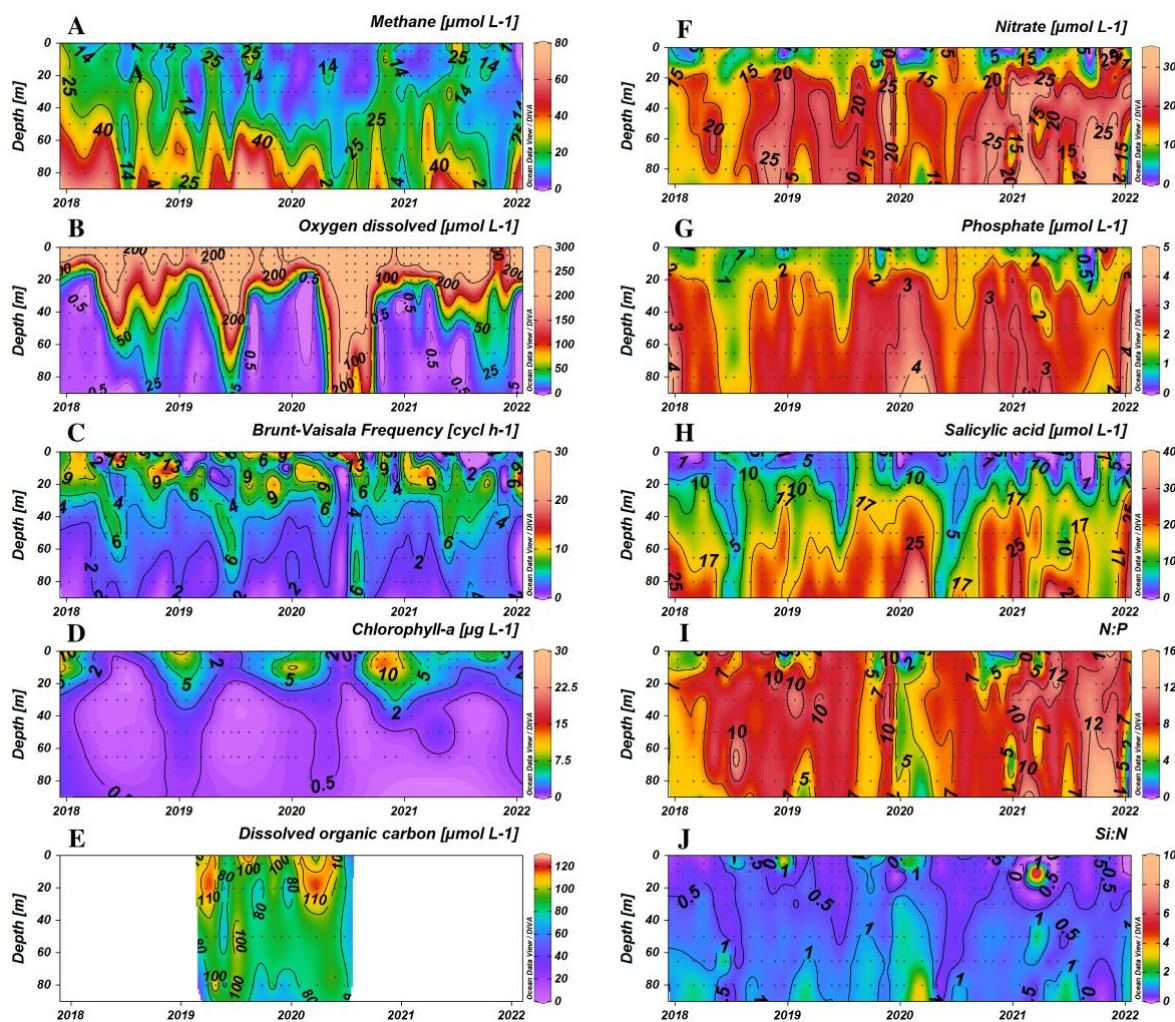

237 3 Results and discussion

238 3.1 Oceanographic features of wind-driven coastal upwelling in central Chile

239 The continental shelf off central Chile experiences wind-driven coastal upwelling, seasonally controlled by the migration of
240 the South Pacific anticyclone (Strub et al., 1998). This process leads to alongshore equatorward winds during the summer-
241 spring period, producing coastal upwelling (Sobarzo and Djurfeldt, 2004; Sobarzo et al., 2007). The area is
242 influenced by Equatorial Subsurface Water (ESSW), which is nutrient rich and has low dissolved O₂ levels (less than 44 μM).
243 The ESSW is carried southward by the Chile-Peru Counter Current (Strub et al. 1998). This subsurface water mass is a source
244 of nutrients for the surface layer during coastal upwelling, but also interacts with sediments, delivering low O₂ concentrations
245 and high organic matter content to the bottom water and sediments. This creates an environment conducive to anaerobic
246 organic matter mineralization, which supports denitrification, sulphate reduction and methanogenesis (Ferderlman et al., 1997;
247 Farías et al., 2004).

248 Thus, advection of CH₄-rich water from the subsurface and bottom layer, rather than in situ aerobic methanogenesis, has been
249 described as the primary CH₄ source in the coastal upwelling regions. This mechanism has been observed in various eastern
250 boundary upwelling systems, including California (Macías-Zamora, 2013; Sansone et al., 2001), Humboldt (Farías et al.,
251 2021; Kelley and Jeffrey, 2002), Canary (Brown et al., 2014; Kock et al., 2008), and Benguela (Emeis et al., 2018;
252 Monteiro et al., 2006; Morgan et al., 2019).

253 Our study reveals elevated CH₄ concentrations in the subsurface/bottom layer ranging from 0.43 to 78.72 nM (mean ± SD =
254 23.44 ± 15.38 nM, Fig. 2A), similar to the values found in long-term climatology (Farías et al., 2021). These elevated levels
255 could be associated with the seasonal dynamics of organic matter mineralization under hypoxic to suboxic conditions during
256 the favorable upwelling period (spring-summer); however, a similar subsurface/bottom CH₄ accumulation ($p = 1.967$) during
257 the upwelling (22.52 ± 14.34) and non-upwelling (24.60 ± 16.65) periods was found (Fig. 2A).

270

271

In the surface layer, CH_4 concentration exhibits a heterogeneous distribution, ranging from 0.140 to 41.72 nM (mean \pm SD = 11.70 ± 7.79 nM). Again, there are no differences in CH_4 levels between non- and upwelling seasons ($p = 1.654$). Indeed, within the mixed layer depth (20 m), during short periods (months), hot moments (local accumulations) of high CH_4 levels ranging from 10.17 (390 % saturation) to 41.72 (1650 % saturation) are present indistinctly throughout the sampling period (Fig. S1). Furthermore, the hot moments consistently occur under oxygenated conditions ($\text{O}_2 > 200 \mu\text{mol L}^{-1}$) (Fig. 2B) and eutrophic conditions (Fig. 2D). Sometimes they do not appear to be associated with vertical advection of CH_4 -rich bottom waters and are present during both coastal upwelling and non-upwelling periods (Fig 2A and B).

272 This raises the question if they could be associated with local microbial processes on the surface or from the well-known
273 vertical advection resulting from the upwelling process (Brown et al., 2014; Capelle and Tortell, 2016; Kock et al.,
274 2008; Farías et al., 2021). Furthermore, the fact that no distinct seasonal difference in CH₄ concentration in surface water
275 may also suggest a lateral advection from the Itata river that can discharge CH₄ (Bello, 2016), DOC (Vargas et al., 2016) and
276 chromophoric DOM (CDOM) (Rain-Franco et al., 2019), which would also stimulate CH₄ regeneration via photooxidation
277 (Li et al., 2020; Zhang and Xie, 2015).

278 Therefore, we assume that a portion of CH₄ exchanged with the atmosphere, ranged from 3.35 to 23.42 μmol m⁻² d⁻¹ (mean ±
279 SD = 10.10 ± 5.77 μmol m⁻² d⁻¹), originates from the surface layer, based on recent reports on *in situ* aerobic methanogenesis
280 linked to the growth and metabolisms of microalgae (Cerbin et al., 2022; Günthel et al., 2020; Hartmann et al.,
281 2020; Lenhart et al., 2016; Del Valle and Karl, 2014; Zhao et al., 2022; Klintzsch et al., 2019) and bacteria
282 (Repeta et al., 2016; Metcalf et al., 2012; Sun et al., 2019). This production has been suggested to be an important source of
283 CH₄ fluxes in various aquatic systems, such as stratified lakes (Bižić-Ionescu et al., 2018; Donis et al., 2017; Fazi et al., 2021;
284 Grossart et al., 2011; Günthel et al., 2019, 2020; Tang et al., 2016; Wang et al., 2018) and in open oligotrophic oceans (Damm
285 et al., 2010; Karl et al., 2008; Repeta et al., 2016; Sosa et al., 2020; Ye et al., 2020), and could be the case of our study area,
286 particularly during the stratified period (winter) due to freshwater discharge.

287 It becomes apparent that *in situ* aerobic methanogenesis could play a significant role in driving CH₄ fluxes in coastal upwelling
288 off central Chile. So far, we know that CH₄ is regenerated in the surface layer through DMS (Florez-Leiva et al., 2013), where
289 several potential CH₄ sources might be active; but further research is needed to better understand the specific mechanisms and
290 the relative contributions of different microorganisms to overall CH₄ production in this dynamic marine environment.

291 **3.2 Biological productivity and other biogeochemical indicators**

292 Considering that upwelling systems have high levels of primary production and concomitant high organic matter cycling; it is
293 pertinent to investigate the extent to which the regenerated CH₄ is produced in the surface layer. Interestingly, while Chl-a
294 levels peak (mean ± SD = 6.60 ± 5.98 μg L⁻¹) in spring and early summer, basal levels of this pigment (mean ± SD = 0.09 ±
295 7.33 μg L⁻¹) remain high throughout the year (Morales and Anabalón, 2012; Testa et al., 2018). Curiously, the
296 accumulation of surface CH₄ does not necessarily coincide with high Chl-a levels (Fig 2D).

297 Based on productivity, biomass, and a shift in the composition of phytoplankton (phytoplankton succession), along with other
298 biophysical variables, the annual cycle of biological productivity has been separated into three distinct periods (Testa et al.,
299 2018): September to January, with high productivity and Chl-a biomass dominated by microplankton such as large diatoms,
300 tintinids, and dinoflagellates; February to April with intermediate productivity, characterized by a shift in plankton composition
301 and biomass from larger to smaller organisms as flagellates; and May to August, with basal level productivity and relatively
302 low Chl-a biomass. The latter (autumn-winter) is impacted by nutrient input from continental runoff and rivers with a

303 prevalence of picoplankton (e.g., *Synechococcus*) including small flagellates and ciliates. Therefore, factors such as
 304 mixing/stratification (Fig. 2C) and a difference in nutrient contents and Si:N ratio (Fig. 2J) among phases (Table 2), due to
 305 differential nutrient consumption or input from other sources, promote a shift in phytoplankton composition, from large
 306 microorganisms during upwelling periods, to pico- and nanoplankton, such as small cyanobacteria (*Synechococcus*) and small
 307 ciliates, during non-upwelling periods (Anabalón et al., 2007; Collado-Fabbri et al., 2011; (Jacob et al., 2018),(Jacob et al.,
 308 2018). This cycle provides insight into the dynamics of primary productivity and CH₄ regeneration.
 309

314

315 Table 2 presents Chl-a levels along with inventories of CH₄, Chl-a, DOC, NO₃⁻, PO₄⁻³, S(OH)₄ and mean inorganic nutrient
316 ratios (N:P and Si:N) in each period. In contrast to CH₄, Chl-a exhibits a marked and expected seasonal cycle, with integrated
317 levels decreasing from spring to winter (Table 2). Hence, there could be a wide range in the composition of the phytoplankton
318 species involved in CH₄ cycling (Klitzsch et al., 2019; Günthel et al., 2020; Klitzsch et al., 2023). Recently, Klitzsch et al.
319 (2023) identified the carbon isotope fingerprint of CH₄ released from six widespread marine phytoplankton species, three
320 haptophyte algae and three cyanobacteria, incubated under laboratory conditions. They were clearly distinguished from CH₄
321 produced by methanogenic archaea, suggesting that algal and cyanobacterial populations may contribute substantially to CH₄
322 formation observed in the surface mixed layer of oceans and lakes.

323 Nutrient concentrations in the surface layer are subject to strong seasonal variability (Fig 2F, G and H) due to the advection of
324 nutrient-rich upwelled water, as well as biological assimilation in surface waters. Therefore, NO₃⁻ levels among upwelling and
325 non-upwelling period are significantly different (p<0,05), and a similar trend is observed for PO₄⁻³ and Si(OH)₄. Remarkably,
326 the inorganic N:P ratio, ranging from 0.15 to 15.01, are generally less than expected (Redfield stoichiometry). This is due to
327 the influence of Oxygen Minimum Zone (OMZ) (associated with ESSW), which is laterally and vertically advected to the
328 surface, indicating denitrified waters (Fernandez et al., 2015) and local denitrification (Silva et al, 2009; Farías et al., 2004).

329 Nutrients inventories show significant differences among the different productivity periods, with elevated levels in the
330 subsurface layer (Table 2). However, at the surface, Si(OH)₄ and the Si:N ratio only slightly increase from basal to high
331 productivity periods (Table 2), while the N:P ratio is higher in the basal productivity period. Moreover, during basal
332 productivity period, the increase of Si(OH)₄ is likely due to the freshwater discharge during the winter. This indicates that at
333 the beginning of upwelling (high productivity), when the water column begins to stratify (Fig. 2C) and there is a higher
334 predominance of Si (Si:N ratio) coming from the advection of cold and nutrient -rich water, the growth of large diatoms is
335 promoted (Morales and Anabalón, 2012; Anabalón et al., 2007), which, to a certain extent, results in the depletion
336 of this nutrient (Table 2). Whereas during the non-upwelling period, when the water column begins to mix (Fig. 2C) and the
337 nutrient regeneration rate change, the N:P ratio increases in basal productivity period, which leads to a predominance of
338 nitrogen-fixing organisms (cyanobacteria) and small ciliates (Anabalón et al., 2007; Collado-Fabbri et al., 2011).

339 High DOC concentrations, typical of highly productive coastal zones (Igarza et al., 2019; Vargas et al., 2013) are found in the
340 study area, ranging from 58.79 to 128.63µM (mean ± SD = 90.37 ± 17.05) and peaking at the surface during late summer and
341 early fall, with low values in subsurface layers (Fig 2E). At the surface, mean DOC inventory decreases between Phase I and
342 Phase III (Table 2), which suggests an increase in picoplanktonic abundance and activity in Phase III (Collado-Fabbri et al.,
343 2011) that allows a high DOC accumulation (Fig 2E) (Herndl and Malacic, 1987). In this period, significant DOC
344 accumulation could be ascribed to a DOC generation greater than its respective heterotrophic bacterial consumption (Hansell
345 and Orellana, 2021), or it may consist of refractory DOC that is difficult to degrade (Bauer and Druffel, 1998).

346 On the other hand, several hot moments (Fig. S1) are identified in different phases of productivity and phytoplankton
347 succession (Collado-Fabbri et al., 2011; Aldunate et al., 2018; Anabalón et al., 2007), even at different nutrients ratios and

348 DOC concentrations (Table 2), indicating that the factors favoring their occurrence are not entirely clear. Furthermore, we
349 found no significant correlation among biochemical variables at the surface (Fig. S2), suggesting that the interactions between
350 these variables are complex and not easily explained by simple linear relationships.

351 This complexity poses a challenge to understanding the dynamics of CH₄ in the studied system. To gain a deeper understanding
352 of CH₄ dynamics, short-term and long-term CH₄ cycling experiments have been conducted, focusing on size-fractionated
353 planktonic communities along with organic substrates. This approach makes it possible to explore and uncover the specific
354 interactions and substrates that may favor CH₄ production. By focusing on the size fractions of planktonic communities, the
355 contributions of diverse groups to CH₄ regeneration, such as phototrophic (primary producers like microalgae) and
356 heterotrophic assemblage's communities, could be assessed.

357 **3.3 Short-term CH₄ cycling by size-fractionated planktonic communities.**

358 The time course of CH₄ accumulation/depletion in fractionated plankton experiments with daily incubations (12 hours of light
359 and 12 hours of darkness) is shown in Fig. 3. The first experiments were conducted in December 2018 (Fig. 3A) and January
360 2019 (Fig. 3B), corresponding to a period of high productivity or phase I (Table S1), and coinciding with strong vertical
361 advection. Surface water exhibits cooling (~12 - 13 °C) and elevated CH₄ levels (9.44 – 17.09 nM), indicative of an active
362 upwelling period (Farias et al., 2021), aligning with other indicators of coastal upwelling (Aguirre et al., 2021).

363

364

 367 **represented in white (light) and gray (dark). Error bars represent standard deviation of triplicate samples, when error bars are not**
 368 **visible, they are within the area of the symbol.**

369

370 In the treatments involving fractions $<0.2 \mu\text{m}$ and $<0.2 \mu\text{m} + \text{HgCl}_2$, which serve as negative controls, CH_4 concentration kept
371 almost constant during incubation, with concentrations below 2.32 nM (Fig. 3A) and 5.51 nM (Fig. 3B). This proves that CH_4
372 production is entirely biological (Table S2). Although abiotic CH_4 production via photooxidation of CDOM has been
373 demonstrated under oxygenated conditions (Li et al., 2020; Zhang and Xie, 2015), our experiments indicated that
374 abiotic processes, such as DOM photochemical reactions (Mopper et al., 2015), did not take place. However, this process may
375 contribute to the DOM pool to be photo oxidized, producing CH_4 at shallower depths ($<10 \text{ m}$) (Li et al., 2020; Zhang &
376 Xie, 2015).

377 In December, CH_4 concentrations in the NC (positive control) and $<3 \mu\text{m}$ fractions experienced slight increases under light
378 conditions (Fig. 3A, Table S2). However, during darkness, the net CH_4 accumulation was significantly higher in the $<3 \mu\text{m}$
379 fraction ($p=0.03$; Table S2). Picoplankton includes autotrophic and heterotrophic unicellular organisms in the size range of 0.2
380 to $2 \mu\text{m}$. The autotrophic organisms include cyanobacteria (*Prochlorococcus* and *Synechococcus*) and diverse picoeukaryotes
381 larger than $1 \mu\text{m}$ (Worden, 2006), while the heterotrophic are primarily prokaryotes, with bacteria overwhelmingly dominating
382 over archaea in the upper layers (Smith et al., 2013). This fraction ($<3 \mu\text{m}$) hosts several coexisting metabolic groups,
383 dependent on or subsidized by different energy sources such as sunlight, DOM, or even a combination of the two
384 (mixotrophy). All together they are critical for the functioning of the microbial food web mainly responsible for DOC cycling
385 (Muñoz-Marín et al., 2020; Raven, 1998; Azam et al., 1983; Reintjes et al., 2020) and its derivative compounds (including
386 CH_4).

387 In January, the incubations displayed a distinctly different behavior, with CH_4 levels decreasing over incubation time in both
388 the NC and $<3 \mu\text{m}$ fractions for both photoperiods (Fig. 3B), although the rate of consumption was lower in the dark (Table
389 S2). These differences suggest that the structure/composition of the microbial community during the high productivity period,
390 as well as the quantity and quality of DOC and nutrient concentrations and their ratios (Allen et al., 2012; Sarmiento et al.,
391 2013; Spilling et al., 2019; Sarmiento et al., 2013), may control CH_4 recycling. Indeed, the environmental conditions during
392 sampling differed (Table S1); although both months were oxygenated, both varied in Chl-a and nutrient levels, including CH_4 .
393 In 2018, December marked the beginning of the upwelling, with the oxycline moving upward at 20 m (Fig. 2B), while in
394 January, the upwelling (vertical advection) was at its strongest (Fig. 2C; Table S1).

395 When the NC and even the $<150 \mu\text{m}$ fraction treatments (data not shown) are compared with the $<3 \mu\text{m}$ fraction, significant
396 differences in CH_4 recycling rates are found ($p < 0.05$), especially in darkness (Table S2). The highest recycling rates occur in
397 the $<3 \mu\text{m}$ fraction, indicating that larger microorganisms do not affect the net CH_4 accumulation/consumption (Table S2),
398 and emphasizing the importance of the microbial loop (Azam et al., 1983) in CH_4 recycling. Additionally, the observed
399 differences between photoperiods in both fractions could suggest coupling mechanisms between autotrophic phytoplankton
400 and heterotrophic bacterioplankton communities (León-Palmero et al., 2020; Morán et al., 2002; Repeta et al., 2016). Here,
401 DOC accumulated in light conditions could be rapidly utilized by bacterioplankton in dark conditions (Hartmann et al., 2020;
402 Thornton, 2014), leading to high CH_4 concentrations.

403 CH₄ consumption by methanotrophs should be considered (Mao et al., 2022), since aerobic CH₄ oxidation can reduce the CH₄
404 accumulation rate (net production vs. consumption) by as much as half (Florez-Leiva et al., 2013). It is known that
405 methanotrophs are inhibited in light conditions (Dumestre et al. 1999; Morana et al., 2020), thus CH₄ accumulation should be
406 higher in this condition. However, this contrasts with our results (light/dark conditions), meaning that both methanotrophy and
407 methylotrophy are very dynamic and complex, making it difficult to decipher in a daily cycle.

408 **3.4 Short-term CH₄ cycling experiment from picoplankton amended with organic substrates.**

409 The picoplankton showed the highest rate of CH₄ accumulation, prompting its selection to be assessed for its potential for
410 methylotrophic methanogenesis through the addition of methylated substrates (MPn and TMA) in a daily cycle. Both MPn
411 and TMA are dissolved methylated compounds known to stimulate CH₄ production because they have a methyl radical (-CH₃),
412 a potential precursor for CH₄ formation in oxygenated environments (Karl et al., 2008; Repeta et al., 2016).

413 These compounds are ubiquitous in various ecosystems (Lohrer et al., 2020; Sun et al., 2019), yet they have distinct metabolic
414 origins. While MPn originates from *Arquea Nitrosopumilus maritimus* (Metcalf et al., 2012) and is found at very low
415 concentrations (~0.01 μM, close to its analytical detection limit), likely due to rapid microbial turnover (Karl et al. 2008;
416 Martínez et al. 2013; Urata et al. 2022), TMA exhibits a wide concentration range in the ocean, from nM levels in the open
417 ocean to μM levels in sediments and near the coast (Sun et al., 2019). Environmental TMA concentrations could be higher,
418 particularly in upwelling events that bring TMA from bottom waters to the surface (Gibb et al., 1999; Sun et al., 2019). In this
419 context, the amendments performed for each substrate, 100-fold for MPn and 1000-fold for TMA, have potential for
420 experimentation.

421 It is important to note that amended experiments were conducted in Phase II (March 2019) and phase III (May 2019), periods
422 of change in phytoplankton succession (composition), biomass and abundance (Testa et al., 2018). In winter, the relative
423 abundance of picoplankton with respect to microplankton (particularly the presence of *Synechococcus* and nitrifying archaea)
424 increases significantly, especially photosynthetic picoeukaryotes (Collado-Fabbri et al., 2011).

425 The time course CH₄ accumulation during incubations is illustrated in Fig. 4. The highest CH₄ accumulation was observed in
426 the MPn-amended treatment, particularly under dark conditions in May (Phase III) (Fig. 4B; Table S1). Interestingly, in both
427 periods, the <3 μm + MPn treatment exhibited contrasting patterns under dark conditions (Fig. 4A and 4B), decreasing in
428 Phase II and increasing in Phase III, suggesting the importance of microbial composition. During winter, a higher DOC
429 concentration was observed (Fig 2E), which may lead to higher bacterial and archaeal activity that could be metabolizing
430 DOC, including MPn under dark conditions.

431

432
433
434
435
436
437

Figure 4. Time courses of dissolved methane concentration (nM) during incubations with the addition of methylated substrates (MPn: methyl phosphonic acid and TMA: trimethylamine) performed with bacterioplankton (<3 μm) and bacterioplankton concentrate (CC). A. March 2019 and B. May 2019. Photoperiod is represented in white (light) and gray (dark). Error bars represent standard deviation of triplicate samples, when error bars are not visible, they are within the area of the symbol.

438 Conversely, the TMA treatment did not result in any CH₄ accumulation. In fact, CH₄ accumulation in this treatment was lower
439 compared to the control and MPn treatments (Fig. 4B), contrary to expectations in a nitrogen-limited ecosystem. Indeed, in
440 the study area inorganic nutrient N:P ratios are consistently below the Redfield ratio of 16 (Redfield et al., 1963), in both
441 surface (mean ± SD: 7.354 ± 2.947) and subsurface (mean ± SD: 8.217 ± 3.443) layers. This N deficit is primarily influenced
442 by the lateral and vertical advection of denitrified water from equatorial origin (ESSW) transported poleward by the Peru-
443 Chile undercurrent (Fernandez et al., 2015; Fernandez & Farías, 2012; Silva et al., 2009), along with a local
444 dissimilative NO₃⁻ reduction during anaerobic organic matter mineralization (Farías et al., 2004) and possibly PO₄⁻³ release
445 from anoxic sediments (Holmkvist et al., 2010).
446 While TMA can be metabolized by marine bacteria (Lidbury et al., 2015; Bižić-Ionescu et al., 2018), the lower CH₄ production
447 in this treatment suggests a different outcome. In contrast, heterotrophic picoplankton might metabolize MPn and produce
448 CH₄, showing *in situ* methanogenesis via the carbon-phosphorus (C-P) lyase pathway (Karl et al., 2008). Although this
449 pathway has primarily been described for PO₄⁻³-limited environments like gyres, the possibility of its occurrence in upwelling
450 areas with PO₄⁻³ excess cannot be dismissed, although the rates might be lower (Bižić-Ionescu et al., 2018).

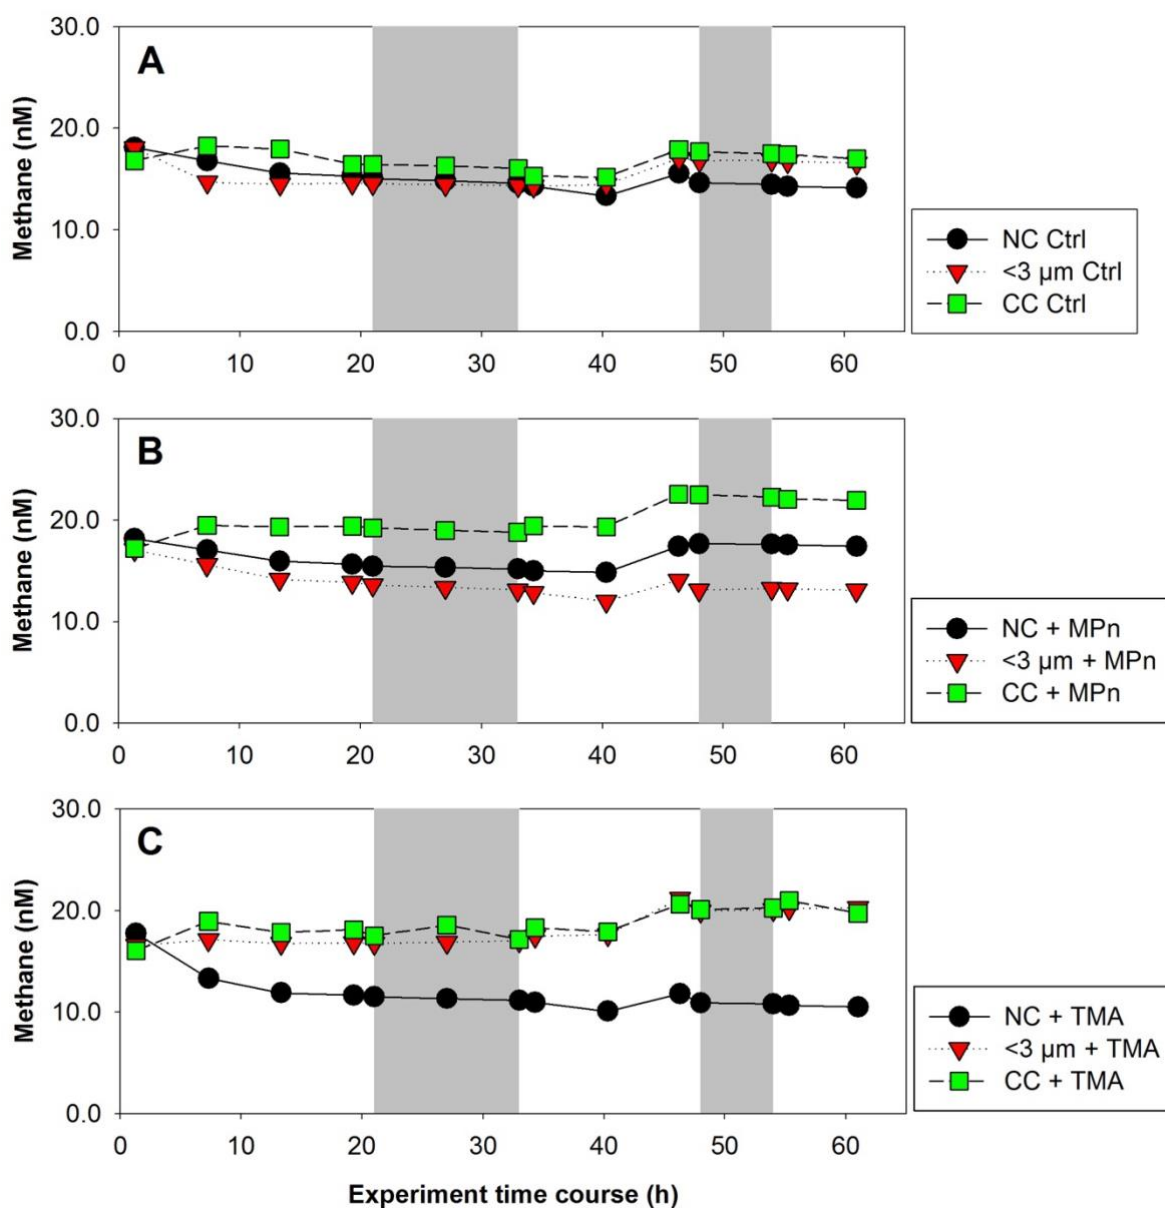

451 **3.5 Long-term CH₄ cycling from concentrated picoplankton amended with organic substrates.**

452 Aiming for comprehensive insights, our study encompassed long-term microcosm experiments strategically performed during
453 two (of three) distinct phases of productivity as was described (Testa et al., 2018). The intermediate productivity phase (Phase
454 II or late summer - autumn time) was characterized by a notable relative prevalence of autotrophic cyanobacteria
455 (*Synechococcus*). In contrast, the high productivity period (Phase I or early spring time) (Fig. S3A and D) was marked by a
456 prevalence of diatoms (Fig. S3B and E), while heterotrophic bacterioplankton exhibited almost constant presence in both
457 periods (Fig. S3C and F). These temporal distributions align with well documented patterns in our study area, where light,
458 oxygen, temperature, and nutrient levels drove the seasonal and vertical segregation of specific cyanobacteria, picoeukaryotes
459 and heterotrophic bacterioplankton, which represent the <3 μm fraction in this study (Aldunate et al., 2018; Collado-Fabbri et
460 al., 2011; De La Iglesia et al., 2020; Molina et al., 2020).

461 Briefly, Flavobacteraceae, SAR11 subclade IA (*Candidatus Pelagibacter* ubique-associated), SAR11 subclade 1b,
462 gammaproteobacterial clades, and SAR86 are prevalent during upwelling seasons, while during non-upwelling seasons or
463 phase III, SAR11 subclade II, Marine Actinobacteria, and unclassified Alphaproteobacteria dominated (Aldunate et al., 2018).
464 Additionally, photosynthetic picoplankton eukaryotes related to Mamiellophyceae (*Bathycoccus*, *Micromonas*, and
465 *Ostreococcus*) were predominantly observed with high significance in the surface layer during the transition period (Collado-
466 Fabbri et al., 2011; De La Iglesia et al., 2020), whereas heterotrophic bacteria abundance ranging from 0.23 to 6.50 x10⁶ cell
467 mL⁻¹ were mainly concentrated in the surface during late summer and autumn, with minima in winter (Molina et al., 2020).
468 However, in our study, heterotrophic bacteria abundance showed no significant differences (p = 0.05) in both periods (1 x 10⁶
469 cells/mL) (Fig. S3C and F). This is due to the low DOC at the beginning of the upwelling period (Fig. 2E).

470 Phase II CH₄ accumulation during time incubations under different treatments is shown in Fig. 5. Concentration of cell
471 abundance treatment or concentrated community (CC) resulted in substantial enrichments of cyanobacteria (*Synechococcus*),
472 picoeukaryotes and heterotrophic bacteria, by factors of 1.9, 1.8 and 4.6, respectively, compared to the NC, and factors of 1.8,
473 1.8 and 6.1 with respect to the <3 μm fraction (Fig. S4A, B and C). In both cases, a substantial increase in bacteria is noted
474 (Fig. S4A, B and C). The microbial abundance proportions in NC at the beginning of the experiment were close to natural
475 observations (Collado-Fabbri et al., 2011; Anabalón et al., 2007; Morales et al., 2007).
476

477

478 **Figure 5. Time courses of dissolved methane (nM) during incubation in long-term microcosm experiments (10L) with the addition**
479 **of methylated substrates (MPn: methyl phosphonic acid and TMA: trimethylamine) performed with three planktonic communities**
480 **(NC: natural community; <3 μm: bacterioplankton and CC: community concentrate) under oxygenated conditions in April 2019.**
481 **Photoperiod is represented in white (light) and gray (dark).**

482
483 Remarkably, Chl-a levels matched with phytoplankton communities expected in each treatment (Table S3). Mean Chl-a levels
484 in the <3 μm fraction were 21.7 and 4.5 times lower than in the NC and CC, respectively (Table S3), indicating that this
485 fraction contains phyto picoeukaryotes in a lower proportion than CC, and that NC included phyto- microeukaryotes that have
486 the highest Chl-a concentration. Additionally, the CC treatment displayed higher basal levels of DOC and nutrients, due to the
487 natural diurnal mortality of picoplankton (Llabrés et al., 2011) and to the type of filtration, tangential flow filtration, one of
488 the most used methods to concentrate DOM (Benner et al., 1992) that reduces the amount of membrane sorption and fouling
489 and is capable of filtering between 10 to 1000L (Minor et al., 2014).

490 When comparing the treatments (NC, <3 μm, and CC) without (controls) and with the addition of MPn and TMA (5),
491 significant statistical differences ($p < 0.05$) and a similar CH₄ evolution pattern were observed, with a slightly higher CH₄
492 accumulation during the second photoperiod, especially in the CC and <3 μm fractions (Fig. 5A), indicating that during the
493 first photoperiod there may be changes and/or acclimation of planktonic communities.

494 With the addition of MPn (Fig. 5B), CH₄ evolution remained constant in the <3 μm fraction, but increased slightly and strongly
495 in the CC and NC, respectively (Fig. 5B). The most significant difference in the CH₄ time course occurred when CC was
496 enriched with MPn (Table S4), suggesting that both heterotrophic bacterioplankton or cyanobacteria could be mediating CH₄
497 regeneration. Additionally, higher chlorophyll concentrations (Table S3) in NC treatment may have supported greater CH₄
498 accumulation compared to the <3 μm fraction (Fig. 5B). Regarding TMA enrichment (Fig. 5C), the CC and <3 μm fraction
499 treatments responded similarly, both increasing CH₄ accumulation ($p < 0.05$; Fig. 5C). Higher accumulation rates were observed
500 in the <3 μm fraction (Table S4), suggesting that the heterotrophic community present in this period weakly metabolizes TMA
501 (De Angelis and Lee, 1994; Bižić-Ionescu et al., 2018).

502 Although the conversion of methylated substrates, such as MPn to CH₄ by various types of bacteria has been extensively
503 documented (Repeta et al., 2016; Del Valle and Karl, 2014; Karl et al., 2008; Metcalf et al., 2012; Zhao et
504 al., 2022; Wang et al., 2018; Damm et al., 2010), this process typically occurs under phosphorus-starved conditions.
505 However, it is unlikely in our study area, which experienced high PO₄⁻³ availability and even in excess compared to N (Table
506 2). Specifically, the expression of phosphonate C-P lyase genes is restrained under P-rich culture conditions (Carini et al.,
507 2014; Taenzer, 2019; Sosa et al., 2019). Thus, an alternative explanation for the significant CH₄ accumulation in the CC with
508 MPn treatment could be related to the presence of cyanobacteria, since using stable isotope labelling techniques recently has
509 shown that CH₄ production comes from cyanobacteria such as *Synechococcus* (Klitzsch et al., 2023).

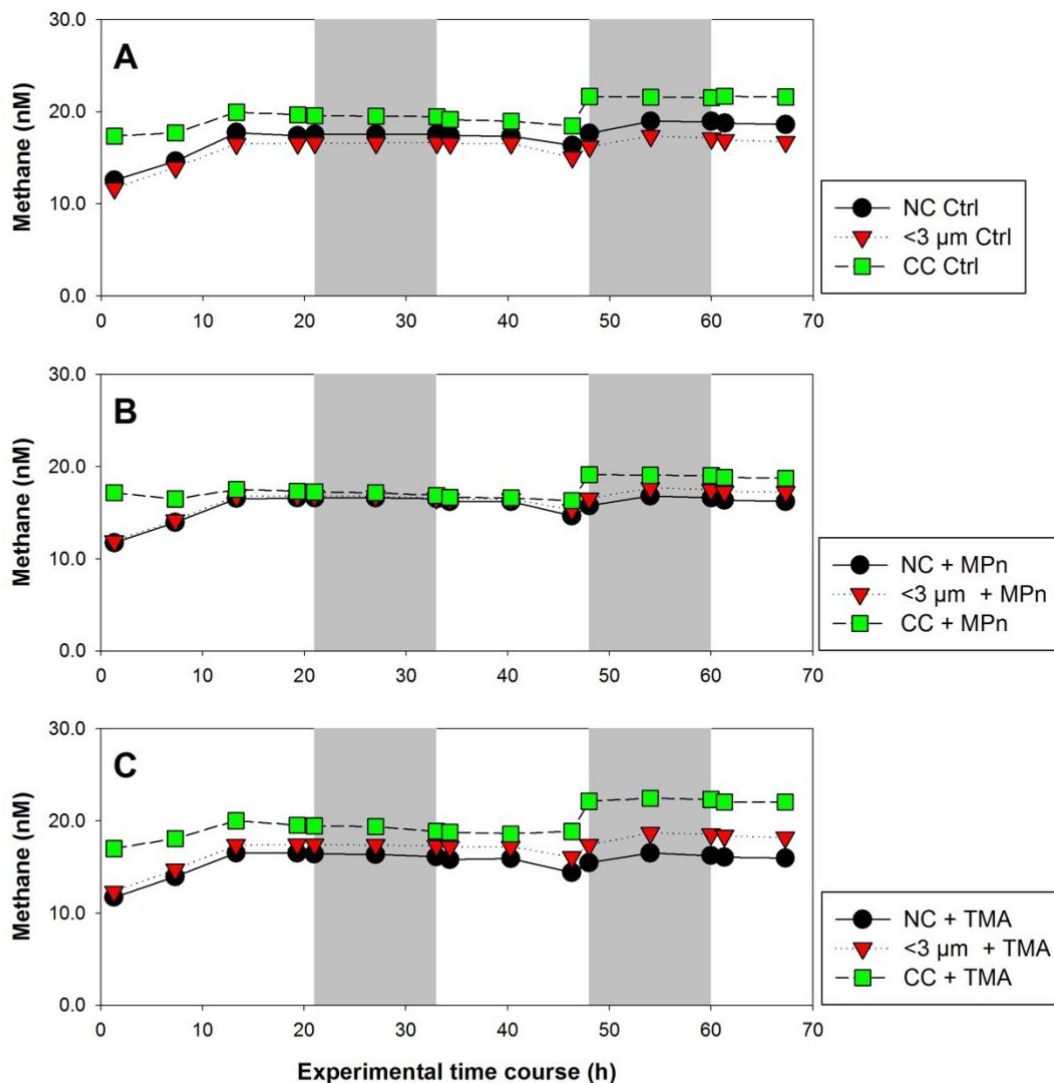

510 Given that *Synechococcus* dominated during the non-upwelling period (autumn winter season) in the photic layer (Collado-
511 Fabbri et al., 2011) it is plausible to consider CH₄ generation mediated by this microorganism in our upwelling system.

512 Consequently, CH₄ generation pathways appear multifaceted, involving complex interplays between photochemical and
513 metabolic processes. The mechanism by which cyanobacteria effectively convert fixed CO₂ to CH₄ under light conditions
514 appears intricately linked to the photosynthetic process (Bižić et al., 2020; Klintzsch et al., 2020), since inhibitors of
515 photosynthesis blocked CH₄ production under light conditions (Bižić et al., 2020). This suggested that distinct mechanisms
516 might govern CH₄ production under light and dark conditions, influenced by freshly synthesized photosynthetic products in
517 light and storage compounds in darkness.

518 During the high productivity period (Phase I), temporal CH₄ accumulation consistently demonstrated higher CH₄ levels in the
519 CC treatment compared to the NC and <3 μm fraction (controls) (Fig. 6A). However, a noteworthy contrast appears when
520 considering the impact of substrate additions. Specifically, in this phase, the introduction of TMA in the CC treatment results
521 in a more pronounced CH₄ regeneration (Fig. 6C) compared to the effect of MPn (Fig. 6B). This pattern, the opposite of that
522 found in Phase II, could potentially be explained by the observed decrease in *Synechococcus* abundance (Fig. S3D), which
523 remains unresponsive to MPn, and the concurrent increase in nano and picoeucaryotes and bacteria at the end of the experiment
524 (Fig. S3E and F), the last of which is conducive to the action of TMA (Bižić-Ionescu et al., 2018; De Angelis and
525 Lee, 1994; Lidbury et al., 2015). Indeed, a marked reduction in *Synechococcus* abundance was observed (showing a
526 4.6-fold decrease) compared to the transition period (Fig. S4A and D), whereas nano- and picoeukaryotes experienced a notable
527 abundance (3.1 to 3.7 times higher than the transition period) (Fig. S3B and E).

528

529

530 **Figure 6. Time courses of dissolved methane (nM) during incubation in long-term microcosm experiments (10L) with the addition**
531 **of methylated substrates (MPn: methyl phosphonic acid and TMA: trimethylamine) performed with three planktonic communities**
532 **(NC: natural community; <3 μm: bacterioplankton and CC: community concentrate) under oxygenated conditions in September**
533 **2019. Photoperiod is represented in white (light) and gray (dark).**

534

535 In this phase, the distribution proportions within the NC treatment were as follows: cyanobacteria, nano and picoeukaryotes,
536 and bacteria accounted for 1.1, 2.3 and 96.6, respectively. In contrast, within the CC treatment, the initial distribution

537 proportions were higher with respect to the NC: cyanobacteria, picoeukaryotes, and bacterioplankton displayed proportions
538 1.6, 0.6, and 2.9 times greater, respectively. This underscores the increased significance of bacteria and autotrophic
539 picoeukaryotes during this phase, as further corroborated by Chl-a measurements (Table S3).

540 An intricate interplay between microbial communities and CH₄ cycling within distinct phases of productivity is elucidated
541 (Fig. 7). The prevalence of cyanobacteria, picoeukaryotes, and heterotrophic bacteria varied significantly between these
542 phases. So, this indicates that substrate utilization is related to the availability of nutrients as well as the complexity of the
543 substrate and the composition of the heterotrophic bacterial community, which depends on the productivity phases, potentially
544 driving CH₄ production dynamics.

545

546

548 **conditions during light and dark phases, where potential planktonic communities and methylated substrates are involved to**
549 **metabolize methane in surface waters. A. Phase I or active upwelling season and B. Phase II and III or late upwelling or non-**
550 **upwelling season. Dashed line shows the 100 μmol L⁻¹ oxycline, above this line oxic methane is produced. TMA: trimethylamine;**
551 **and MPn: methyl phosphonic acid.**

552

553 CC treatment always exhibited elevated CH₄ levels and therefore reflects the relative dominance of cyanobacteria in Phase II
554 (autumn-winter), which are mediating CH₄ cycling via MPn. Indeed, high CH₄ levels in surface water observed in the non-
555 upwelling period, even comparable to upwelling period, could be due to *in situ* production mediated by *Synechococcus*, or
556 archaea such as *Nitrosopumilus maritimus* that are providing MPn to heterotrophic bacteria to be metabolized (cleaved) and

557 subsequently release CH₄ (Fig. 7A). On the other hand, although the trimethylamine methyltransferase enzyme has been
558 described as involved in the demethylation of TMA in methanogen microorganisms (Paul et al., 2000), it cannot be ruled
559 out that in the upwelling period, heterotrophic bacteria dominance in spring time can metabolize TMA through an alternative
560 pathway still unknown (Fig. 7B). Nor can it be ruled out that the upwelling brings methanogens with the necessary machinery
561 to metabolize TMA at the ocean surface.

562 4 Conclusions

563 Overall, picoplankton recycled CH₄ in all experiments conducted in both light and dark conditions, although the net CH₄
564 production rate was higher in dark conditions. Moreover, laboratory experiments demonstrated that organic compounds such
565 as TMA and MPn are metabolized by heterotrophic bacterioplankton, contributing to the recycling of oxic CH₄ in the
566 oxygenated surface layer. This reflects the importance of these microorganisms in the gas' cycling, which could be sustaining
567 the supersaturations and the presence of CH₄ hotspots in the surface layer.

568 Coastal upwelling could bring with it organic compounds such as TMA from sediments, which added to plankton
569 decomposition compounds (e.g. TMA), and change in picoplanktonic composition (bacteria and the remarkable increase of
570 pico- and nanoeukaryotes) during the favorable upwelling period, could promote recycling CH₄ via TMA, through a pathway
571 that is still unknown, but would potentially add to CH₄ supersaturation in the oxygenated surface layer, beyond the contribution
572 of CH₄ by advection.

573 *Synechococcus* could be responsible for CH₄ regeneration through photosynthesis. These cyanobacteria are abundant in the
574 non-upwelling period, and together with other picoeukaryotes, maintain intermediate and basal Chl-a levels during this period
575 that matched with higher DOC levels and inorganic N:P ratios (compared to the upwelling period). This may stimulate
576 heterotrophic bacteria to metabolize MPn and thus contribute to the recycling of oxic CH₄.

577 It is important to note that amended experiments were conducted in Phase II (March 2019) and phase III (May 2019), periods
578 marked by changes in the phytoplankton succession (composition), biomass and abundance (Testa et al., 2018). In winter, the
579 relative abundance of picoplankton with respect to microplankton (particularly the presence of *Synechococcus* and *nitrifying*
580 *archaea*) increases significantly, especially photosynthetic picoeukaryotes (Collado-Fabbri et al., 2011).

581 **Acknowledgements** Thanks to Gerardo Garcia for his experience and teaching in the use of laboratory equipment and his help
582 in setting up the experiments; and Karen Sanzana for nutrient analysis; Oliver Alarcon for oxygen analysis. Both the crew of
583 R/V Kay Kay (II) and the Dichato Marine Station of the University of Concepcion provided valuable help during fieldwork,
584 as well as all participating colleagues in the time series station (University of Concepcion), who provided the core
585 measurements. We also appreciate the work done during the COVID pandemic by Juan Faúndez. This research was funded
586 by the Fondo Nacional de Investigaciones Científicas y Tecnológicas (FONDECYT) grant N° 1200861 and also Millennium
587 Science Initiative Program ICM 2019-015 (SECOS) and CR2 FONDAP-CONICYT N° 1522A001.
