17

18 **Abstract.** Most phosphorus (P) in soils is unavailable for direct biological uptake as it is locked within primary or secondary
19 mineral particles, adsorbed to mineral surfaces, or immobilized inside of organic material. Deciphering the composition of
20 different P forms in soil is critical for understanding P bioavailability and its underlying dynamics. However, widely used
21 global estimates of different soil P forms are based on a dataset containing few measurements in which many regions or soil
22 types are unrepresented. This poses a major source of uncertainty in assessments that rely on these estimates to quantify soil P
23 constraints on biological activity controlling global food production and terrestrial carbon balance. To address this issue, we
24 consolidated a database of six major soil P 'forms' containing 1857 entries from globally distributed (semi-)natural soils and
25 11 related environmental variables. These six different 'forms' of P (labile inorganic P (Pi), labile organic P (Po), moderately
26 labile Pi, moderately labile Po, primary mineral P, and occluded P) were measured using a sequential P fractionation method.
27 As they do not represent precise forms of specific discrete P compounds in the soil but rather resemble operational pools, we
28 will now refer to them as P pools. In order to quantify the relative importance of 11 soil-forming variables in predicting soil P
29 pools concentrations and then make further predictions at the global scale, we trained random forest regression models for
30 each of the P pools and captured observed variation with R² higher than 60%. We identified total soil P concentration as the
31 most important predictor of all soil P pool concentrations, except for primary mineral P concentration, which is primarily
32 controlled by soil pH and only secondarily by total soil P concentration. When expressed in relative values (proportion of total
33 P), the model showed that soil pH is generally the most important predictor for proportions of all soil P pools, with also
34 prominent influences of soil organic carbon, total P concentration, soil depth and biome. These results suggest that, while
35 concentration values of P pools logically strongly depend on soil total P concentration, the relative values of the different pools
36 are modulated by other soil properties and the environmental context. Using the trained random forest models, we predicted
37 soil P pools' distributions in natural systems at a resolution of 0.5° × 0.5°. Our global maps of different P pools in soils as well
38 as the pools' underlying drivers can inform assessments of the role of natural P availability for ecosystem productivity, climate
39 change mitigation, and the functioning of the Earth system.

40 **1 Introduction**

41 Phosphorus (P) is a key nutrient limiting plant growth across a wide range of ecosystems (Augusto et al., 2017; Elser et
42 al., 2007; Hou et al., 2020). Soil is typically the major P source for plants in natural terrestrial ecosystems (Weihrauch and
43 Opp, 2018). P supplied by the soil plays a vital role in determining the structures, functions, and processes in terrestrial
44 ecosystems (Peltzer et al., 2010; Wardle et al., 2004). For example, soil P availability imposes a major constraint on plant
45 productivity in terrestrial ecosystems worldwide (Augusto et al., 2017; Ellsworth et al., 2022; Elser et al., 2007; Hou et al.,
46 2020; Hou et al., 2021) and affects modeled projections of terrestrial carbon cycle responses to climate change and increasing
47 atmospheric carbon dioxide concentrations (Cunha et al., 2022; Fleischer et al., 2019; Goll et al., 2012). The size of soil P
48 stocks is large compared to annual plant P requirements (Wang et al., 2018) and the amount of P stored in vegetation (Wang
49 et al., 2018; Zhang et al., 2021). However, only a small proportion of soil P can be directly taken up by plants (Morel et al.,
50 2014), with most P tightly sorbed to soil minerals, organic compounds, or organo-mineral complexes with a turnover time of
51 centuries to millennia or longer (Helfenstein et al., 2020; Vitousek et al., 2010). Consequently, vegetation growth is often
52 limited by P availability in ecosystems across the globe (Vitousek et al., 2010; Wardle et al., 2004). For these reasons, the
53 investigation of P dynamics and P bioavailability in the soil requires the identification and separation of different soil P pools
54 (Crews et al., 1995; Walker and Syers, 1976).

55 Our knowledge of the various pools of P existing in soils is largely based on soil chronosequence and climosequences
56 that investigated how P is cycled during pedogenesis (Crews et al., 1995; Walker and Syers, 1976). These studies revealed that
57 chemical weathering results in the release of P from primary minerals, after which it can be converted to organic P through
58 biological uptake, sorbed to soil particles, or occluded within secondary minerals. The most commonly used procedures for
59 the sequential fractionation of P in soils were developed by Hedley et al. (1982) and later modified by Tiessen and Moir (1993).
60 This method exploits differences in solubility to separate different ‘forms’ of P occurring in the soil. Though it cannot be used
61 to identify specific discrete P compounds in the soil, this approach has proven indispensable for the study of soil P cycling and,
62 as such, is widely used (Condon and Newman, 2011; Klotzbücher et al., 2019; Barrow et al., 2021). In addition to forming
63 the basis for modeling soil P dynamics, these procedures yield operationally defined pools that are used to assess soil fertility
64 and soil development (Wang et al., 2010; Wang et al., 2022). Several studies have called the validity of sequential extractions
65 into question, pointing out that, while it is often assumed that pools from sequential extractions contain distinct forms of P, the
66 reality is much more complex (Condon and Newman, 2011; Gu and Margenot, 2021; Klotzbücher et al., 2019). Nevertheless,
67 radioisotope tracer experiments show that sequentially extracted pools have distinct P exchange behaviors that result in
68 significantly different turnover times (Bünemann et al., 2004; Helfenstein et al., 2021; Helfenstein et al., 2018; Vu et al., 2010).

69 Numerous studies have used data from P fractionations to explore drivers of spatial differences in soil P pools from local
70 to global scales (e.g., Brucker and Spohn, 2019; Hou et al., 2018a; Yang and Post, 2011; Chen et al., 2015). Yang and Post
71 (2011) compiled Hedley P pools data from 178 soil samples to explore P dynamics along a soil development gradient. Their
72 results generally supported the conceptual model proposed by Walker and Syers (1976): the gradual decrease of primary
73 mineral-bound P; the continual increase and eventual dominance of occluded P; and the overall decrease of total P as
74 pedogenesis progresses. However, the conceptual model of Walker and Syers (1976) disagreed with the results of Yang and
75 Post (2011), who found that labile Pi and moderately labile Pi (non-occluded P in Walker and Syers’ model) formed a
76 significant fraction of total P at every stage of pedogenic development. Augusto et al. (2017) compiled 1684 measurements of
77 P pools that were taken worldwide using the Hedley fractionation method. This work found that total P content was a main
78 factor determining the concentrations of labile Pi and organic P pools. Almost concomitantly, Hou et al. (2018a) used a global
79 dataset compiled from analyses of 802 soil samples to examine climate effects on the soil P cycle and P availability and found
80 that soil labile Pi concentration decreased with increasing mean annual temperature, which was mainly due to decreasing soil
81 organic P and primary mineral P with increasing temperature. Although those studies advanced our understanding of factors
82 controlling the size of various soil P pools, their focus was largely contained to the effects of climatic factors or soil weathering

83 stage on a few select P pools, mainly labile Pi, and organic P. Thus, we still lack a comprehensive understanding of the
84 relationships between environmental drivers and the various soil P pools at a global scale.

85 Despite significant efforts to synthesize global Hedley soil P pool data, to our knowledge, only a single mapping of soil
86 P fractions across natural terrestrial ecosystems exists, and this work was based on the upscaling of measurements taken from
87 only 178 samples (Yang et al., 2013). These global estimates and associated maps of soil P pools have been used to explore
88 global patterns of soil P supply and to estimate P availability in natural and managed systems (*e.g.*, Ringeval et al., 2017; Sun
89 et al., 2017). They have also been used to calibrate or initialize a range of global P models (Wang et al., 2010; Yang et al.,
90 2014). However, the poor global coverage of the underlying data introduces significant uncertainty, potentially resulting in
91 misinformed model predictions and assessments.

92 We recently developed a new global map of soil total P concentrations and explored the underlying drivers, taking
93 advantage of improved data availability and the use of non-linear statistical modeling (He et al., 2021). Here, we constructed
94 a database of soil P pools in 1857 globally distributed (semi-)natural soils collected from 274 published studies, one order of
95 magnitude larger than the dataset used by Yang et al. (2013) (see comparison in Fig. S1). Using this database, we trained
96 random forest models to capture observed variations in Hedley P pool concentrations at the site level with two aims: (1) to
97 quantify the relative importance of different drivers of spatial variation in each soil P pool and (2) to develop global distribution
98 maps of various P pools at a spatial resolution of $0.5^\circ \times 0.5^\circ$ using the calibrated random forest regression model.

99 **2 Material and Methods**

100 **2.1 Soil P fractionation terminology and procedure**

101 In the present study, we use the word ‘pool’ to indicate the concentrations quantified in each step during sequential
102 fractionation and the word ‘proportion’ to represent the size of a pool relative to total P. We try to avoid using ‘fraction’ to
103 describe different P forms anymore, because it is easy to confuse with ‘proportion’. There is disagreement about how to
104 interpret the different pools yielded by sequential fractionation (Gu et al. 2019; Barrow et al., 2021; Klotzbücher et al., 2019;
105 Condron and Newman, 2011; Helfenstein et al., 2020). Here, we adopt a widely used regime for understanding these pools,
106 which correspond to different forms of soil P: The resin Pi pool represents the soil soluble Pi pool, which is immediately
107 accessibly to plants. The HCO_3^- Pi pool can be released by ligand exchange with bicarbonate ions; This pool is available to
108 plants and persists for only short periods (*e.g.*, a growing season). Due to their functional similarity, the resin and HCO_3^- Pi
109 pools can be combined and used as an index of labile inorganic P (*i.e.*, ‘available’ P). The HCO_3^- Po pool represents labile Po
110 that can be utilized by plants after mineralization. The OH^- P (Pi and Po) pools mainly indicate moderately labile P that is
111 bound to both amorphous and crystalline Al and Fe; These pools represent P that is moderately available to plants. The 1 M
112 HCl Pi pool represents primary mineral P that is bound to calcium and that can be utilized by plants after it is released by
113 weathering. And other P pools, such as residual P, are least available to plants due to their particularly low solubility.

114 To integrate data from studies that use different interpretations, we consider a set of six simplified P pools (Fig. 1): labile
115 Pi, labile Po, moderately labile Pi, moderately labile Po, primary mineral P, and occluded P. Labile Pi includes the resin Pi and
116 HCO_3^- Pi pools; labile Po and moderately labile Po are organic pools extracted by carbonate and NaOH, respectively;
117 moderately labile Pi is the NaOH Pi fraction; primary mineral P represents the 1 M HCl Pi pool; and occluded P includes any
118 remaining P (Hou et al., 2018b).

119 We collected, filtered, and processed soil P pool data (see section 2.2.) from the literature (Supplementary Text 1 Data
120 source references). First, we added all measured P pools together to calculate total soil P, unless at least one pool had a missing
121 value. In this case, we instead used the measured value of total soil P presented in that paper. Second, if phosphate was extracted
122 using deionized water before the resin P extraction step, the labile Pi pool includes both resin and aqueous P. If the extraction
123 procedure began by using sodium bicarbonate solution instead of resin P, we classified HCO_3^- Pi as labile Pi. Third, the labile

124 Po pool and the moderately labile Po pool represent the HCO_3^- -extracted Po and NaOH-extracted pools, respectively. The raw
125 data contained other organic P pools (e.g., Po extracted by sonication and NaOH or by hot, concentrated HCl) which we
126 included as part of occluded P. Fourth, if occluded P was not reported, we calculated this pool's concentration by subtracting
127 the sum of the five other pools from total P.

128 **2.2 Data source and processing**

129 We collected soil P pool data by aggregating all the publications that cited either one of two main references dedicated
130 to Hedley's method (Hedley et al., 1982; Tiessen and Moir, 1993). We included all studies that reported data from (semi-)
131 natural soils that supported primary vegetation or that had been reforested with a stand older than 10 years and no documented
132 history of P fertilization. We excluded observations taken from pot experiments, mine zones, and intertidal zones, as P pools
133 in these soils could be affected by factors different from those influencing (semi-) natural soils. Despite our best efforts, we
134 cannot rule out that our database includes data collected from soils affected by undocumented anthropogenic activities in the
135 past (e.g., P fertilization occurring before reforestation), particularly in western Europe and eastern USA (e.g., De Schrijver et
136 al., 2012). All data were collected at the plot scale. For data that included replicates within a plot or soil layer, average values
137 were calculated.

138 To compile our database, we first combined the two existing global databases (Augusto et al., 2017; Hou et al., 2018b).
139 Detailed information about the methods used to construct these datasets can be found in the original publications. We extracted
140 observations from these two databases by selecting only unfertilized, uncultivated, and (semi-) natural soils. This yielded 1684
141 observations from 182 studies from the dataset developed by Augusto et al. (2017) and 802 observations from 99 studies from
142 the dataset developed by Hou et al. (2018). Next, we removed 375 duplicates, after which our dataset contained 2111
143 observations from 245 studies (Figure S2). Because we use total soil P concentration as a predictor of soil P pools, we removed
144 data that did not include total soil P (calculated as the sum of P pools or measured by a separate method) or that did not identify
145 the concentration of at least one pool (e.g., labile Pi, labile Po, moderately labile Pi, moderately labile Po, primary mineral P,
146 or occluded P). In this step, 816 observations were removed, resulting in a dataset that included 1295 observations from 178
147 studies.

148 Next, we added additional observations by compiling data from literature published after 2016, the final year included
149 in the database compiled by Hou et al. (2018b). We used Google Scholar to search for studies published between 2016 and
150 08/08/2021 that referenced either Hedley et al. (1982) or Tiessen & Moir (1993). This search returned 701 publications citing
151 Hedley et al. (1982) and 245 citing Tiessen & Moir (1993). From this set, we selected studies that presented soil P data collected
152 using the fractionation method for (semi-)natural soils. The resulting 562 observations from 96 studies were added to our final
153 dataset, which includes a total of 1857 observations collected from 729 sites from 274 studies (Supplementary Text 1).

154 In addition to soil P pool concentration and site coordinates, our dataset contains site characteristics including climate
155 variables (i.e., mean annual temperature (MAT), mean annual precipitation (MAP), and potential biome), soil physicochemical
156 properties (e.g., soil organic carbon concentration (SOC), soil clay and sand content, and soil pH), and elevation (Table 1).
157 Potential biome was identified using a global map of potential natural biomes (i.e., the global distribution of biomes that would
158 exist in the absence of human activity) (Hengl et al., 2018). This categorization includes seven ecosystem types, including
159 tropical forest, temperate forest, boreal forest, grassland, savanna, desert, and tundra. We did not include parent material type
160 because it can be inferred from soil total P concentration and other soil properties (e.g., soil texture and pH) (Augusto et al.,
161 2017; He et al., 2021). Because soil age was rarely reported, we used USDA soil order identity as a proxy for 3 age classes:
162 slightly, intermediately, and strongly weathered (Smeck, 1985; Yang et al., 2013). Among the 12 USDA soil orders, Entisols,
163 Inceptisols, Histosols, Andisols, and Gelisols are classified as slightly weathered soils. Alfisols, Mollisols, Aridisols, and
164 Vertisols are classified as intermediately weathered soils. Oxisols, Ultisols, and Spodosols are classified as strongly weathered
165 soils (Yang et al., 2013; Smeck, 1985). Given that atmospheric P inputs are small ($0.3 \text{ kg P ha yr}^{-1}$, on average) compared to

166 soil P stocks (Mahowald et al., 2008; Wang et al., 2015) and are also highly uncertain over timescales relevant to soil
167 development, we do not consider atmospheric inputs as a predictor of P pools. As such, we did not include this information in
168 our dataset. We extracted data from each publication as available. In cases in which relevant information was not reported, we
169 extracted the missing data from gridded datasets (Table S1) based on the geographic coordinates of the study sites.

170 In random forest modelling, correlated predictors can be substituted for each other so that the importance of correlated
171 predictors will be shared, making each predictor's estimated importance smaller than its true value (Strobl et al., 2008). Thus,
172 we did not include soil total nitrogen content as it is strongly correlated with SOC ($r = +0.94$), nor did we include aridity index
173 as it is strongly correlated with MAP ($r = +0.72$). We also did not include rarely reported variables that were included in the
174 referenced studies (e.g., soil extractable aluminum and iron concentrations).

175 2.3 Statistical modelling

176 All statistical analyses and plotting were performed in the R environment (v. 4.0.2) (R Core Team, 2018).

177 The database includes some extreme values in each P pool. These values were likely observed in exceptional geological
178 contexts (Porder and Ramachandran, 2013) or in special soils (e.g., very young volcanic soils). We included these extreme
179 values in the shared version of the dataset. However, these values were excluded from data used in model training, as the
180 extremely high values could have a large influence on modeled relationships between soil P pools and predictors. To this end,
181 we only included values falling in the interval between 1% and 99% (Table 2). As we only generate predictions in top 100 cm
182 depth, the training of the model was done using observations in 0-100 cm.

183 We used random forest regression models (Breiman, 2001) to predict global patterns of distribution for individual soil P
184 pools. It is a type of ensemble learning algorithm that combines multiple decision trees to make predictions. It reduces the risk
185 of overfitting and improves the generalization performance by using random subsets of input variables and training data. The
186 output is the average prediction of all the trees (James et al., 2013). All models included the same 11 predictors: MAT, MAP,
187 potential biome, total P, soil depth, SOC, soil clay and sand content, soil pH, elevation, and soil weathering stage. The random
188 forest analysis accounts for interactions and nonlinear relationships between predictors and is appropriate for handling the
189 multicollinearity problem in the multivariate regression (Delgado-Baquerizo et al., 2017). We performed random forest
190 regression analysis using the R package *caret* by applying the embedded R package *randomForest* version 3.1 (Liaw and
191 Wiener, 2002) with an automated *mtry* parameter. Five-fold cross-validation was performed using the R package *caret* (v. 6.0-
192 86) (Kuhn, 2020) to evaluate model performance. The mean decrease in accuracy (%IncMSE) was used to evaluate the relative
193 importance of each variable as a predictor of a soil P pool. The mean decrease in accuracy plot shows how the accuracy of the
194 fitted model declines with the exclusion of a predictor. The greater the decline in accuracy, the more important the variable is
195 for prediction. In this study, the importance measure was calculated for each tree and averaged across the forest (500 trees).
196 Our model found that all 11 variables are important for predicting pool concentrations; thus, all were used as predictors as we
197 developed the global distribution map. Partial dependence plots are a graphical technique used in machine learning to show
198 how the value of a particular input variable affects the predictions of a model, while holding all other input variables constant
199 at their average values in the training data (James et al., 2013). We used the *partial_dependence* function in the R package
200 *edarf* version 1.1.1 (Jones and Linder, 2016) to calculate the partial dependence of the response on an arbitrary dimensional
201 set of continuous predictors from a fitted random forest model.

202 Finally, we applied the above trained models for each of the soil P pools to global databases of the 11 predictors to generate
203 global predictions of each soil P pools. The gridded predictors variables used for the global prediction were all re-gridded to a
204 spatial resolution of $0.5^\circ \times 0.5^\circ$ (the original resolution can be found in Table S1). The *predict* function in the *ranger* package
205 (Wright and Ziegler, 2017) can compute the standard error of a predicted value. To estimate standard errors based on out-of-
206 bag predictions, we used the infinitesimal jackknife for bagging approach (Wager et al., 2014). We did not mask croplands or

207 other areas heavily influenced by human activity (*e.g.*, urban areas), so pool concentrations predicted for these regions should
208 be interpreted as the natural state prior to anthropogenic activity.

209 Soil depth was used as a predictor, allowing models to predict soil P pool concentration for any given depth (Hengl et al.,
210 2017). The partial dependence plot indicated that soil P pool concentration changed with soil depth in the top 50 cm but not in
211 deeper layers (>50 cm) (Fig. S3E). As such, we generated predictions at six standard depths for all soil P pool concentration:
212 0 cm, 10 cm, 20 cm, 30 cm, 50 cm, and 100 cm. Averages for a depth interval (*e.g.*, 0-30 cm or 0-100 cm) can be derived by
213 calculating the weighted average of the predictions within that interval (Hengl et al., 2017).

214 **3 Results**

215 **3.1 Characters of P pools in natural soils across the world**

216 Our soil P pool database includes 1857 measurements from 729 geographically distinct sites and covers 6 continents, all
217 major biomes, and all 12 USDA soil orders in terrestrial ecosystems (Fig. 2). The database includes pool concentrations
218 measured in samples collected from the 0.5 cm to a depth of 450 cm, with 83% of the measurements taken from the topsoil
219 (0-30 cm).

220 From the global median values (Table 2), the largest pool among the six pools considered is the occluded P, accounting
221 for more than 40% of the soil total P; followed by the moderately labile pools (Pi and Po mainly bound to Al and Fe), accounting
222 for about a quarter of total P; primary mineral P (bound to calcium) accounted a minor proportion (7.9%) of soil total P; labile
223 P pools (Pi and Po) represents the smallest proportions of total P (around 4%, respectively).

224 **3.2 Model performance of different P pools in soils**

225 The random forest regression models explained 62%, 64%, 60%, 83%, 76%, and 82% of the variance in the concentrations
226 of labile Pi, labile Po, moderately labile Pi, moderately labile Po, primary P, and occluded P, respectively (Fig. 3). Using the
227 importance measure (%IncMSE), we identified total P concentration as the most important predictor for concentrations of soil
228 labile Pi, labile Po, moderately labile Pi, moderately labile Po, and occluded P, and soil pH as the most important predictor for
229 soil primary P (Fig. 3). The random forest regression models explained 48%, 58%, 52%, 64%, 80%, and 58% of the variance
230 in proportions of labile Pi, labile Po, moderately labile Pi, moderately labile Po, primary P, and occluded P, respectively (Fig.
231 S4). Based on the importance measure, soil pH is generally the most important predictor for proportions of all soil P pools,
232 with also prominent influences of total P concentration, soil organic carbon, soil depth and biome (Fig. S4). These results
233 suggest that, while concentration values of P pools logically strongly depend on soil total P concentration, the relative values
234 of the different pools are modulated by other soil properties and the environmental context.

235 **3.3 Global patterns and drivers of P pools in natural soils**

236 Our global predictions (Fig. 4) revealed that average values across all P pools were higher in slightly weathered soils
237 compared to those in more weathered soils (Fig. 5A), reflecting the strong effect of the initial stages of soil development on
238 soil P depletion. While occluded P proportion increased with soil development, the proportions of labile and moderately labile
239 P (Pi and Po) were fairly independent of soil weathering stage (Fig. 5B).

240 Our global predictions also indicated that soil P pool concentrations varied substantially among different biomes. Lower
241 P pools concentrations were found in warm and/or humid biomes (*e.g.*, tropical forest and savanna), while higher P pool
242 concentrations were found in northern cold biomes (*e.g.*, tundra and boreal forest) (Fig. 5C). The spatial patterns of pool
243 proportions were different from those of pool concentrations across biomes (Fig. 5D). For example, variation in the proportion

244 of labile Pi was relatively small compared to the variation observed in labile Pi concentrations; moreover, the proportion of
245 occluded P tended to increase in the transition from tundra and boreal forest to tropical forest and savanna (Fig. 5D). It should
246 be noted that the mapped predictions of P pool concentrations across biomes (see Fig 5C) are not consistent with the measured
247 data (Fig. S5), which indicate that total soil P in tropical forests is higher than in any other biome. This result suggests a
248 sampling bias due to overrepresentation of high total soil P sites in the tropical forest data.

249 Partial dependence plots (Fig. S3) and the results of Pearson correlation analysis (Table 3) were generally consistent.
250 Both analyses revealed that concentrations for all six pools were significantly and positively correlated with total P
251 concentration. SOC was significantly and negatively correlated with primary mineral P concentration, but positively correlated
252 with the other five pool concentrations. MAT and MAP were significantly and negatively correlated with concentrations of all
253 soil P pools. Soil pH was significantly and positively correlated with primary mineral P concentration, but significantly and
254 negatively correlated with concentrations of the other five P pools. The results of Pearson correlation analysis also indicated
255 that P pool concentrations were well correlated with each other, except for primary mineral P; this pool was negatively
256 correlated with labile Po and not correlated with moderately labile Po concentration. Partial dependence plot indicated the
257 variation of P pools concentrations with increasing soil depth (Fig. S3E). We found a drastic decrease of P pools with soil depth
258 in top 50 cm soil, then became relatively stable at 50-100 cm soil depth. Labile and moderately labile P (both Pi and Po)
259 concentrations also decreased with an increase in soil depth in top 50 cm, while primary mineral P and occluded P
260 concentrations generally increased with soil depth.

261 As for the P pools' proportions, Pearson correlation analysis (Table 3) revealed that soil pH was positively correlated with
262 the primary mineral P proportion and negatively correlated with the other five P pool proportions. Soil labile Po, moderately
263 labile Pi, and moderately labile Po proportions decreased substantially with an increase in MAT, while the occluded P
264 proportion increased with MAT. Soil labile Po, moderately labile Pi, and moderately labile Po proportions increased
265 substantially with increasing total P concentration, while the soil labile Pi and occluded P proportions decreased substantially
266 with total P concentration.

267 There are significant differences between our predictions and those made by Yang et al. (2013) (Fig. S6) in both the
268 magnitude and the spatial patterns associated with most P pool concentrations. The two global estimates were only weakly to
269 moderately correlated (Pearson correlation coefficients between 0.09 and 0.38) (Fig. 6). Yang et al.'s predictions are lower
270 than ours for organic P, moderately labile Pi, primary mineral P, and occluded P concentrations (Table S2). Although average
271 values for labile Pi concentrations estimated by Yang *et al.* were close to ours, they were only weakly correlated with each
272 other (Pearson correlation coefficient of 0.09) (Fig. 6).

273 **4 Discussion**

274 **4.1 Improved mapping of different P pools in global natural soils**

275 We trained random forest regression models using 11 variables to predict six soil P pools at different depths in
276 (semi-)natural terrestrial ecosystems, resulting in significant improvements over earlier estimates (Yang et al., 2013). First, we
277 used a new global map of total P concentrations in natural soils (He et al., 2021) as a predictor. Because total P is an important
278 predictor and is highly correlated with all other P pools, a higher quality map of total soil P will also lead to improved
279 predictions of other P pools. Further improvements in global P data availability will thus also be useful to improve maps of
280 other P pools. Second, Yang *et al.* (2013) used a limited number (n=178) of measurements of Hedley P pools across soils. Our
281 database represents a nearly ten-fold increase, which can better represent the heterogeneous conditions on Earth. Third, Yang
282 *et al.* (2013) estimated P pools concentrations using total soil P concentrations, global soil order maps, and average proportions
283 of various P pools for different soil orders. However, there still are considerable variabilities in P concentrations within any

284 given soil order, though it could be a good predictor of P pools variation (Cross and Schlesinger 1995, Yang and Post 2011).
285 Indeed, we found that soil orders were less informative than other environmental predictors. By including more predictors
286 (e.g., SOC, climate, and soil pH) our model offers significant improvements for capturing the variation observed in soil P
287 composition across the globe.

288 The above-named technical improvements have made it possible to produce more accurate maps. For example, while
289 Yang et al.'s global predictions indicated that the highest organic P concentrations were found in the temperate zone, our maps
290 suggest they are in boreal forest and tundra. This is more consistent with general understanding of global soil organic matter
291 distribution (Hengl et al., 2017). Differences between our estimates of different P pools and those presented by Yang *et al.*
292 (2013) have significant implications for soil P availability to vegetation. The averages and median values of Yang *et al.*'s
293 predicted soil organic P, moderately labile Pi, and occluded P concentrations were substantially lower than our estimates.
294 Evidence suggests that soil organic P and moderately labile Pi remain bioavailable on timescales of days to months (Helfenstein
295 et al., 2020; Augusto et al., 2017; Maharjan et al., 2018), while occluded P is bioavailable on the order of years to millennia
296 (Hou et al., 2016; Wang et al., 2007). Thus, soil P availability might be larger than previously assumed in assessments based
297 on estimates by Yang *et al.* (2013) (e.g., Sun et al. 2017).

298 **4.2 Major drivers of different P pools in natural soils**

299 Our results indicate that global variation in soil P pools is jointly controlled by total P concentration, soil pH, soil
300 development, climatic factors, and soil depth. Given that our models explain > 48% of the variance observed in P pools
301 (concentration and proportion), our results suggest that edaphic properties and climatic factors play significant roles in the size
302 and composition of different soil P pools globally.

303 **Effects of total soil P concentration on P pools**

304 We found that total soil P concentration was a prominent predictor of most soil P pools at the global scale and that total
305 P was positively correlated with all P pool concentrations and Po pool proportions. This is consistent with findings at local
306 (Turner and Blackwell, 2013) and global (Augusto et al., 2017; Hou et al., 2018; Harrison, 1987) scales. Total soil P is
307 influenced by multiple soil forming factors (e.g., parent material P concentration, climate, soil organic carbon content, and soil
308 texture) (He et al., 2021). Thus, total soil P provides an integrated measure of factors that regulate the size of the P pools.
309 Moreover, this result is consistent with the emerging idea of substrate-based P cycling in natural ecosystems (Lang et al., 2017;
310 Lang et al., 2016): Soils with high total P content are usually also associated with a large primary mineral P pool. At these P-
311 rich sites, plant and microbial communities tend to promote P release from primary minerals, with subsequent biological and
312 abiotic transformations resulting in high concentrations in all other P pools (Lang et al., 2016; He et al., 2021) and higher
313 proportions of organic P (Hou et al., 2018c). In contrast, at P-poor sites, plant and microbial communities are more reliant on
314 P recycling systems that promote the mineralization of Po by soil microbes (Achat et al., 2009; Marklein and Houlton, 2012)
315 and the mobilization of moderately labile Pi or even occluded P (Augusto et al., 2017) to sustain the P supply. Therefore, soil
316 P pool concentrations are expected to strongly co-vary with total soil P concentration.

317 **Effects of soil pH on P pools**

318 Consistent with previous studies (Hou et al., 2018c; Kruse et al., 2015; Oburger et al., 2011; Barrow et al., 2020), our
319 results indicate that soil pH is an important predictor of P pool concentrations and proportions in natural soils globally. The
320 relative importance of pH is unsurprising, since the sequential fractionation procedure is based on dissolving a soil sample in
321 solutions of varying acidity/alkalinity. However, the observed pH effects also support the existing mechanistic understanding
322 of the various P forms. The strong positive correlation of primary P and soil pH is expected because 1) the primary P pool is
323 composed mainly of calcium phosphate/apatite, which is highly soluble at low pH but becomes less soluble with increasing
324 pH and 2) soil pH declines with soil weathering intensity (Delgado-Baquerizo et al., 2020) (e.g., the highest values of soil pH

325 are usually found in dry regions where chemical weathering rates are limited by water availability (Slessarev et al., 2016)).
326 Both factors affect the transformation of primary mineral P to other forms.

327 Soil pH shows important but negative influences on the proportions of other soil P pools (*i.e.*, proportions of labile Po,
328 moderately labile Pi and Po, occluded P, and labile Pi). There are several possible explanations for these relationships. First,
329 low soil pH values (< 5.0) inhibits soil microbial activities and the extracellular activity of phosphatase enzymes (Aciego Pietri
330 and Brookes, 2008; Eivazi and Tabatabai, 1977; Xu et al., 2017). Thus, in acidic soils, more organic P (*i.e.*, labile, and
331 moderately labile Po) may accumulate than in neutral soils. Second, decreasing soil pH is associated with the accumulation of
332 Fe and Al oxides, which leads to enhanced adsorption of P (*i.e.*, moderately labile Pi and Po). Third, pH tends to decrease as
333 soil weathering advances and base cations are progressively washed out (Slessarev et al. 2016). As soils weather, occluded P
334 accumulates. Therefore, the occluded pool proportion decreases with increasing pH. Fourth, increasing soil pH is associated
335 with enhanced adsorption of dissolved Pi to Ca and Mg, reducing the amount of labile Pi available for plants and soil
336 microorganisms (Fink et al., 2016; Gerke, 2015). This could explain the negative relationship between soil pH and the labile
337 Pi proportion as identified in this study. But increasing soil pH in acidic soils favors soil microbial growth and phosphatase
338 enzymes activity, which could increase P availability. These conflicting mechanisms may be responsible to the relative low
339 importance in predicting the spatial variation of labile Pi proportion.

340 **Effects of climate on P pools**

341 Our global predictions indicated negative effects of climatic factors (*i.e.*, MAT and MAP) on the soil P concentrations,
342 which means a decrease in soil P concentrations as MAT increases from northern cold biomes (e.g., tundra and boreal forest)
343 to warm tropical biome (e.g., tropical forest) or MAP increases from arid to humid regions. These results fit well with our
344 understanding of broad P concentration variation with increasing weathering (Walker and Syers, 1976). Also, these results are
345 expected as the main factor determining soil P pools concentrations, soil total P, shows a similar pattern (He et al., 2021).
346 Interestingly, we found contrasting responses of labile Pi pool's proportions along the MAT and MAP gradients. The positive
347 correlations between labile Pi proportion and both MAT and MAP indicated labile Pi concentration decreased slower than the
348 soil total P as temperature and precipitation increasing. This result supported the idea that biological systems evolved to retain
349 soil labile Pi levels despite overall decrease in total soil P as long as climate factors are favorable for biological activity. In
350 strongly weathered soil with limited soil P stocks but otherwise optimal growing conditions like in warm and humid tropical
351 forests, the mineralization of Po and mobilization of moderately labile Pi or occluded P could contribute to maintain high levels
352 of labile Pi due to the high soil temperature for soil enzyme kinetics and abundant carbohydrate supply from photosynthesis
353 to fueling biological activity (Vitousek, 1984; Achat et al., 2009; Chacon et al., 2006; Liptzin and Silver, 2009).

354 **Effects of soil development on P pools**

355 The variations of P concentrations and proportions across weathering stages predicted by our model partially support
356 Walker and Syers' (1976) theory based on soil chronosequences. While our results are consistent with expectations from Walker
357 and Syers' theory about the increase in the proportion of occluded P that occurs at the expense of primary and organic P during
358 soil development, our results disagree with Walker and Syers' ideas regarding the evolution of the labile Pi and moderately
359 labile Pi pools during soil development. The evolution of occluded P is commonly explained by the increase of Al and Fe oxide
360 minerals and the decrease of soil pH; In addition to being fixed onto Fe and Al oxides, P that is released from primary minerals
361 or mineralized from organic matter can be occluded by being adsorbed onto mineral surfaces or precipitating in poorly-soluble
362 secondary soil minerals (Crews et al., 1995; Quesada et al., 2010; Selmants and Hart, 2010).

363 In the Walker and Syers' model, non-occluded inorganic P increases initially to a peak value and then declines to very
364 low levels during pedogenesis. However, our results showed that labile Pi and moderately labile Pi (non-occluded P in Walker
365 and Syers' model) formed significant proportions of total P throughout all soil orders across weathering stages. This could be
366 due to the coarse classification of weathering stages in our study, which may be insufficient to characterize the end members
367 of the range. This explanation is supported by the small proportion of primary mineral P in the slightly weathered soil and the

368 moderate amounts of primary P remaining in strongly weathered soils. In addition, the theory of P distributions along soil
369 development stages stems largely from relatively isolated island locations on New Zealand (Walker and Syers, 1976) and
370 Hawaii (Crews et al. 1995). However, in most other places in the world there is higher dust deposition from surrounding land
371 masses, which is a source of primary P even to highly weathered soils (Vogel et al., 2021). Nevertheless, the contribution of
372 dust deposition to primary P and other forms of P in soil remain unquantified in most of land areas.

373 **Effects of soil depth on P pools**

374 We found that soil P pools concentrations varied significantly with soil depth. Total soil P concentration is often higher
375 in topsoil than in subsoil due to biological uplift, which was reported by previous studies (Jobbágy and Jackson, 2001; Porder
376 and Chadwick, 2009). The labile and moderately labile P (in both inorganic and organic pools) concentrations were higher in
377 topsoil, which can also be explained by biological uplift and highly available P inputs from plants and dust to the topsoil. In
378 contrast, the primary P and occluded P concentrations in topsoil were lower than in the subsoil. This can be explained by the
379 fact that topsoil tends to be more weathered and developed than the subsoil (Achat et al., 2012; Chen et al., 2021).

380 **4.3 Limitations and prediction uncertainty**

381 In our database, some regions were underrepresented (*e.g.*, northern Canada, middle and northern Asia, and inner Africa),
382 which may result in low accuracy of the predicted values in those regions. In the tropics, high P soils were overrepresented
383 and accuracy of predicted values in tropical regions may be quite low. Our database contains four times as many observations
384 from surface mineral soils (0-30cm) than it does from soils deeper than 30 cm. As such, the predicted concentrations of different
385 P pools for deep soils may suffer from larger uncertainties. Finally, large portions of variation remain unexplained by our
386 models, especially variation in soil labile Pi concentrations and proportions (40% and 52% unexplained, respectively),
387 indicating that other significant factors were not accounted for in our modeling. These factors may include microbial processes,
388 Fe and Al oxide concentrations, plant community composition, atmospheric deposition, and soil erosion (Kruse et al., 2015;
389 Achat et al., 2016). These limitations highlight the need for additional measurements, particularly from underrepresented
390 regions and the subsoil as well as measurements of closely associated variables, especially those related to labile Pi.

391 **5 Conclusion**

392 Here, we compiled the largest database to date of different soil P pools. Using machine learning modelling, we quantified
393 the relative importance of multiple predictors for estimating different soil P pools and estimated these pools at the global scale.
394 Our results indicated that the global concentrations of soil labile Pi, labile Po, moderately labile Pi, moderately labile Po, and
395 occluded P could be generally predicted mainly by the total soil P concentration, while primary P concentration was mainly
396 predicted by soil pH and total soil P concentration. For predicting proportions of different P pools, soil pH and to a lesser extent
397 soil depth, SOC and total P were the most important predictors for all P pools proportions at the global scale. In addition, our
398 results also revealed significant effects of climate and other edaphic factors on spatial variation in P pools. We concluded that
399 edaphic properties and climatic factors were significant predictors of soil P pools, including concentration and proportion of
400 total P. These findings represent a significant step towards improving understanding of global variations in different soil P
401 pools. Our global maps of predictions of different P pools will be important to improving global models of terrestrial P cycle.

402 **Data availability**

404 Raw datasets, data source reference, R script, and global maps generated in this study are available at
405 <https://doi.org/10.6084/m9.figshare.16988029> (He et al., 2022).

406 **Author contributions**

407 D.S.G., Y.W. and E.H designed this study. L.A., E.H, and X.H. collected the data. X.H., E.H., L.A., D.S.G., B.R., Y.W., J.H.,

408 and Y.H. discussed analyzing methods. X.H. conducted the analysis and drafted the manuscript. All authors discussed the
409 results and contributed to the manuscript.

410 **Financial support**

411 This research was funded by the China Postdoctoral Science Foundation (2020M673123), the National Natural Science
412 Foundation of China (32271644), and the ANR CLAND Convergence Institute.

413 **Acknowledgements**

414 We would like to thank Dr. Joseph Elliot at the University of Kansas for his assistance with English language and grammatical
415 editing of the manuscript.

416 **Competing interests**

417 The authors declare that they have no conflict of interest.

668

669 **Table 1. Summary of training data used to predict soil P pool concentrations.** P10 and P90 indicate percentile rank of 10%
670 and 90%, respectively. Proportions from literature (PFL) and proportions from gridded maps (PFGM) indicate proportions of
671 measurements from the literature and extracted from global gridded maps, respectively.

Group	Variables	Unit	Min	P10	Median	P90	Max	PFL*	PFGM#	
Climate	MAT	°C	-12	1.1	12.8	25.7	30.0	96%	4%	
	MAP	mm yr ⁻¹	10	414	970	2750	5180	96%	4%	
Soil property	Total P	mg kg ⁻¹	4.8	114.0	455.5	1107.9	14973.6	100%	0%	
	SOC	g kg ⁻¹	<0.1	4.8	24.4	130	545.2	87%	13%	
	Soil pH	unitless	3.0	4.2	5.7	8.1	10.5	92%	8%	
	Soil clay	g kg ⁻¹	<0.1	70.0	195.5	410.7	945.5	52%	48%	
	Soil sand	g kg ⁻¹	<0.1	164.9	420.0	757.6	982.0	49%	51%	
	Depth	cm	0.5	4.2	10.0	47.5	450.0	100%	0%	
	Soil order	unitless	12 USDA soil orders						80%	20%
Vegetation	Biome	unitless	8 major biomes						0%	100%
Topography	Elevation	m	-2	37	616	3015	4813	85%	15%	

672 MAT: Mean annual temperature; MAP: Mean annual precipitation; SOC: Soil organic carbon. * PFL: Proportion from
673 literature; # PFGM: Proportion from gridded map. PFL and PFGM indicate proportions of measurements from literature and
674 extracted from global gridded maps, respectively.
675

676

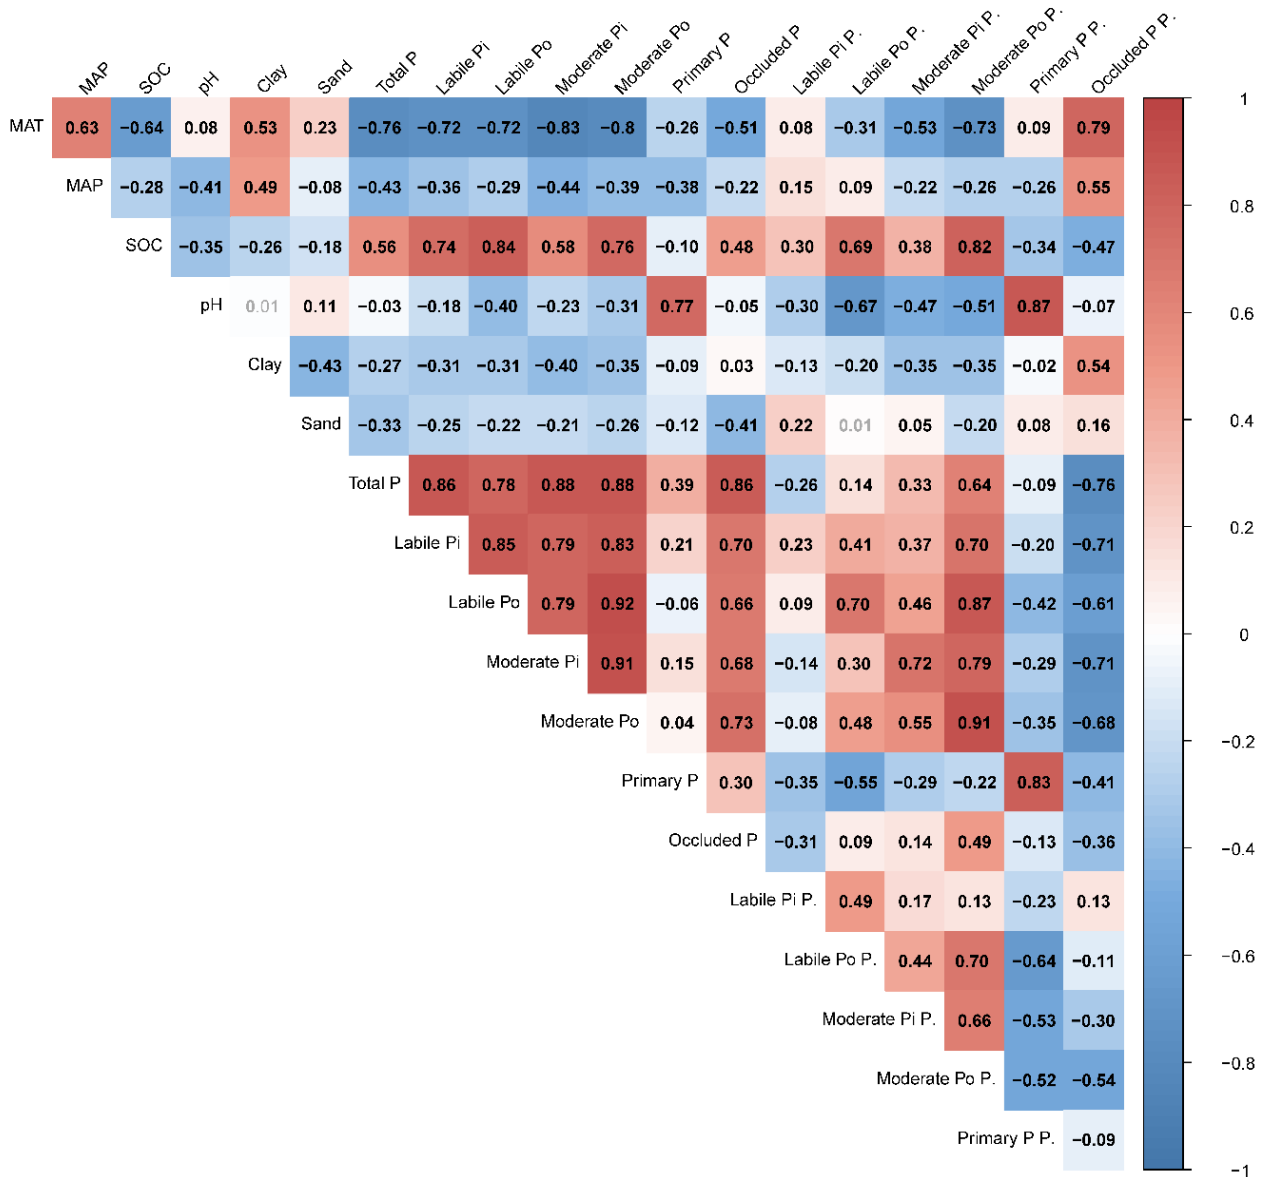

677

678 **Table 2. Statistical summary of P pools in global (semi-)natural soils.** Results based on our collected sites database. P1,
 679 P10, P25, P75, P90, and P99 indicate percentile rank of 1%, 10%, 25%, 75%, 90%, and 99%, respectively.

	Count	P1	P10	P25	Median	Mean	P75	P90	P99
<i>Concentration (mg kg⁻¹)</i>									
Labile Pi	1722	0.1	2.2	6.2	14.3	37.1	34.3	78.6	444.6
Labile Po	1567	0.6	2.5	5.9	14.0	31.1	35.0	85.2	225.4
Moderately labile Pi	1742	0.1	4.0	10.0	25.0	58.4	57.7	122.4	378.6
Moderately labile Po	1588	1.2	8.3	22.1	60.8	120.3	155.1	333.4	631.1
Primary P	1629	<0.1	1.2	4.7	38.9	106.8	145.0	328.3	635.2
Occluded P	1453	5.5	34.5	86.2	178.0	260.5	309.6	532.9	2172.9
<i>Proportion of total P (%)</i>									
Labile Pi	1448	<0.1	0.6	1.7	4.0	5.9	7.7	13.6	29.6
Labile Po	1331	0.1	0.8	1.7	4.1	5.9	7.8	13.1	29.3
Moderately labile Pi	1448	0.1	0.9	3.0	7.5	9.3	12.9	20.2	39.3
Moderately labile Po	1384	0.4	3.1	8.0	18.0	19.5	27.1	38.5	59.8
Primary P	1448	<0.1	0.5	1.6	7.9	19.0	29.4	60.9	83.2
Occluded P	1448	4.2	15.4	26.8	42.4	41.9	56.4	67.9	83.0

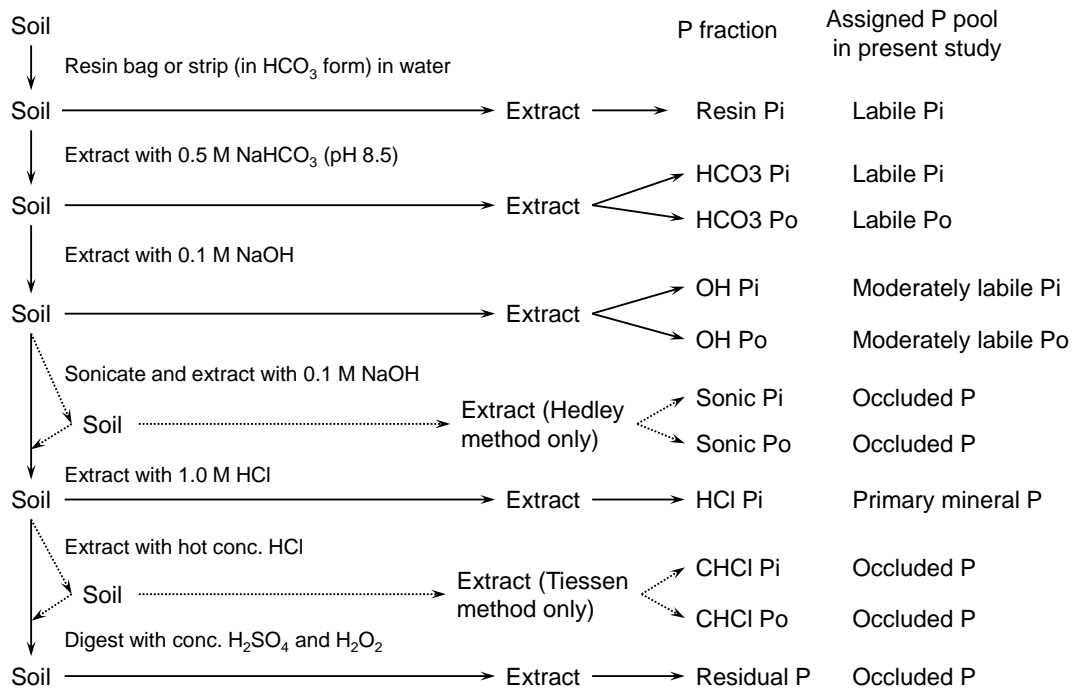

680

681 **Table 3. Coefficients of Pearson correlations among proportions and concentrations of soil P pools.** Results based on the
 682 average global predictions in top 30 cm soils. Coefficients with $P < 0.001$ are shown in black and bold. Labile Pi P. indicated
 683 the labile Pi proportion. The same meanings to the Labile Po P., Moderately labile Pi P., Moderately labile Po P., Primary P P.,
 684 and Occluded P P.. Elevation is not included this plot as it is not well correlated with P pools variation in our results.

685
686

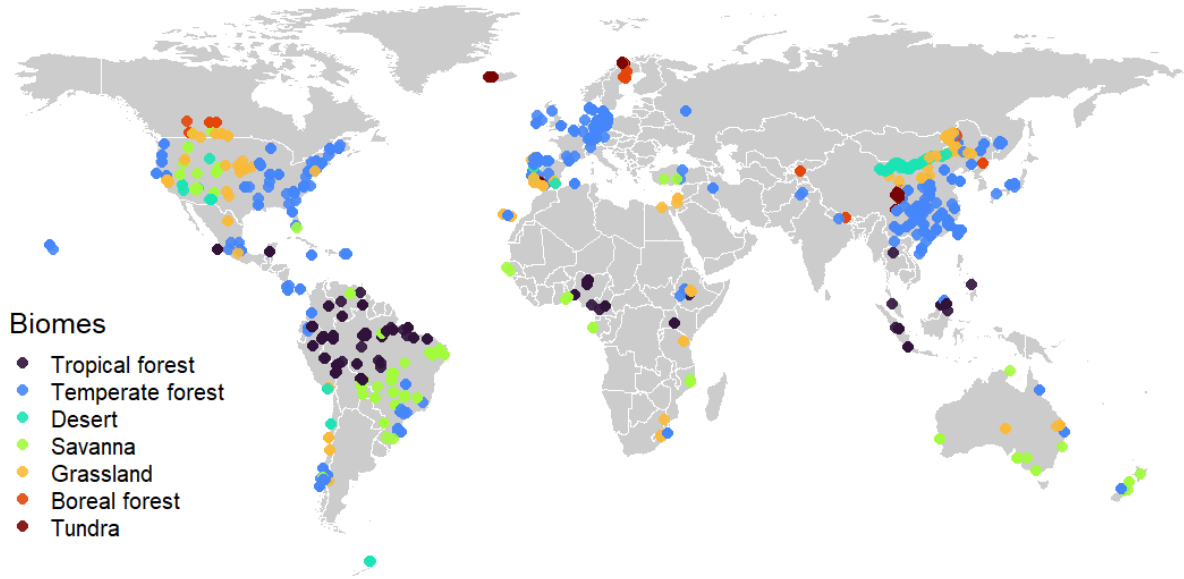

687 **Figure 1. Flow chart of soil P fractionation.** The flow chart follows the procedures outlined by Hedley et al. (1982) and
 688 Tiessen and Moir (1993). Redrawn according to Hou et al. (2018).

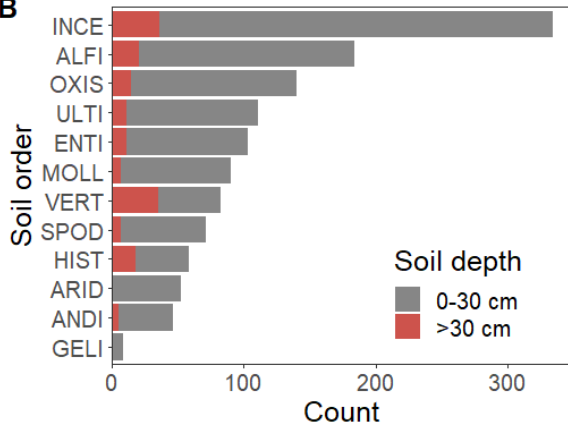

689
690

691 **Figure 2. Distribution of site-level training data.** The database contains 1838 observations covering 12 USDA soil orders
 692 (B) and all major terrestrial biomes (C).

695 **Figure 3. Relative importance of variables for predicting concentration of soil P pools quantified using random forest**
 696 **models.** Mean decrease accuracy (%IncMSE) indicates the relative importance of each variable for predicting soil P pools.
 697 SWS: soil weathering stage.

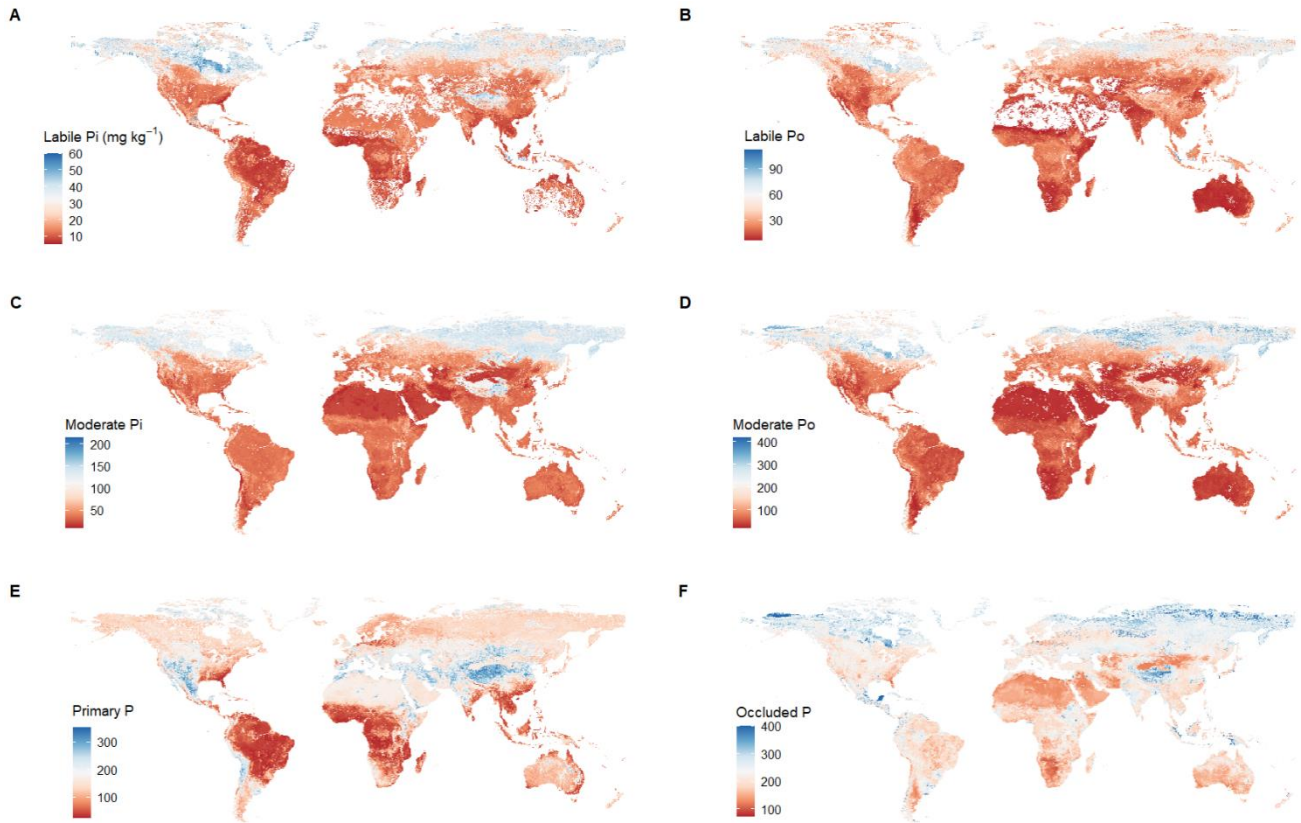

698

699

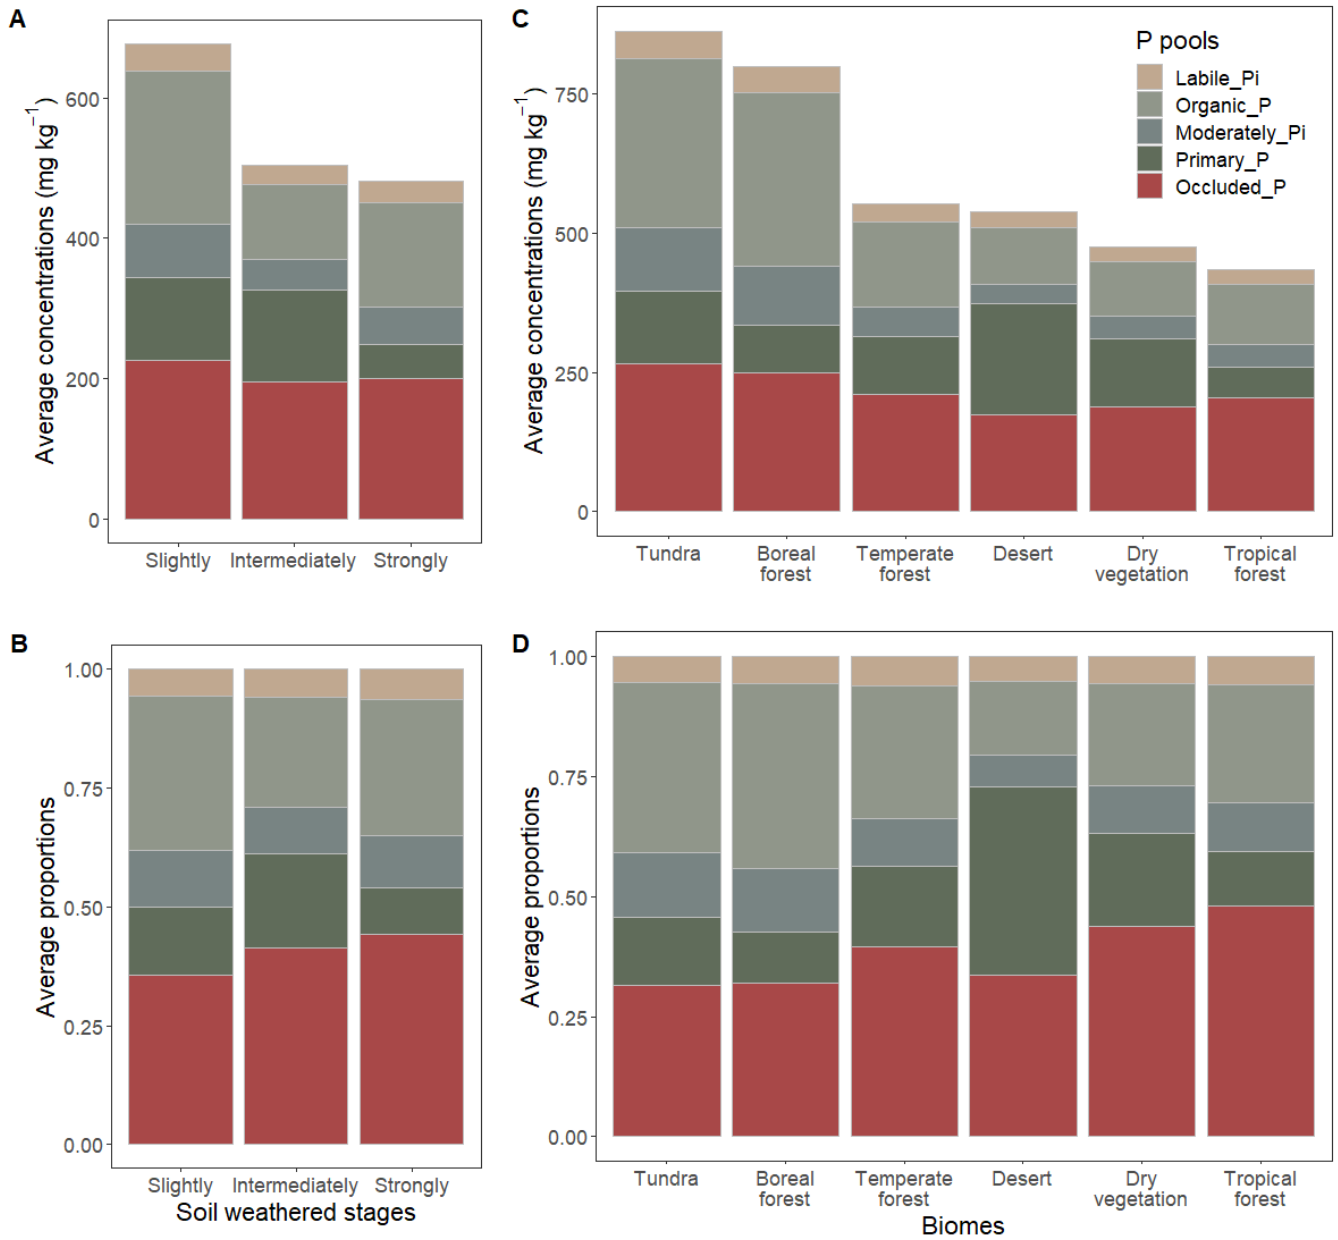

700

701 **Figure 4. Global maps of P pool concentrations at depths of 0-30 cm.** Note that croplands and other heavily influenced
702 areas were not masked from the maps, so soils in these areas can be used to represent soils without extensive anthropogenic
703 activity.

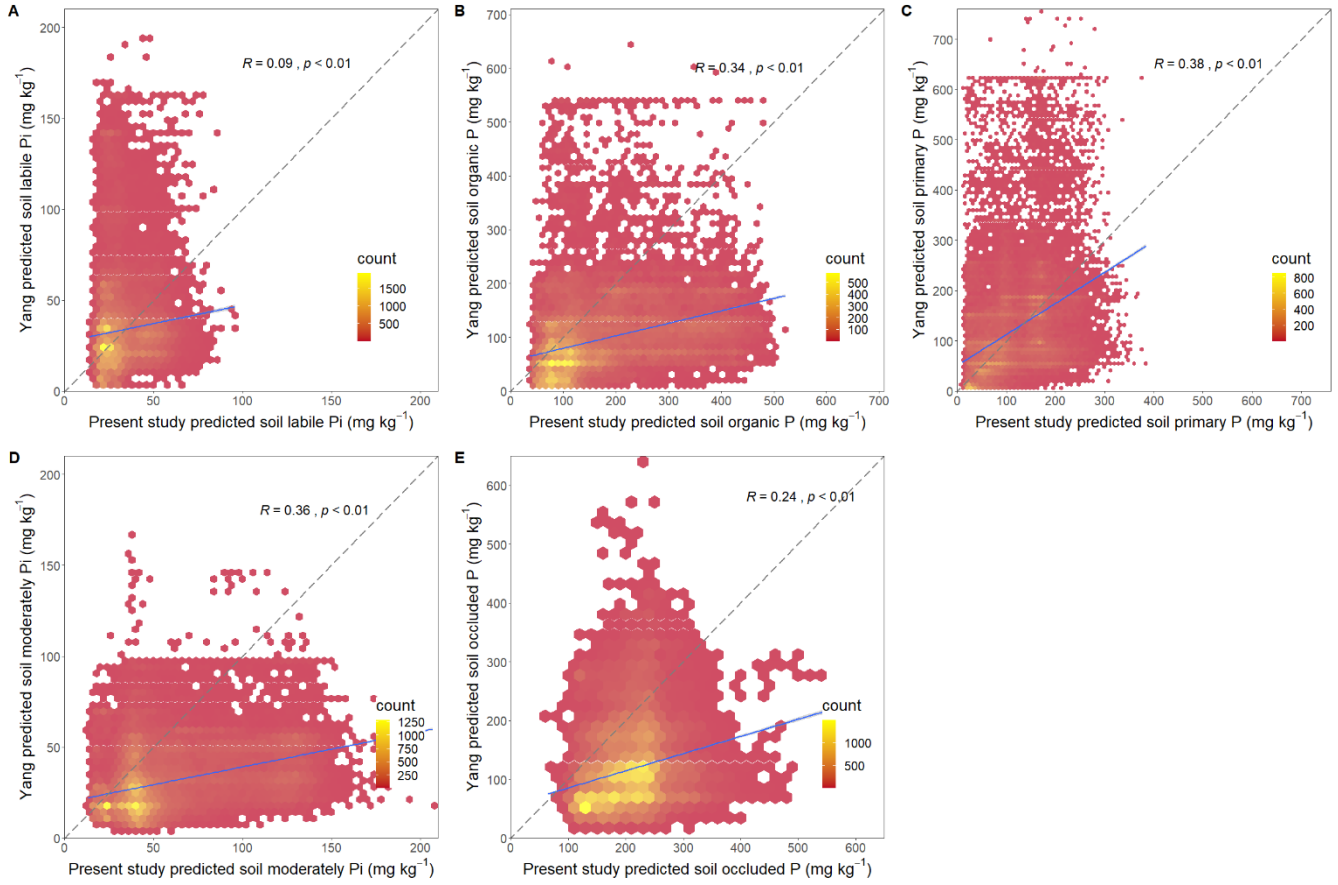

704
705

706 **Figure 5. Average concentrations of P pools and their proportions of total soil P concentration across soil weathering**
 707 **stages and biomes. Labile and moderately labile Po form the organic pool.** Results based on global estimates for 0-30 cm
 708 depth. Dry vegetation combines grassland and savanna biomes to simplify the figure.

709
 710
 711

712 **Figure 6. Relationship between our predicted P fraction concentrations and Yang et al.'s predictions.** Panels A, B, C, D,
713 E, and F depict correlations between both sets of predictions for soil labile Pi, organic P, primary mineral P, moderately labile
714 Pi, and occluded P, respectively. Dashed lines indicate the 1:1 line; blue lines indicate the regression line.
