15 **Abstract**

16 Through the constant rain of sinking marine particles in the ocean, carbon (C) trapped within
17 is exported into the water column and sequestered when reaching depths below the
18 mesopelagic zone. Atmospheric CO₂ levels are thereby strongly related to the magnitude of
19 carbon export fluxes in the mesopelagic zone. Sinking particles represent the main source of
20 carbon and energy for mesopelagic organisms, attenuating the C export flux along the water
21 column. Attempts to quantify the amount of C exported versus consumed by heterotrophic
22 organisms have increased in recent decades. Yet, most of the conducted estimations have led
23 to estimated C demands several times higher than the measured C export fluxes. The choice
24 of parameters such as growth efficiencies or various conversion factors is known to greatly
25 impact the resulting C budget. In parallel, field or experimental data are sorely lacking to
26 obtain accurate values of these crucial overlooked parameters. In this study, we identify the
27 most influential of these parameters and perform inversion of a mechanistic model. Further,
28 we determine the optimal parameter values as the ones that best explain the observed
29 prokaryotic respiration, prokaryotic production, and zooplankton respiration. The consistency
30 of the resulting C-budget suggests that such budgets can be adequately balanced when using
31 appropriate parameters.

35

36 **1. Introduction**

37 The biological carbon pump (BCP) is the main mechanism by which CO₂ is exported and stored
38 in the deep ocean in the long term. This ecosystem service is defined as the sum of the
39 biological processes that lead to carbon export from the euphotic zone into the deep ocean
40 (Eppley and Peterson 1979). This process exports from 5 to 20 Gt C yr⁻¹ in the form of
41 particulate organic carbon (POC) gravitationally sinking from the sunlit ocean to the
42 mesopelagic zone typically located between 200 and 1000 m (Henson et al. 2011). Therefore,
43 atmospheric CO₂ levels are strongly related to any change in carbon export into the
44 mesopelagic zone (Kwon et al. 2009). Five downward pathways of organic matter export to
45 the mesopelagic zone are defined: phytoplankton (senescent cells, colonies, spores, cysts),
46 zooplankton (carcasses or fecal pellets), aggregates (marine snow of different compositions
47 including the two latter categories), vertical migration of zooplankton and
48 mixing/diffusion/advection (Siegel et al. 2016; Le Moigne 2019).

49 Gravitational sinking POC supply, combining the 3 first pathways described above, constitutes
50 the main organic carbon input to the mesopelagic zone (Boyd et al. 2019). Consequently, the
51 downward flux of organic carbon is attenuated with increasing depth as it is fragmented,
52 metabolized and remineralized by different biological processes until only the refractory
53 material remains. The majority of POC flux attenuation occurs in the mesopelagic zone (Martin
54 et al. 1987; Marsay et al. 2015; Fuchs et al. 2022). The remineralization of exported carbon is
55 mainly performed by two types of organisms: microorganisms (mostly heterotrophic
56 prokaryotes i.e. Bacteria and Archaea) and zooplankton. Heterotrophic prokaryotes primarily
57 use dissolved organic carbon (DOC) as a source of carbon. However, some prokaryotes,
58 colonizing particles upon formation, undergo changes in environmental conditions during their
59 descent, such as the increase of the hydrostatic pressure and the variations of temperature
60 (Tamburini et al. 2003, 2021; Baumas et al. 2021). Such particle-attached prokaryotes
61 primarily use POC as a carbon source. Only organic matter of size below 600 Da diffuses
62 directly through prokaryotic membranes, therefore attached prokaryotes produce ectoenzymes
63 required to solubilize larger molecules (Weiss et al. 1991). Smith et al. (1992) observed that
64 the amount of DOC produced by ectoenzymatic solubilization of POC may be 10 to 100 times
65 greater than the absorption capacity of a cell. DOC is thereby released into the surrounding

66 water (the so-called solubilization). This increases the amount of DOC available for free-living
67 prokaryotes. In addition, several types of zooplankton are involved in marine particles: POC-
68 feeding detritivores (e.g. copepods), prokaryotes consumers (e.g. flagellates), and carnivores
69 (e.g. chaetognaths). Besides, zooplankton lose POC through excretion (moult, mucilage, urine),
70 fecal pellets (decomposed organic matter), and sloppy feeding. Giering et al. (2014) specify
71 that 30% of a particle supplied by the downward flux is fragmented by the action of the
72 detritivores and is transformed into suspended matter.

73 Given their importance regarding the BCP, all the processes described above were extensively
74 studied in the last decades (e.g. Alldredge and Silver 1988; Smith et al. 1992; Kiørboe et al.
75 2002, 2003; Kiørboe 2003; Lampitt et al. 2008; Steinberg et al. 2008; Iversen et al. 2010;
76 Giering et al. 2014; Koski et al. 2020 and references therein). However, the scientific
77 community has struggled to reconcile the mesopelagic carbon budget with measurements and
78 estimates showing a biological carbon demand often greater than the amount of known organic
79 carbon sources (Reinthal et al. 2006; Steinberg et al. 2008; Burd et al. 2010; Collins et al.
80 2015; Boyd et al. 2019). In other words, the measured export flux cannot sustain measured
81 metabolic demands of prokaryotes and zooplankton altogether in the mesopelagic zone, leading
82 to a discrepancy in C budgets.

83 A first explanation may lie in the choices of the boundaries of the mesopelagic zone used to
84 integrate fluxes and to estimate the carbon budget as investigated in Fuchs et al. (2022). Indeed
85 they specifically designed a method to determine from CTD-cast variables (fluorescence, O₂
86 concentration, potential temperature, salinity, and density) accurate boundaries which vary in
87 space and time. With their method named RUBALIZ, they show that 90% of the POC flux
88 attenuation occurs within new determined boundaries which is not the case of the fixed 200-
89 1000m often used. Besides, integrating prokaryotic C demand within RUBALIZ boundaries
90 helps to reduce the discrepancy. Other sources of discrepancy may be found focusing on the
91 carbon demand of prokaryotes (which are responsible for the final step of the remineralization),
92 whose estimation is usually provided by adding rates of prokaryotic heterotrophic production
93 (PHP) to that of prokaryotic respiration (PR) (Burd et al. 2010). PHP rates are often measured
94 from tritiated leucine incorporation rates in incubations which are then multiplied by a
95 conversion factor Leu/Carbon (CF) (Kirchman et al. 1985). The PR is more challenging to
96 measure (especially in the dark ocean, (Nagata et al. 2010) and, therefore, often estimated from
97 measurements of PHP and a prokaryotic growth efficiency (PGE) taken from the literature (as
98 $PR = PHP \times (1-PGE)/PGE$, del Giorgio and Cole 1998). Unfortunately, *in-situ* measurements

99 of both CF and PGE are time-consuming and operationally complex to perform (especially for
100 the mesopelagic zone). In addition, such data for particle-attached prokaryotic communities are
101 scarce since the adequate sampling devices (to specifically sample biologically intact sinking
102 particles) were only recently validated (Baumas et al. 2021). Besides, PHP and PR data are
103 usually obtained after decompression or carried out from experiments at atmospheric pressure,
104 being a source of misvaluation (Tamburini et al. 2013). As a result, mean values from global
105 literature compilation or theoretical values are often used as references for both CF or PGE
106 (Burd et al. 2010; Giering and Evans 2022) and may be far from the actual *in situ* values.

107 In parallel, model predictions help to estimate unmeasurable processes along with the
108 comparison and validation of data. The biological processes occurring in the mesopelagic zone
109 are not yet well constrained (see sections above). Consequently, only a few models specifically
110 designed to assess the fluxes governing the BCP in the mesopelagic zone exist (e.g. Tian et al.
111 2000; Anderson and Ryabchenko 2009; Anderson and Tang 2010; Fennel et al. 2022). For
112 instance, the model developed by Anderson and Tang (2010) enables the evaluation of the
113 remineralization of different compartments such as particle-attached prokaryotes to sinking and
114 suspended particles, free-living prokaryotes and up to six trophic levels of zooplankton. This
115 model describes the various known biological processes involved in the BCP system. However,
116 the model also requires to be set up with parameters such as the PGE. For example, Anderson's
117 model requires 20 parameters which often present large uncertainties.

118 Giering et al. (2014) attempted to reconcile carbon input and biological carbon demand in the
119 mesopelagic zone using the Anderson and Tang (2010) model and measurements carried out
120 in the North Atlantic (Porcupine Abyssal Plain site, 49.0°N 16.5°W, summer 2009). They
121 found that prokaryotes were responsible for 70-92% of the remineralization of organic carbon.
122 In this study, the model results were consistent with the measurements performed *in situ*,
123 showing a reconciliation of the carbon budget between 50 and 1000 m depths. Giering et al.
124 (2014) balanced their C-budget by using a rather low CF ($CF = 0.44 \text{ kg C mol}^{-1}$) compared to
125 the one generally used in the literature ($CF = 1.55 \text{ kg C mol}^{-1}$) and a PGE of 8% for free-living
126 prokaryotes and 24% for particle-attached prokaryotes. All these values were chosen as
127 medians of literature values compiled from various measurement methods. Wisely choosing
128 these parameter is therefore crucial to determine the reconciliation or the imbalance of carbon
129 budget.

130 In this respect, we rely on model inversion methods (Tarantola 2005) to provide meaningful
131 estimations of parameters of interest. For a given phenomenon, inversion methods rely on a

132 model taking as input the parameters to be estimated and whose outputs can be compared with
133 *in situ* measurements. The inversion procedure thus gives the value of the parameters that best
134 replicate the *in situ* measurements. This type of procedure has already been used in
135 oceanography modeling. For instance, Saint-Béat et al. (2018) studied phytoplankton marine
136 food web in the Arctic and Saint-Béat et al. (2020) examined pelagic ecosystems of two
137 different zones in the Arctic Baffin Bay using inversion method and sensitivity analyses to
138 identify which biological processes impact the most the planktonic ecosystem functioning.

139 Here, we investigate the impact of widely but inadequately used parameters associated with
140 the prokaryotic remineralization (e.g. CF, PGEs) on the magnitude of the discrepancy. Our
141 aims are: 1) to highlight the most sensitive parameters for which the determination of an
142 accurate value is critical in the context of balancing the mesopelagic carbon budget; 2) to
143 perform a mathematical inversion method to estimate the most plausible *in situ* values of the
144 most sensitive parameters from a limited field dataset; 3) to discuss our results in the context
145 of mesopelagic carbon budget.

146 **2. Material & methods**

147 **2.1 *In situ* Data**

148 Most of the data used in this study originated from the DY032 (June-July 2015) cruise at the
149 PAP (Porcupine Abyssal Plain) site in the North Atlantic onboard the RRS Discovery. Some
150 data unavailable for DY032 were estimated from a previous PAP cruise, D341 (July-August
151 2009). Most of the *in situ* data were compiled from already published cruise data (e.g. Giering
152 et al. 2014; Belcher et al. 2016; Baumas et al. 2021; Fuchs et al. 2022). Their post-treatments
153 to suit our study framework are described below. Additionally, we used data (ectoenzymatic
154 activities along with total hydrolysable amino acids and carbohydrates, depth profile of
155 heterotrophic prokaryotic production and respiration under *in situ* pressure versus atmospheric)
156 from the PEACETIME cruise (Guieu et al. 2020) that occurred in May 2017 in the
157 Mediterranean Sea to illustrate some points in our discussions (see supp data).

158 **2.1.1 Carbon fluxes**

159 **a) Determination of the Active Mesopelagic zone boundaries**

160 Fuchs et al. (2022) introduced the “RUBALIZ” method, using CTD data, which allows the
161 estimation of vertical boundaries targeting the zone of the dark ocean where most of the POC

162 fluxes attenuation occurs. At station PAP during cruise DY032, this so-called “Active
163 Mesopelagic Zone” was located between 127 and 751 m.

164 **b) Carbon inputs**

165 The POC inputs to the active mesopelagic zone mainly involve the gravitational export of POC.
166 Gravitational input was taken from Fuchs et al. (2022) who fitted a power law Martin curve (b
167 of 0.84) on data obtained from 30 to 500m using Marine Snow Catcher (Belcher et al. 2016).
168 However, gravitational input is not the only POC input known in the literature. Recently, Boyd
169 et al. (2019), provided an estimation of other particle-injection pumps (PIPs) such as the mixed
170 layer pump, physical pump, the seasonal lipid pump or the active transport related to metazoans
171 migrations. At the PAP site during summer, only the eddy subduction pump, metazoans
172 migrations, and large-scale physical pumps were relevant to take into account. Other PIPs do
173 not correspond to the location and season considered in our study. From Boyd et al. (2019)
174 review, these three particle-injection pumps seem to represent altogether around 52% of the
175 gravitational export of POC. We therefore add up this proportion of POC to the purely
176 gravitational inputs. This yields an overall POC flux of $134 \text{ mg C m}^{-2} \text{ d}^{-1}$ exported into the
177 active mesopelagic zone. The corresponding net POC input is $117 \text{ mg C m}^{-2} \text{ d}^{-1}$ (that is POC
178 fluxes at the end - 751 m - of the active mesopelagic zone subtracted to the one at the start -
179 127 m - for PAP DY032).

180 DOC inputs are taken from Giering et al. (2014) and are considered as the sum of direct DOC
181 export via physical processes (advection-diffusion) and active flux from zooplankton
182 migrations. We estimated from their extended Data Fig. 2 that the DOC gradient below 100m
183 is hardly visible meaning that physical vertical DOC export is insignificant for the active
184 mesopelagic zone which is studied here. As a result, we set the DOC export at $3 \text{ mg C m}^{-2} \text{ d}^{-1}$,
185 which corresponds only to the active flux from zooplankton migrations from Giering et al.
186 (2014).

187 **c) Carbon demands**

188 As explained above, prokaryotic carbon demand is generally assessed by adding rates of
189 prokaryotic heterotrophic production (PHP) to that of prokaryotic respiration (PR). PHP of
190 non-sinking prokaryotes (that is, free-living and attached to suspended particles prokaryotes)
191 are derived from leucine incorporation measurements on seawater samples and are taken from
192 Fuchs et al. (2022). These data did not permit the separation of the free-living from attached to
193 suspended particles (Baumas et al. 2021). Hence, in the sequel, we no longer make this

194 distinction and group both types under the term “non-sinking prokaryotes”. During DY032,
195 Marine Snow Catchers (MSC) were deployed to separate slow and fast-sinking particles from
196 100L of samples (Riley et al. 2012; Baumas et al. 2021). PHP rates associated with prokaryotic
197 communities of fast-sinking particles were taken from Baumas et al. (2021) and slow-sinking
198 particles are presented here. Briefly, slow-sinking particle fractions were sampled in the 7L
199 base of the MSC. Samples were incubated and leucine incorporation rates were measured as
200 for fast-sinking particles in Baumas et al. (2021). The formula described in Baumas et al. (2021)
201 was then applied to normalize to 100L as particles were concentrated in 7L after 2h of
202 decantation and to remove the contribution of non-sinking prokaryotes which were initially in
203 this compartment around slow-sinking particles of interest. Total sinking prokaryotes PHP
204 rates were obtained by adding both fast-sinking and slow-sinking prokaryotes PHP rates. In
205 addition, we were able to use the respiration rates of fast-sinking particle-attached prokaryotes
206 particles obtained at the PAP site during the DY032 cruise by Belcher et al. (2016). For each
207 depth (30-500m) the mean total O₂ consumption per particle in nmol particle⁻¹d⁻¹ was converted
208 to mg C m⁻³ d⁻¹ (assuming a respiration quotient RQ(CO₂/O₂) = 1) by multiplying by the total
209 number of particles (i.e. fecal pellets + phytoplanktonic aggregates) and dividing by 95L which
210 is the volume of the MSC used (Riley et al. 2012). It is also important to note that PR for slow-
211 sinking particles is missing. Thus, when we mention the respiration of sinking prokaryotes,
212 only fast-sinking particle-attached prokaryotes are taken into account which certainly
213 underestimates the respiration used. All prokaryotic carbon demand (PHPs and PRs) estimates
214 were integrated within RUBALIZ boundaries (i.e. 127m - 751m). Non-sinking prokaryotes
215 PHP rates were integrated using a piecewise model with a single node on the log-data as
216 described in Fuchs et al. (2022). Sinking prokaryotes PHP rates were integrated using power
217 law. Sinking PR were integrated using trapeze because data are only available until 500m and
218 without any *a priori* on the curve shape, this method is certainly the most conservative.

219 Zooplankton activities are known to be related to POC concentration (Steinberg et al. 2008).
220 Zooplankton respiration data were available only for the cruise D341 when the net POC input
221 into the active mesopelagic layer was 59 mg C m⁻² d⁻¹ (including PIPs) instead of 134 mg C m⁻²
222 d⁻¹ for DY032 (see above). For D341, zooplankton respiration integrated within the active
223 mesopelagic zone (135-726m, Fuchs et al. 2022) was 9 mg C m⁻² d⁻¹. Zooplankton respiration
224 was integrated using a power law as in Giering et al. (2014). Zooplankton respiration data are
225 missing for DY032, thus we consider this quantity as a percentage of the POC input that we
226 calculate from the D341 data set, i.e. 14.67%. The zooplankton respiration value used here is
227 therefore 17 mg C m⁻² d⁻¹.

228 *Table 1: Fluxes and their associated values used in this study. Anderson & Tang model's terms*
 229 *(Anderson and Tang 2010) corresponding to these fluxes are also shown. Values are integrated*
 230 *between 127 and 751m which are boundaries of the active mesopelagic zone defined by Fuchs*
 231 *et al. (2022). POC and DOC refer respectively to Particulate and Dissolved Organic Carbon,*
 232 *PHP to Prokaryotic Heterotrophic Production, and PR to Prokaryotic Respiration.*

Name	Anderson and Tang's Model term correspondence	Values	units	sources
Net POC input	D_{lex}	117	mg C m ⁻² d ⁻¹	Belcher et al. (2016); Boyd et al. (2019)
DOC input	DOC_{ex}	3	mg C m ⁻² d ⁻¹	Giering et al. (2014)
Non-sinking prokaryotes PHP	$F_{BFL} + F_{BAD2}$	1.10E+07	pmol Leu m ⁻² d ⁻¹	Baumas et al. (2021)
Sinking prokaryotes PHP	F_{BAD1}	1.02E+06	pmol Leu m ⁻² d ⁻¹	Baumas et al. (2021)
Sinking prokaryotes PR	R_{BAD1}	19	mg C m ⁻² d ⁻¹	Adapted from Belcher et al. (2016)
Zooplankton respiration	$R_{VA} + R_{VFL} + R_{H} + R_{Z1:6}$	17	mg C m ⁻² d ⁻¹	Adapted from Giering et al. (2014)

233

234 **2.2 Mathematical methods**

235 **2.2.1 Parameter estimation**

236 The scope of our study is to estimate *in situ* parameters by inverting the model introduced by
 237 Anderson and Tang (2010), adapted by Giering et al. (2014). We do not intend to present the
 238 model in details here. The details of the equations constituting the version of the model used
 239 can be found in the original paper (Anderson and Tang 2010), in the R code available at
 240 <https://github.com/RobeeF/InverseCarbonBudgetEstim> and the specific terms related to
 241 variables used are reported in Table 1. The model is calibrated by choosing the set of input

242 parameters that yields the best fit between the model output and the data. As the model outputs
243 85 outfluxes, we used a subset of four measurable outfluxes to calibrate the model: the PHP of
244 non-sinking prokaryotes, the PHP of sinking prokaryotes, the PR of sinking prokaryotes and
245 the respiration of zooplankton. These fluxes have been chosen because of their near direct
246 correspondence with outputs of the model linked to the C demand of all groups (sinking
247 prokaryotes, non-sinking prokaryotes, detritivores, bacterivores, and carnivores).

248 Similarly, the model relies on 20 input parameters (Table S1), which makes the parameter
249 space of significant size and therefore challenging to explore. As such, we first determine the
250 set of parameters that have the largest impact on the output of the model. Then for these
251 parameters, the values that give the best fit between the data and the solution given by the
252 model are determined.

253 **a) Sensitivity of the model to its inputs**

254 In order to reduce the size of the input parameter space, Sobol Indices (Sobol 1993) were used
255 to determine the most influential parameters. These indices enable quantification of the share
256 of the variation of the output that can be imputed to each input parameter.

257 In essence, the first-order Sobol indices account for the direct influence of an input variable on
258 the output. However, first-order Sobol indices neglect the interactions existing between this
259 input variable and the other input variables. As such, in addition to the first-order Sobol Indices,
260 we used the total Sobol indices introduced by Homma and Saltelli (1996) which encompass
261 both the direct effect of a parameter and also its interactions with the other parameters.

262 First-order and total Sobol indices were computed to quantify the influence of each parameter
263 over each of the four outfluxes. Only the parameters which had significant Sobol indices (i.e.
264 Sobol indices > 0.20) for at least one outflux were kept.

265 **b) Estimation of the parameters**

266 The parameters which had no substantial effects on the output of the model were set to the
267 values indicated by Anderson and Tang (2010) and Giering et al. (2014) and given in Appendix
268 (Table S1). The other parameters were estimated by minimizing the distance existing between
269 the four outfluxes predicted by the model and their *in situ* measured counterpart. The distance
270 chosen here is a standardized Euclidean distance:

271

272

$$\sum_{i=1}^4 \left(\frac{\text{outflux}_{\text{obs},i} - \text{outflux}_{\text{model},i}}{\text{outflux}_{\text{obs},i}} \right)^2 \quad (1)$$

273

274

275

276

277

278

279

280

where $\text{outflux}_{\text{obs},i}$ is the i -th measured flux and $\text{outflux}_{\text{model},i}$ its modeled counterpart. The optimization method used is the Nelder-Mead algorithm (Nelder and Mead 1965): if the function to minimize depends on N variables (the number of input parameters here), a simplex constituted by $N + 1$ points is defined. The coordinates of the simplex are updated in turn so that the simplex vertices get closer to the local minimum. Even if this method gives little theoretical guarantees of convergence, it has proven to work well in practice (Lagarias et al. 1998) and has the advantage that it does not require computing the gradient of each outflux with respect to each input parameter.

281

282

283

284

285

286

287

288

289

290

291

As the model takes 20 inputs and outputs 85 fluxes, concerns might be raised about the uniqueness of the solution found to minimize the term (1). To make the model identifiable (i.e. sufficiently constrained to estimate the true value of the parameters), the number of input parameters to estimate is limited to the number of output fluxes available, here four. In this respect, the CFs have been fixed to $0.5 \text{ kg C mol Leu}^{-1}$ (Estimates without fixing the CFs have however been carried out, see Table S4 in supp. data). This value, contrary to the previously classically used value of $1.55 \text{ kg C mol Leu}^{-1}$ (Simon and Azam 1989; Nagata et al. 2010), was determined by Giering and Evans (2022) as the median value of 15 studies conducted in the mesopelagic zone. Doing so, we limit the number of free parameters to be estimated to four so that the model remains identifiable. The model is mostly linear and our experiments have shown the solution to be unique and independent of the initial values taken.

292

293

The codes and data to reproduce the results are available at <https://github.com/RobeeF/InverseCarbonBudgetEstim>

294

3.Results

295

3.1 Most sensitive parameters

296

297

298

299

300

Using Sobol indices, we identified the most sensitive parameters from the 20 of the Anderson and Tang (2010) model on the 4 fluxes outputs of the model for which we have the measured counterpart (i.e. PHP and PR of sinking prokaryotes, PHP of non-sinking prokaryotes and respiration of zooplankton). All parameter definitions are given in Table S1. For the outflux “PHP of non-sinking prokaryotes”, only the $\text{PGE}_{\text{non-sinking}}$ appears to be sensitive with a Sobol

301 index of 0.68 meaning that it explains 68% of the variance (Table 2). Fluxes related to sinking
302 prokaryotes, i.e. their PHP and their PR, appear to be highly influenced both by Ψ , α , and
303 PGE_{sinking} . For instance, our analysis yields to indices of 0.22 and 0.23 for Ψ , 0.24 and 0.24 for
304 α and 0.27, 0.25 for PGE_{sinking} respectively. Surprisingly, zooplankton respiration is more
305 impacted by the $PGE_{\text{non-sinking}}$ (Sobol index of 0.52) than proper zooplankton parameters. All
306 other parameters exhibit Sobol indices below 1%. Total Sobol indices, indicating the part of
307 the variance of fluxes due to the parameter alone and in interaction with the others, were similar
308 to the first-order indices, suggesting no interactions of parameters regarding the variance of
309 fluxes. This sensitivity analysis enabled the identification of Ψ , α , and both PGEs as the most
310 influential parameters, suggesting that their values should be set with particular care. Especially
311 for the $PGE_{\text{non-sinking}}$ which can be responsible for more than 50% of the variance of $PHP_{\text{non-}}$
312 $_{\text{sinking}}$ and zooplankton respiration. PGEs are growth efficiencies defined as the amount of new
313 prokaryotic biomass produced per unit of organic C substrate assimilated and is a way to relate
314 PHP and PR (del Giorgio and Cole 1998). Ψ corresponds to the percentage of POC consumed
315 by prokaryotes and α to the fraction of hydrolyzed POC which is lost into the surrounding
316 water, i.e. not assimilated by sinking prokaryotes that hydrolyzed it.

317 *Table 2: First-order Sobol indices for the parameters of the model by Anderson and Tang*
318 *(2010). The definition of each parameter can be found in Table S1. Significant Sobol indices*
319 *(>0.2) are shown in red. PHP and PR respectively refer to Prokaryotic Heterotrophic*
320 *Production and to Prokaryotic Respiration.*

	Ψ	PGE_{sinking}	$PGE_{\text{non-sinking}}$	α	Φ_v	β_v	K_v	Φ_v	β_v	K_v	Φ_z	β_z	λ_z	K_z	Φ_h	β_h	λ_h	K_h	ζ	ζ^2

3.2 Model inversion

The optimization method, described in the material and method section, enabled the determination of the 4 parameters identified as sensitive above: Ψ , α , PGE_{sinking} , and $PGE_{\text{non-sinking}}$ in the case study of PAP DY032. Table 3 reports the combination found by model inversion. By construction of the procedure (e.g. same number of input and output), the solution is unique, explaining why no confidence intervals are reported. The errors between the four fluxes generated by the model and their measured counterparts were less than 1%, far lower than potential measurement errors. The zooplankton flux was the best matched, followed by the PR of the sinking prokaryotes, the PHP of the non-sinking prokaryotes, and of the sinking prokaryotes.

333

Table 3: Estimation of the parameters Ψ , α , PGE_{sinking} and $PGE_{\text{non-sinking}}$ obtained by inversion of the model by Anderson and Tang (2010). As the model was made identifiable, the solutions are unique, explaining the absence of confidence intervals. The remaining differences between the model outfluxes deriving from the estimated input values and the actual in situ measurements are referred to as “Errors” and are expressed in percentage. PHP, PR, and ZR respectively stand for Prokaryotic Heterotrophic Production, to Prokaryotic Respiration and to Zooplankton Respiration.

Estimations				Errors			
Ψ	α	PGE_{sinking}	$PGE_{\text{non-sinking}}$	$PHP_{\text{non-sinking}}$	PHP_{sinking}	PR_{sinking}	ZR
0.675	0.777	0.026	0.087	-0.487%	0.524%	0.184%	-0.05%

341

342

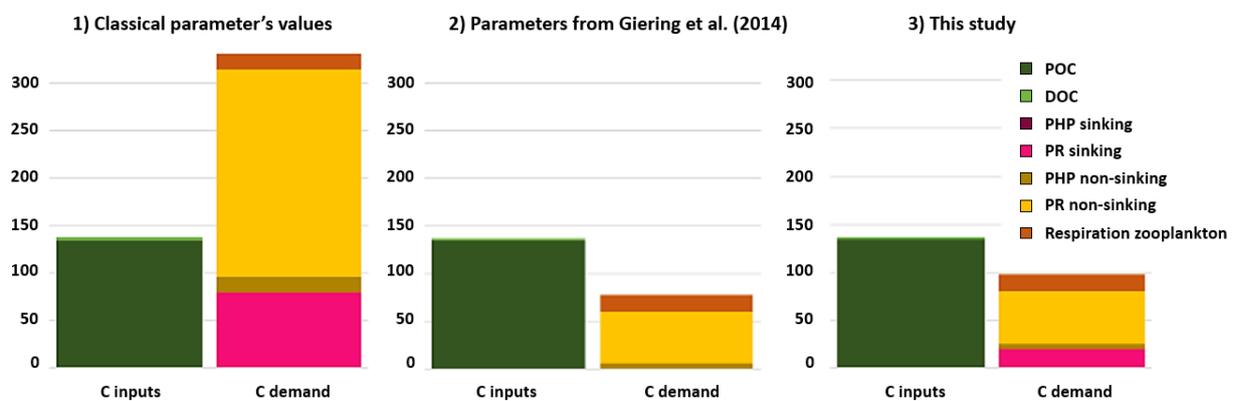

3.3 C budget

344

The two PGEs presented above along with CF of $0.5 \text{ kg C mol Leu}^{-1}$ were applied to leucine-incorporation rates measurements to build the corresponding active mesopelagic C budget. The resulting C budget was compared with two other C budgets calculated with different sets of parameters. The three active mesopelagic zone C budgets resulting from DY032 measurements or estimation are represented in Fig. 1 with the budget (1) obtained with the classical CF value of $1.55 \text{ kg C mol Leu}^{-1}$ and median literature values for PGEs, i.e. 0.07 for $PGE_{\text{non-sinking}}$ (Arístegui et al. 2005; Reinthaler et al. 2006; Baltar et al. 2010; Collins et al. 2015) and 0.02 for PGE_{sinking} (Collins et al. 2015); the budget (2) obtained with the parameter values from

352

353 Giering et al. (2014) who reconcile C budget, i.e. CF of 0.44 kg C mol Leu⁻¹, PGE_{non-sinking} of
 354 0.07, and PGE_{sinking} of 0.24 and the budget (3) obtained with a CF, PGE_{sinking} and PGE_{non-sinking}
 355 of 0.5, 0.026 and 0.087, respectively, determined in this study. The combination yielding to the
 356 largest discrepancy is the budget (1) (Fig. 1) (discrepancy of -194 mg C m⁻² d⁻¹). The C input
 357 seems to support the zooplankton respiration and total C demand of sinking prokaryotes but
 358 not the one of non-sinking prokaryotes especially due to their PR of 218 mg C m⁻² d⁻¹.
 359 Combination of budget (2) and (3) presented both an excess of C (60 and 40 mg C m⁻² d⁻¹
 360 respectively) compared to the biological C demand. These two differ mainly on the PR of
 361 sinking prokaryotes which is negligible in combination (2) but which is the second largest flux
 362 in the C demand in our study. In all cases, the C demand of non-sinking prokaryotes accounts
 363 for most of the total C demand.

364

370 4. Discussion:

371 As stated in the introduction, the scientific community has struggled to reconcile the
 372 mesopelagic carbon budget with measurements and estimates showing a carbon demand often
 373 greater than the amount of known organic C sources (e.g. Reinthaler et al. 2006; Steinberg et
 374 al. 2008; Burd et al. 2010; Collins et al. 2015; Boyd et al. 2019). Building C budget involves a
 375 plethora of parameters whose impacts are overlooked and often neglected, mainly because
 376 neither their ideal values nor their underlying mechanism in the water column across space and
 377 time are clearly understood. The scientific community is concerned about this issue (e.g. Burd
 378 et al. 2010; Giering and Evans 2022), but in the absence of a better option and in an attempt to

379 encourage comparisons, the same parameter values are universally used. A first step towards
380 this direction was conducted thanks to the RUBALIZ method (Fuchs et al. 2022) which
381 precisely determines the vertical location of the “active mesopelagic zone” and thereby
382 estimates the boundaries between which to integrate C fluxes. In the current study, we pursue
383 this investigation and combine measurements with modeling approaches to investigate the role
384 of sensitive parameters related to the remineralization of POC in the mesopelagic zone.

385 **4.1 Optimization method: Consistency of parameters estimated**

386 The Anderson and Tang (2010) model takes as inputs the measured C inputs as well as 20
387 parameters related to the activity of organisms such as sinking prokaryotes, non-sinking
388 prokaryotes, zooplankton detritivores, bacterivores, and carnivores. Among the 20 parameters,
389 four have been found to be particularly sensitive in assessing the carbon demands of the various
390 groups: Ψ (percentage of particle consumption by prokaryotes), α (percentage of C hydrolyzed
391 released in surrounding water), $PGE_{\text{non-sinking}}$ and PGE_{sinking} (growth efficiencies of sinking and
392 non-sinking prokaryotes). It is interesting to note that zooplankton respiration (which is the
393 sum of detritivores, bacterivores and carnivores respiration) is mostly sensitive to one
394 parameter: $PGE_{\text{non-sinking}}$ but not to a parameter specific to zooplankton. This counter-intuitive
395 result suggests a strong synergy between the two model compartments. At this point, it is
396 challenging to establish whether this is the outcome of a complex ecological process or a model
397 artifact.

398
399 In the model, the consumption of particles is done by two groups: prokaryotes (Ψ) and
400 detritivores ($1-\Psi$). It can be estimated by taking the average ratio between PHP and ZR.
401 Anderson and Ryabchenko (2009) estimated Ψ using calculations of POC consumption by
402 prokaryotes and zooplanktons between 150 and 1000m performed by Steinberg et al. (2008) in
403 the Pacific. Following this, they set Ψ at 0.76. The inversion of the Anderson and Tang model
404 (2010) leads to a well-identified solution of Ψ , i.e. 0.67 in the case of PAP DY032 cruise. This
405 value is in line with the one used by Anderson and Tang (2010). However, data are lacking to
406 compare and explore variations of Ψ value across seasons, locations or depths. In the model, Ψ
407 participates in the repartition of POC input between prokaryotes and detritivores. Whether for
408 modeling purposes to determine Ψ or to build a C-budget without a model, PHP and ZR are
409 required. It remains too rare to have both together and more future efforts should be devoted to
410 get PHP and ZR concomitantly.

411

412 Beyond Ψ , according to Sobol indices, α is the second parameter of interest. When prokaryotes
413 consume POC using hydrolytic enzymes, a major fraction of the hydrolyzed C is lost to the
414 surrounding environment as DOC (Smith et al. 1992; Vetter et al. 1998). This loss is
415 represented by α and is very difficult to quantify accurately. Two major experiments, focused
416 on amino acid hydrolysis, aimed to determine such losses: Smith et al. (1992) and Grossart and
417 Ploug (2001). Smith et al. (1992) sampled particles at 25m and showed that 97% of particulate
418 combined amino acids are released in the surrounding water. Later, Grossart and Ploug (2001)
419 using aggregates from phytoplankton cultures show a loss of POC of 74%. Relying on these
420 two studies, Anderson and Tang (2010) followed by Giering et al. (2014) consider that the
421 value should be lower than that of a fresh detritus and choose a conservative value of 0.5. In
422 the case of these two experiments, only the amino acids are considered and the experiments
423 were conducted under laboratory-controlled settings. However, both, amino acids and sugar
424 are major components of POC, constituting between 40 to 70% of POC in the mesopelagic
425 zone (Wakeham et al. 1997). Conversely, we used unpublished data from PEACETIME cruise
426 (see methods details in supp. data) of *in situ* hydrolysis rates of aminopeptidase and β -
427 glucosydase from sinking prokaryotes (which hydrolyze amino acids and sugar, respectively)
428 that we were able to convert into hydrolyzed carbon fluxes (see measurements and calculation
429 details in supp. data). Unfortunately, total hydrolyzed C fluxes were most of the time below
430 the C demand of the sinking prokaryotes which is unrealistic and probably due to the low
431 amount of POC (sinking POC concentration of $<1 \text{ mg L}^{-1}$ in the sinking fraction) resulting in
432 insufficient sinking prokaryotes abundance to detect their activity by volume. However, when
433 total hydrolyzed C fluxes were superior to $\text{PHP}_{\text{sinking}}$ (indicating that some hydrolyzed C is not
434 assimilated and is released), α was estimated between 0.19 and 0.79 with a mean of 0.41 ± 0.24
435 and seems to decrease with depth (see calculations details in supp data). This could confirm
436 Grossart and Ploug's (2001) work showing that the older a detritus is, the less enzymatic
437 activity there is and therefore the less amino acid loss. Even if α is not measurable easily, this
438 parameter is identified at 0.78 by the inversion method during a post-bloom period at the PAP
439 site. This value is consistent with Smith et al. (1992) and Grossart and Ploug (2001) evidencing
440 high α for surface aggregates (0.97) with laboratory-made phytoplankton aggregates (0.74), or
441 with our calculations for the Mediterranean Sea (0.41 ± 0.24), an oligotrophic region. This
442 suggests that the optimization method is a relevant alternative to determine α . In addition, α
443 corresponds to a release of C in the surrounding water. Regarding the model, the C demand of
444 free-living prokaryotes matches the hydrolyzed C released which constitutes their main C
445 sources. The relationship between enzymatic activities and heterotrophic production of free-

446 living prokaryotes is well documented in the deep-sea ocean (Cho and Azam 1988; Smith et
447 al. 1992; Hoppe and Ullrich 1999; Tamburini et al. 2002, 2003; Nagata et al. 2010). Total C
448 demand of non-sinking prokaryotes is challenging to measure due to the diversity of existing
449 methods, especially the PR (e.g. Table S2), which leads to an incredibly wide range of
450 estimated values. Subsequently, identifying α via the optimization method could help to avoid
451 these conflicting PR measurements.

452

453 The last two sensitive parameters according to Sobol indices were $PGE_{\text{non-sinking}}$ and PGE_{sinking} .
454 A wide range of $PGE_{\text{non-sinking}}$ has been estimated using $PHP_{\text{non-sinking}}$ and $PR_{\text{non-sinking}}$ in the open
455 ocean (e.g. Sherry et al. 1999; Lemée et al. 2002; Carlson et al. 2004; Arístegui et al. 2005;
456 Reinthaler et al. 2006; Baltar et al. 2009, 2010; Collins et al. 2015). Overall it varies from 0.001
457 to 0.64 (Collins et al. (2015) and Sherry et al. (1999), respectively). However, these values
458 were produced from different protocols for the PHP (changes in biomass, thymidine or leucine
459 incorporation, each with its own conversion factors and/or constants) and for the PR methods
460 (by ETS measurements, micro-winkler titration, changes in dissolved O_2 , or using optodes
461 sensors spots, see Table S2) and correspond to various locations, seasons and depths. These are
462 all valid reasons that can potentially explain the stark contrast in the values reported. If one
463 focuses only on the mesopelagic zone in the North Atlantic, the median is 0.07 (Arístegui et al.
464 2005; Reinthaler et al. 2006; Baltar et al. 2010; Collins et al. 2015). The optimization method
465 yielded to a value of 0.087 and therefore produces very consistent results for a post-bloom
466 period at the PAP site. Concerning PGE_{sinking} , too few values are available. To our knowledge,
467 only Collins et al. (2015) provided *in situ* values associated with sinking prokaryotes (from
468 0.01 to 0.03) at 150m. This is the only comparison we have, and our value of 0.026 matches
469 this order of magnitude. As a further comparison, the non-integrated data from DY0312 allows
470 us to calculate a PGE_{sinking} (using $PGE_{\text{sinking}} = PHP_{\text{sinking}} / (PHP_{\text{sinking}} + PR_{\text{sinking}})$) according to del
471 Giorgio and Cole (1998). The result is thus, a depth-specific PGE instead of a depth-integrated
472 PGE. This led to a variation from 0.033 at 70m to 0.0013 at 500m. Although the lack of
473 datapoints deeper than 500m and the low number of points forces us to stay cautious about
474 these estimates, it may indicate that PGE_{sinking} is not constant throughout the mesopelagic zone
475 and decreases with depth. Constraining conditions due to the increase of hydrostatic pressure
476 and decrease in temperature experienced by prokaryotes attached to sinking particles could
477 explain this decrease in PGE_{sinking} (Stief et al. 2021; Tamburini et al. 2021). Under highly
478 constrained conditions, Russell and Cook (1995) explained that maintaining respiration at the
479 highest possible rate would allow the supply of active membrane transporters which are vital
480 to the cell. This implies a low but optimal PGE (Westerhoff et al. 1983) which could thus

481 decrease with depth and time as the POC becomes less labile (Grossart and Ploug 2000). On
482 the contrary, the Anderson and Tang (2010) model, and the associated model inversion
483 presented here, is built so that the mesopelagic zone is considered as one homogeneous entity.
484 Explicitly, specifying depth-dependent PGE_{sinking} in the mesopelagic zone could lead to more
485 realistic modeling, but would entail a non-negligible additional model complexity.

486

487 It is worth noting that the PGE_{sinking} and $PGE_{\text{non-sinking}}$ estimated here rely on a leucine-to-carbon
488 Conversion Factor (CF) of $0.5 \text{ kg C mol Leu}^{-1}$. This value comes from the median of 15 values
489 obtained on the free-living prokaryotes of the mesopelagic zone (between 300 to 1000m),
490 which do not sink and are adapted to their place in the water column (Giering and Evans 2022).
491 However, to our knowledge, there are no such values measured for the specific case of sinking
492 prokaryotes. The latter are surface prokaryotes that have attached to the particles and will
493 experience changes in conditions (e.g. pressure, temperature) linked to their sink (Baumas et
494 al. 2021; Tamburini et al. 2021). The CF depends, among other things, on the leucine fraction
495 in the proteins and the cellular carbon/protein ratio (Kirchman and Ducklow 1993). It is known
496 that stresses can affect the incorporation of leucine into proteins and general protein production
497 (e.g. Young 1968; Welch et al. 1993) and that these parameters can vary with prokaryotic
498 diversity, especially between bacteria and archaea (Bogatyreva et al. 2006). Stresses occur
499 during the descent throughout the water column and sinking prokaryotes experienced a drastic
500 decrease in diversity following the sink at PAP DY032 (Baumas et al. 2021; Tamburini et al.
501 2021). We can therefore easily imagine that the CF for sinking prokaryotes could be impacted.
502 Despite this, without having further data, we applied the same CF on sinking as the 0.5
503 recommended by Giering and Evans (2022) for non-sinking prokaryotes.

504

505 **4.2 Influence on mesopelagic C Budget**

506 As stated in the introduction, mesopelagic C budgets are constructed by applying a CF and a
507 PGE on leucine incorporation rates data to assess prokaryotic C demand. In Fig. 1, we applied
508 three different combinations of CFs and PGEs to the same data. The combination using
509 conventional CF of $1.55 \text{ kg C mol Leu}^{-1}$, $PGE_{\text{non-sinking}}$ of 0.07, and PGE_{sinking} of 0.02 led to an aberrant
510 discrepancy such that more than the entire C pool would be remineralized in the active
511 mesopelagic zone and that there would be no source of C to sustain deeper zone life nor
512 sequestration by the BCP. As stated above, this was a recurrent issue in the field (Reinthal et
513 al. 2006; Steinberg et al. 2008; Burd et al. 2010; Collins et al. 2015; Boyd et al. 2019) with the
514 exception of Giering et al. (2014) who reconcile the C budget of the mesopelagic zone. Giering

515 et al. (2014) results were mainly due to the difference in CF applied on their data, i.e. 0.44 kg
516 C mol Leu⁻¹. However, from a model point of view, the main difference between C budgets
517 estimated using Giering et al. (2014) parameters and those determined by our optimization
518 method is due to the 10-fold difference between PGE_{sinking} used. Giering et al. (2014) used 0.24
519 which is the mean of a 14 days incubation experiment during which PGE varied from 0.45 in
520 the first 3 days to 0.04 at the end for riverine aggregates (Grossart and Ploug 2000). Despite
521 the fact that PGE_{sinking} data are very scarce, riverine values of 0.24 seem highly unlikely and
522 inappropriate to mesopelagic sinking prokaryotes compared to what is known in marine
523 environments (e.g. Collins et al. 2015). Indeed, if we consider that enzymes account for a large
524 proportion of the proteins produced by cells (see above) the PGE_{sinking} must be low due to the
525 high metabolic cost of their production (Grossart and Ploug 2000). Finally, the C budget built
526 from a combination of CFs of 0.5 kg C mol Leu⁻¹ and PGEs revealed by our optimization method
527 seems the most reasonable option (from the three budgets built, Fig. 1) with an excess of C
528 input of 40 mg C m⁻² d⁻¹. In this case, PGEs were determined by the model, which in addition
529 to PHP and PR of sinking and non-sinking prokaryotes and zooplankton respiration, also
530 accounts for the production of zooplankton biomass into calculations. We do not have
531 measurements or estimates for the production of zooplankton biomass but based on the model,
532 this biomass production is 11 mg C m⁻² d⁻¹. Adding this value to the C demand implies a leftover
533 of 29 mg C m⁻² d⁻¹ that is not used and is exported below the active mesopelagic zone via
534 gravitational sinking POC. This value is in accordance with the POC flux estimated from
535 measures at 751m (thus at the exit of our zone): 17 mg C m⁻² d⁻¹. Being aware of the biases that
536 may exist in the fluxes used as well as in the construction of the model itself, our optimization
537 method enables the determination of realistic values of parameters and thus constructing robust
538 C budgets. As far as we know, the combination of field measurements (using consistently
539 defined integration depths, such as RUBALIZ (Fuchs et al. 2022) with the use of optimization
540 method on the Anderson & Tang model has led to the most complete and realistic mesopelagic
541 carbon budget.

542

543 **4.3 Model: reliability and potential biases**

544 The Anderson and Tang model (Anderson and Tang 2010) was originally parametrized with
545 20 input parameters and 85 output fluxes, and is hence by definition an underdetermined model
546 as the number of outputs is higher than the number of inputs. To make the model identifiable,
547 i.e. obtaining unique solutions for each parameter value, the number of parameters allowed to
548 vary, namely: Ψ , α , PGE_{non-sinking}, and PGE_{sinking}, was restricted to the number of measurable

549 outputs (here four, PHP_{sinking} , PR_{sinking} , $PHP_{\text{non-sinking}}$, and zooplankton respiration).
550 Measurement errors (e.g. measurement device errors, *in situ* variabilities, errors due to
551 integration methods) are typically challenging to characterize. Furthermore, even if these four
552 outfluxes well describe the prokaryotic and zooplankton compartment fluxes, one may wonder
553 about the sensitivity of the results to the fact that a given outflux is not available or estimated
554 with error.

555

556 As a result, we have tested two settings: a model inversion without the zooplankton respiration
557 flux (using only three fluxes) and a second setting where the PGEs were estimated from the
558 leucine incorporation rate using freely varying CFs, i.e. with CFs no more fixed at 0.5 as a
559 value. The results are reported in Table S3 and S4. Not using the zooplankton flux to inverse
560 the model mechanically adds some variability to the estimation results, especially concerning
561 Ψ , α , and $PGE_{\text{non-sinking}}$, in decreasing order of variability (Table S3). The PGE_{sinking} was not
562 affected as its confidence interval length was inferior to 10^{-7} : this underlines the very limited
563 interaction between the zooplankton and sinking prokaryote compartments in the model
564 (contrary to the zooplankton and non-sinking prokaryote compartments). Yet, the difference
565 between the four-flux and three-flux parameter estimations was negligible (<1% variation for
566 each estimate), highlighting the robustness of the estimates to the potential unavailability of
567 the zooplankton respiration. On the contrary, as made visible in Table S4, not fixing the CFs
568 to estimate the PGEs created more variations in the PGE estimations, while the estimations of
569 Ψ and α changed by less than 5% with respect to Table 2 estimations. The PGEs of the attached
570 and free-living parameters get significantly closer to their fixed boundaries (10%), while the
571 CFs rise, especially the CF of the attached particles ($=1.87 \text{ kg C mol Leu}^{-1}$). Similarly, if PGEs
572 are no longer bounded, the estimates of PGEs (0.17 for attached prokaryotes and 0.23 for free-
573 living prokaryotes) and CFs ($3.93 \text{ kg C mol Leu}^{-1}$ for attached prokaryotes and 1.53 kg C mol
574 Leu^{-1} for free-living prokaryotes) become unrealistic. This can be explained by the fact that the
575 PGEs and CFs play similar mathematical roles in the current formulation of the model. Hence,
576 without additional fluxes ensuring full model identifiability, one of these two types of
577 quantities needs to be fixed to estimate the other.

578

579 In addition to these sensitivity analyses, an uncertainty analysis has been run by simulating
580 errors in the measurements of the POC, DOC and the four output fluxes (see Table S5 in supp.
581 data). Simulating errors from -10% to 10% for each flux, the estimation of the four parameters
582 of interest were lowly affected: 1%, 2%, 3% and 1% on average for the Ψ , PGE_{sinking} , $PGE_{\text{non-}}$
583 sinking and α , respectively. The $PGE_{\text{non-sinking}}$ was mostly sensitive to measurement errors of POC

584 flux, DOC flux and $\text{PHP}_{\text{non-sinking}}$ (generating variations of 6%, 5% and 5%, respectively).
585 Similarly, the $\text{PGE}_{\text{sinking}}$ was logically mostly sensitive to errors in the $\text{PHP}_{\text{sinking}}$ and $\text{PR}_{\text{sinking}}$
586 (generating variations of 6% for both). For the measurement errors, the generated variations all
587 remained under 3% which is reassuring concerning the stability of the estimation.

588

589 Finally, the last potential source of estimation bias results from the assumed stationarity
590 hypothesis of the mesopelagic system. For logistical and technical reasons, measurements and
591 sampling between the upper and lower boundary of the mesopelagic zone are typically
592 performed simultaneously. The stationarity assumption is thus a natural foundation ground
593 upon interpretations and models. However, there is a temporal delay in flux variations between
594 the upper layer and lower measurements (Giering et al. 2017; Stange et al. 2017). This delay
595 depends on the particles sinking speed typically ranging from 2 to 1500 m d⁻¹ (Alldredge and
596 Silver 1988; Armstrong et al. 2002; Trull et al. 2008; Turner 2015), their morphotype, density
597 and porosity as well as the timing of their production. Strong meteorological events can also
598 perturbate C fluxes from the water column with an increasing time lag over depth (e.g. Pedrosa-
599 Pàmies et al. 2019). Admittedly, C budgets suffer from lack of time integration into the
600 analysis. Our study regarding PAP site is also concerned as it undergoes a substantial
601 seasonality (Cole et al. 2012; Giering et al. 2017). Although, we do not have enough
602 understanding of vertical time lag to change the model and to avoid such bias yet. Some long-
603 term observatories such as BATS in the Bermuda Atlantic or HOT in Hawaii provide
604 biogeochemical flux time series but monthly sampling focuses mostly on the euphotic zone
605 and does not investigate the mesopelagic zone enough. Sampling at discrete times following
606 the sink of a bloom (e.g. Le Moigne et al. 2016) could be a solution, which would nevertheless
607 entail a significant cruise planning effort.

608

609 **4.4 Grounds for improvements**

610 Anderson & Tang model allowed us to have a comprehensive vision of the remineralization
611 processes in the mesopelagic zone by including the interactions between various
612 compartments, completing *in situ* measurements with a comprehensive vision of the
613 mechanisms at stake. The described inversion of the Anderson & Tang model provided
614 meaningful estimations of the parameters of interest. However, as most models represent
615 complex phenomena, some processes are not fully and properly captured by the model. Below,
616 we provide a list of processes that may help refining mesopelagic C budget estimations.

617

618 **4.4.1 Other microorganisms**

619 The role of microbial eukaryotes, viruses, and the input of C by chemolithotrophs (Herndl and
620 Reinthaler 2013; Lara et al. 2017; Kuhlisch et al. 2021; Luo et al. 2022) are not included in the
621 model. For instance, eukaryotes can dominate microbial biomass on bathypelagic particles
622 (Bochdansky et al. 2017), and have the potential to promote the aggregation of particles (Jain
623 et al. 2005; Chang et al. 2014; Hamamoto and Honda 2019; Xie et al. 2022). Viruses could be
624 the main cause of prokaryotic and phytoplanktonic mortality. Thus, DOC fluxes could be
625 attributed to them, in particular with the cell lyses they provoke (Fuhrman 2000 and ref within,
626 Lara et al. 2017; Kuhlisch et al. 2021). In the North Atlantic, 9 to 12% of cells could be infected
627 by viruses which would cause a DOC production of $0.1 \text{ mg C m}^{-3} \text{ d}^{-1}$ (Wilhem and Suttle 1999).
628 For comparison, PHP results on PAP before integration (with a conversion factor of 0.5 kg C
629 $\text{mol}^{-1} \text{ Leu}$) were mostly below this value. In addition, inorganic C fixation by chemoautotrophy
630 would be of the same order of magnitude as $\text{PHP}_{\text{non-sinking}}$ rates (Herndl et al. 2005; Reinthaler
631 et al. 2010). It would be important to verify what microbial eukaryotes, chemolithotrophs or
632 viruses contributions are, even if the poor understanding of these processes currently prevents
633 properly integrating them into models.

634

635 **4.4.2 Lifestyles**

636 Sinking prokaryotes are poorly considered as they are not sampled with the Niskin bottles
637 classically used in oceanography (Planquette and Sherrell 2012; Baumas et al. 2021). However,
638 the use of the MSC at PAP DY032 allows us to access fractions of particulate organic carbon
639 that will allow us to evaluate the importance of sinking prokaryotes. We have seen that their C
640 demand is not negligible and represents 18% of total C demand. Anderson & Tang model
641 distinguishes sinking particles from neutrally buoyant particles, each with distinct attached
642 communities. Since sampling with MSC only allows us to separate what is sinking from what
643 is not, we merged free-living prokaryotes with those attached to neutrally buoyant particles
644 without distinction. However, unlike free-living prokaryotes, prokaryotes attached to neutrally
645 buoyant particles have access to POC and must produce enzyme activity with different
646 metabolisms than their free-living counterparts. In contrast, prokaryotes attached to neutrally
647 buoyant particles are also different from prokaryotes attached to sinking particles since they do
648 not undergo changes in temperature and pressure related to the sink. They must therefore surely
649 have intrinsically different PGE and associated remineralization rates. It would therefore be
650 valuable to consider them as a third distinct group in laboratory experiments and sampling.
651 Contrary to the sinking or ascending particles which are naturally split by their

652 sinking/ascending velocity (e.g. respectively Smith et al. 1989; Cowen et al. 2001; McDonnell
653 et al. 2015), no means allow the selective and exclusive sampling of neutrally buoyant particles.
654 The only valid way is to use the MSC to let the sinking particles fall into the lower
655 compartments and to filter the "non-sinking" part to retain the particulate fraction. However, it
656 is known that filtration affects the activities of prokaryotes and generates biases (Edgcomb et
657 al. 2016). This makes investigations of prokaryotes associated with neutrally buoyant particles
658 particularly challenging and future endeavors should urgently attempt to target them.

659

660 **4.4.3 OC inputs**

661 Continuing in the same line, the inputs of C that the model takes into account are only the
662 gravitational POC and the DOC. We chose to artificially increase the gravitational POC flux
663 to add sources of neutrally buoyant particles in the form of PIPs (eddy subduction pump,
664 metazoans migrations and large-scale physical pumps). Indeed, Boyd et al. (2019) clearly
665 showed that these PIPs can be of paramount importance (here we have estimated them at 51.6%
666 of the gravitational flux). Yet, explicitly describing them in a dedicated compartment of the
667 model could be an improvement for future research, as these neutrally buoyant particles have
668 an effect on the whole system, including the prokaryotes linked to various types of particles
669 and their predators or on particle fragmentation. Given the existence of the neutrally buoyant
670 particle compartment, it is feasible to adapt the model to account for these C inputs. This is
671 even more relevant as new optical instruments have flourished (e.g. Briggs et al. 2013; Giering
672 et al. 2020; Picheral et al. 2022) and would make it easier to better quantify these neutrally
673 buoyant particle fluxes.

674

675 **4.4.4 *In situ* pressure effect**

676 Our last major concern deals with the fact that neither Niskin nor MSC avoid disruption
677 introduced through the process of depressurization when samples are collected at depth
678 (Tamburini et al. 2013; Garel et al. 2019). Heterotrophic activities associated to non-sinking
679 prokaryotes are known to decrease with depth but were mostly sampled without taking care of
680 the *in situ* pressure (e.g. Turley and Mackie 1994; Arístegui et al. 2009). From our knowledge,
681 some devices such as the IODA₆₀₀₀ (Robert 2012) were specifically designed to measure *in situ*
682 PR of non-sinking prokaryotes. However, enigmatically high PR values (2-3 orders of
683 magnitude higher than PHP) are measured by IODA₆₀₀₀, making it difficult to have confidence
684 in these *in situ* measured PR rates. During the PEACETIME cruise, we use a pressure-retaining
685 sampler (methods presented in supp data), allowing for the first time to access both PHP_{non-}

686 PR_{sinking} and $PR_{\text{non-sinking}}$ rates and to compare it with classical depressurization procedures (Fig.
687 S1). We observed that activity rates of non-sinking prokaryotes kept under pressure were
688 always higher when kept at *in situ* hydrostatic pressure than their decompressed counterparts
689 and, surprisingly, seem to increase with depth rather than decrease typically depicted and found
690 when the samples are decompressed (Fig. S1). From a C-budget point of view, taking *in situ*
691 pressure into account will increase C demand of free-living prokaryotes well adapted to their
692 living depth.

693

694 The effect of pressure acts inversely on sinking prokaryotes, as they are surface prokaryotes
695 (unadapted to high-hydrostatic pressure) that undergo a dynamic pressure increase as the
696 particle sinks (Baumas et al. 2021; Tamburini et al. 2021). Besides, repeated results (Tamburini
697 et al. 2006, 2009, 2021; Riou et al. 2018) have shown that, while performing a sinking
698 simulation experiment the activities of sinking prokaryotes are affected during the sink. For
699 instance, they noticed that the aminopeptidase activity was always lower with increasing
700 pressure over time than at atmospheric pressure on diatom aggregates (Tamburini et al. 2006).
701 Handling high-pressure sampling or experiments requires much more effort and material than
702 usual methods. However, it seems highly worthy when investigating both, sinking and non-
703 sinking prokaryotes activities, in regard to C-budget purposes.

704

705 **5. Conclusion**

706 By combining *in situ* data from the DY032 cruise at the PAP site with inversion of the
707 Anderson & Tang model which includes known processes from the biological C pump, we
708 provide robust and ecologically realistic estimates of key parameters and to better characterize
709 the patterns at stake.

710 1) We showed that the most sensitive parameters in the model are the ones related to
711 prokaryotes such as prokaryotic growth efficiencies and C hydrolyzed by sinking
712 prokaryotes released to the surrounding water.

713 2) By inversion of Anderson and Tang's model, we determined consistent values of the
714 parameters listed above.

736 *prokaryotes. In turn, viruses and chemoautotrophs can increase the amount of usable labile C.*
737 *Quantifying C demand and role on POC fluxes of these different groups is crucial to truly assess C*
738 *sequestration in the deeper layer of the water column. However, a multitude of uncertainties remains*
739 *for each group. The quantities enclosed in green are well known, in blue lack data and in pink are*
740 *unknown. C demand is the sum of heterotrophic production (PHP) and respiration (PR). The*
741 *understanding of these two quantities is currently better for the free-living prokaryotes whereas data*
742 *are still insufficient for sinking prokaryotes and even absent for prokaryotes attached to non-sinking*
743 *particles. Moreover, to build C budgets, these variables are integrated over a few hundred meters of*
744 *water column and the relationship between in situ pressure and C demand remains often neglected even*
745 *if this relationship highly depends on the prokaryote type considered (not constant for sinking*
746 *prokaryotes unadapted to the increased pressure, constant for free-living prokaryotes well adapted to*
747 *their living depth and constant for prokaryotes attached to non-sinking particles which can be adapted*
748 *or not if the particle was sinking before being stopped in its sink).*
749

750 **Code/Data availability**

751 The codes and data to reproduce the results are available at
752 <https://github.com/RobeeF/InverseCarbonBudgetEstim>

753 **Author contribution**

754 The idea was conceived by CB, CT and JCP. Sampling and experiments onboard PEACETIME
755 cruise were conducted by CT and MG. The data processing of PAP DY032 data was conducted
756 by CB with advices from FLM, and the one from PEACETIME data by CB and MG. RF
757 designed the inversion detection methodology and performed the estimation with advices from
758 LM. CB and RF led the writing with significant contributions from all authors.

759

760 **Acknowledgement**

761 We thank the crew and officers of the R.R.S. DISCOVERY (NERC) for their help during the
762 PAP DY032 cruise and of the N/O Pourquoi Pas? during the PEACETIME cruise. This study
763 is a contribution to the PEACETIME project (MISTRALS CNRS INSU, doi:
764 10.17600/17000300) managed by Cécile Guieu (LOV) and Karine Desboeufs (LISA). We
765 warmly thank F. Van Wambeke, S. Guasco and B. Zancker for onboard works (enzymatic

766 activities, sugar and amino acids concentrations measurements) during PEACETIME cruise.
767 We wish to express our gratitude to F. Van Wambeke, S. Giering, T. Anderson and A. Belcher
768 for stimulating and informative discussions. This manuscript is a contribution of the APERO
769 project funded by the National Research Agency under the grant APERO [grant number ANR
770 ANR-21-CE01-0027] and by the French LEFE-Cyber program.
