Abstract. Changes in the nitrogen (N) status of forest ecosystems can directly and indirectly influence their carbon (C) sequestration potential by altering soil organic matter (SOM) decomposition, soil enzyme activity, and plant-soil interactions. However, model representation of linked C-N cycles and SOM decay are not well-validated against experimental data. Here, we use extensive data from the Fernow Experimental Forest long-term, whole-watershed N fertilization study to compare the response to N perturbations of two soil models that represent decomposition dynamics differently (first-order decay versus microbially-explicit reverse Michaelis-Menten kinetics). These two soil models were coupled to a common vegetation model which provided identical input data. Key responses to N additions measured at the study site included a shift in [plant allocation](#) to favor woody biomass over belowground carbon inputs, reductions in soil respiration, accumulation of particulate organic matter (POM), and an increase in soil C:N ratios. The vegetation model did not capture the often-observed shift in [plant C allocation](#) with N additions, which resulted in poor predictions of the soil responses. We modified the [parameterization of the](#) plant C allocation scheme to favor wood production over fine root production with N additions, which significantly improved the vegetation and soil respiration responses. [Additionally, to](#) elicit an increase in the soil C stocks and C:N ratios with N additions, as observed, we ~~also~~ modified the decay rates of the particulate organic matter (POM) in the soil models. With ~~all of~~ these modifications, ~~only the microbially-explicit~~ [both models](#) captured [a negative soil respiration and](#) positive soil C stock [responses in line with observations, but only the microbially-explicit model captured an increase in and soil C:N response in](#) ~~line with observations.~~ Our results highlight the ~~importance-need for further model development to~~ [of](#) accurately representing plant-soil interactions, such as rhizosphere priming, and their responses to environmental change.

1 Introduction

Northern temperate forests are a globally important carbon (C) sink (Friedlingstein et al., 2022; Pan et al., 2011), but are experiencing rapid changes to their environment that could impact C sequestration rates. Predicting forest responses to environmental change over decadal time scales (or longer) is a challenge that requires the integration of long-term experimental manipulations and models that can detect and simulate changes in ecosystem patterns and processes. For example, many

temperate forests have received decades of N deposition from the combustion of fossil fuels and agricultural sector, which likely released them from N limitation and contributed to significant C sequestration (Vitousek and Howarth, 1991; Litton et al., 2007; Thomas et al., 2010; Vicca et al., 2012; Li et al., 2016; Du and de Vries, 2018). Additionally, many N enrichment studies report reductions in soil respiration rates and an accumulation of soil C, which are likely driven by plant reductions in belowground C allocation and lower soil microbial and enzyme activity (Du and de Vries, 2018; Janssens et al., 2010; Schulte-Uebbing and de Vries, 2017). While most existing models capture the enhancement in plant productivity with N additions, they fail to capture changes in plant C allocation or the reduction in soil respiration fluxes since these fluxes are represented by a positive relationship to plant productivity and litter inputs (Jian et al., 2021; Koven et al., 2015; Wieder et al., 2019a).

This shortcoming is especially concerning because, as N deposition declines and forest soils recover, the C that accumulated in these soils may become vulnerable to decomposition and loss. Furthermore, the response of soil heterotrophic respiration to global change will likely determine the overall magnitude of the land C sink (Bond-Lamberty et al., 2018). Thus, to create meaningful emission reduction targets and mitigate climate change, it is of high priority to predict the drivers and fate of the soil C stock under global change scenarios.

Recent theoretical advancements in the understanding of soil organic matter (SOM) formation and destabilization offer a framework for improving the representation of soil C and N cycling in models (Cotrufo et al., 2015; Lehmann and Kleber, 2015; Sokol et al., 2019). These emerging views highlight how plant productivity and belowground C allocation interact with soil microbial community composition and activity to regulate soil C persistence and heterotrophic respiration fluxes. Nonetheless, the Earth System Models (ESMs) used to predict future C cycles and inform global change policy do not explicitly represent microbial physiology and are limited in their abilities to predict SOM dynamics under environmental change (Varney et al., 2022; William R. Wieder et al., 2015b). Instead, these models typically represent soil C turnover as a linear process with first-order decay dynamics, and soil C formation is directly related to soil C inputs.

Recently, significant effort has gone towards incorporating explicit microbial communities and microbial physiology into soil models, which This incorporation may improve the predictive ability of these microbially-explicit models—especially under future conditions of environmental change—by incorporating additional mechanisms in the soil C cycle (Sulman et al., 2018; Wieder et al., 2013). For example, by Such microbially-explicitly models representing microbial physiology through parameterized catabolic processes (e.g., Michaelis-Menten kinetics of decomposition: V_{max} , K_m) and anabolic processes (e.g., C use efficiency, N use efficiency, turnover rates); † These models can simulate changes in the temperature sensitivity of decomposition and soil heterotrophic respiration as the microbial community shifts or microbial growth efficiency acclimates to soil warming (Wieder et al., 2013). Additionally, as the N cycle is incorporated into more models, some are being structured to capture the process of priming with N limitation (Guenet et al., 2013; Sulman et al., 2014). that Priming can occur when fresh soil inputs of organic matter to the soil lead to increased microbial demand for nutrients, and, thus, accelerated microbial growth, and higher rates of SOM decomposition (Bernard et al., 2022) of SOM (Sulman et al., 2014; Guenet et al., 2013).

65 ~~Furthermore~~On the other hand, reductions in microbial catabolic activity and shifts in community composition with N additions may contribute to the widely observed reduction in soil respiration with experimental N additions (Carreiro et al., 2000; Moore et al., 2021; Ramirez et al., 2012), ~~and~~ ~~in~~ Microbially-explicit models may have an advantage over first-order decay models at predicting this plant-microbe response and the downstream impacts of N availability this has on soil C storage and cycling. However, even microbially explicit models often have rather linear pathways of soil organic matter formation and destabilization that are driven by the quantity and quality of litter inputs as opposed to more complex plant-microbial interactions. Furthermore, few studies have compared the responses of first-order versus microbial models to N perturbations. 70 Therefore, there is a need to combine modelling and empirical efforts to assess model performance in response to N additions, and to identify any potential benefits of including an explicit representation of microbes and microbial processes (Wieder et al., 2019a).

In this study, we compared how implicit and explicit representations of microbial activity influence ecosystem biogeochemical 75 projections under conditions of elevated N deposition. We evaluated model performance with the results from a 30-year, whole-watershed, N addition field experiment at the Fernow Experimental Forest (Fernow Forest) in West Virginia, USA. The duration and spatial scale of this field experiment provides a unique opportunity to evaluate model assumptions about soil biogeochemical responses to N enrichment. Long-term experimental manipulations at relatively large scales (e.g., watersheds or large forested plots) are rare but important because significant ecosystem processes can respond slowly to sustained changes 80 in their environment. Observations from this long-term field manipulation found that N additions stimulated aboveground wood production and reduced total belowground C flux (Eastman et al., 2021). Furthermore, this reduced belowground C allocation likely caused a reduction in soil microbial activity as observed through a decrease in soil respiration and leaf litter decomposition, lower rates of ligninolytic enzyme activity and mycorrhizal colonization, and an accumulation of particulate organic matter (POM) in surface mineral soils (Carrara et al. 2018; Eastman et al. 2021, 2022). These soil responses are 85 observed at other N addition studies, as well, and may be difficult to capture with a first-order, linear decay soil model because they are driven by shifts in microbial activity and plant-soil interactions—mechanisms that may not be represented in microbially-implicit models.

The main objectives of this study were to compare the default model steady-state C stocks to observations from the Fernow Forest, and to compare observations to the results of three 30-year N addition modelling experiments. These three experiments 90 were: (1) default model responses to N additions; (2) modified model parameterizations that shift plant C allocation with N additions, in accordance with field observations; and (3) modified model parameterizations that both shift plant C allocation and slow the decomposition of POM with N additions. We hypothesized that the default models (experiment 1) would be N limited and, thus, respond to N additions with a reduction in N limitation, increase in plant productivity, and subsequent increase in soil respiration and soil C stocks as plant C production and inputs increase. We hypothesized that shifting model 95 representation-parameterization of plant C allocation (experiment 2), and thus reducing plant litter inputs to the soil, will lead

Formatted: Font: (Default) Times New Roman, 10 pt, Not Bold, Not Italic, Font color: Auto

to better model-observation agreement by reducing soil respiration rates and shifting the microbial community composition in MIMICS-CN to favor the oligotrophic (K-type) microbes. Finally, we hypothesized that modifying [parameters that control](#) POM decomposition rates (slower, experiment 3) will help the models reflect observed increases in POM abundance and soil C:N ratios with N additions.

100 2 Methods

2.1 Site description

The Fernow Experimental Forest (Fernow Forest) is a broadleaf deciduous forest located in the Central Appalachian Mountains near Parsons, WV (39.03° N, 79.67° W). Elevations at the Fernow Forest range from 530-1,115 m with steep slopes between 20-50% grade. The predominant soils at the Fernow Forest are shallow (<1 m) Calvin channery silt loam (*Typic Dystrochrept*) underlain with fractured sandstone and shale parent material. Mean monthly temperatures range from about -1.8 °C in January to about 25 °C in July, and annual precipitation is about 146 cm with an even distribution across seasons (Kochenderfer 2006). The Fernow Forest is the site of a long-term, whole-watershed, N-addition experiment. N additions to the experimental watershed catchment area (Watershed 3; 34 ha) were applied annually by aerial applications of 35.4 kg N ha⁻¹ yr⁻¹ as ammonium sulfate from 1989-2019 (30 years). The experimental N addition rate was about double the ambient N deposition measured in throughfall concentrations at the start of the experiment, and about four times the rate of N deposition by the end of the experiment (<https://nadp.slh.wisc.edu/>; www.epa.gov/CASTNET). Aerial application of (NH₄)₂SO₄ was distributed in three applications per year to simulate the seasonal, ambient N deposition rates. An adjacent watershed (Watershed 7; [24 ha](#)) of similar topography and forest age ([24 ha](#)) is used as a reference, receiving only ambient N deposition.

The vegetation at the Fernow Forest is classified as mixed mesophytic forest. The fertilized watershed (~~Watershed 3~~) was harvested using selection harvesting and patch-clearcutting from 1958-1968 before being clear-cut in 1970 and allowed to regrow naturally for 19 years before fertilization treatment began. The adjacent reference watershed (~~Watershed 7~~) was clear-cut in two sections, the upper half in 1963 and lower half in 1966. Following cutting, both sections of the reference watershed were kept barren with herbicide treatment until 1969 when the vegetation was allowed to regrow. No legacy effects of the herbicide treatment were observed ten years into regrowth (Kochenderfer and Wendel, 1983). The Fernow Forest has relatively diverse vegetation, and tree species are similar in both watersheds, dominated by *Prunus serotina*, *Acer rubrum*, *Liriodendron tulipifera*, and *Betula lenta*; although, the fertilized watershed has a greater % basal area of *Prunus serotina* and less *Liriodendron tulipifera* than the reference watershed.

The observational data from the Fernow Forest used in this study were collected over various time scales and locations in the fertilized and reference watersheds, with most of these data described and summarized by Eastman et al. (2021). In brief, tree aboveground net primary productivity (ANPP) measurements were estimated from 25 permanent growth plots per watershed.

~~in which~~ The aboveground biomass of all trees >2.54 cm diameter at breast height (DBH) was estimated six times during the 30-year experiment using measurements of ~~DBH the diameter at breast height~~ and allometric equations (in years 1990, 1996, 1999, 2003, 2009, and 2018). Also at these plots, autumnal fine litterfall was measured annually from the start of the experiment (1989) through 2015, and in 20 additional plots per watershed from 2015-2017. Fine root biomass was measured several times throughout the experiment in various sets of plots using soil cores ~~(ranging in depth from 0-10 cm to 0-45 cm~~ (in years 1991, 2012, 2013, 2015, 2016); ~~and~~ Fine root production (0-10 cm) was estimated in 2016-2017 using in-growth cores. Soil organic horizon C and N stocks were measured in 2012 and 2013 (which included all organic horizons), and mineral soil C and N stocks were measured from soil pits (0-45 cm depth) in 2016. The top 0-45 cm of soil typically included the A horizon and most of the B horizon. At the study site, the A, B, and C horizons are typically found between depths of 0-12 cm, 12-56 cm, and 56-75 cm (expert opinion, Mary Beth Adams, unpublished data). Soil respiration was measured at 80 locations per watershed approximately weekly during the growing season and monthly during the dormant season for two years (2016-2017) using an infrared gas analyzer. Stream inorganic N export has been monitored at the Fernow Forest from continuous streamflow measurements and weekly or biweekly streamwater chemistry samples since 1983 by the US Forest Service. Additionally, we used measurements of the partitioning of mineral SOM into different soil density fractions in the fertilized and reference Fernow Forest watersheds to compare observed versus modelled SOM distributions and stoichiometry (Eastman et al., 2022). These mineral soil samples were collected in 2018 at 20 plots per watershed, in four subplots per plot, to a depth of 15 cm.

2.2 Soil biogeochemical model testbed description

The soil biogeochemical model testbed, developed by Wieder et al. (2018, 2019b), provides a framework to compare the performance of two structurally different soil C and N biogeochemical models by coupling them to a common vegetation model. The soil model testbed was originally developed to facilitate the comparison among three structurally distinct soil C models in their abilities to predict global soil C stocks and their responses to environmental change. Two of these models in the testbed have been recently modified to include the N cycle and its interactions with the C cycle: one first-order soil C and N model, the Carnegie-Ames-Stanford Approach (CASA-CN; Potter et al., 1993; Randerson et al., 1996; Wang et al., 2010); and one microbially explicit soil C and N model, Microbial-Mineral Carbon Stabilization (MIMICS-CN) (Kyker-Snowman et al., 2020; W. R. Wieder et al., 2015; Wieder et al., 2014). While both models were developed and parameterized to run at the global scale, the testbed allows these models to be run at single-point scale, for comparisons against site-level, empirical data.

The soil biogeochemical model testbed provided a computational framework for comparing the response to elevated N inputs of a first-order decay model to a microbially-explicit representation of soil biogeochemical cycles. After calibrating these models to our study site (Sect. 2.3), we ran three 30-year N addition experiments that simulated the long-term N addition study at The Fernow Forest. The first experiment was performed using the default models calibrated to the study site. In the second experiment, we addressed the assumptions in the common vegetation model about fixed plant allocation. And in the third

experiment, we tested the mechanism that N additions can directly inhibit enzyme activity and the decomposition of chemically recalcitrant POM.

160 2.2.1 Overview

The soil biogeochemical model testbed was developed to investigate how model structural assumptions and parameterizations influence global-scale soil biogeochemical projections over the historical record and in future climate change scenarios (Wieder et al., 2019b, 2018). The testbed uses common environmental drivers and a shared vegetation model (CASA-CNP) to reduce uncertainties among soil models that are not directly related to their representation nor the parameterization of soil biogeochemical dynamics. The C and N version of the testbed includes the CASA-CN and the MIMICS-CN soil models. Both models have three-two litter pools—(metabolic, structural), and a coarse woody debris pool (CWD)—and three SOM pools with various turnover times and stoichiometry (Fig. 1). Neither soil model distinguishes between an organic horizon and mineral horizon, but rather includes the litter pools and classifies three SOM pools by physicochemical properties and microbial availability. The three SOM pools in CASA-CN and MIMICS-CN, respectively, include (1) a microbial or SOMa (microbially available) pool with fast turnover; (2) a slow or SOMc (chemically protected); and (3) the passive or SOMp (physicochemically protected) pool (Fig. 1). In this study, we equate the relative abundance of the slow: passive (for CASA-CN) and SOMc: SOMp (in MIMICS-CN) to empirical measurements of POM and mineral-associated organic matter (MAOM) from the Fernow Forest.

Key differences between the models are described in previous work (Wieder et al. 2018; 2019), but here we highlight differences in their representation of soil organic matter turnover and stoichiometry. Litter and SOM turnover in CASA-CN occurs via an implicit representation of microbial activity, with decomposition controlled by linear, first-order dynamics. Soil C turnover times are defined by biome- and pool-specific decay constants that are modified by environmental scalars for soil temperature and soil moisture availability. The stoichiometry for each of the five organic matter pools in CASA-CN is diagnostic (i.e., minimum and maximum values are assigned), and are defined by pool- and biome- specific parameter values (Randerson et al., 1996; Wang et al., 2010; Fig 1a). Conversely, turnover of litter and SOM in MIMICS-CN are determined via temperature sensitive reverse Michaelis-Menten kinetics so that organic matter turnover and heterotrophic respiration fluxes are dependent both on the size of the donor (substrate) and receiver (microbial biomass) pools. MIMICS-CN also represents two functionally distinct microbial communities that correspond to fast/copiotrophic and slow/oligotrophic growth strategies (or r- and K-type communities, MIC_r and MIC_k; Fig 1). These microbial communities have different catabolic potential, anabolic traits, C:N ratios, and substrate affinities (Wieder et al. 2015; Kyker-Snowman et al. 2020). The MIC_r functional group requires more N and has a greater affinity for organic matter with lower C:N (LIT_m). In contrast, the MIC_k functional group is relatively more efficient and has a greater affinity for organic matter with higher C:N ratios (LIT_s). These functional trait differences lead to varied stoichiometries of the microbial biomass pools, which are parameterized as C:N ratios of 6 and 10 for MIC_r and MIC_k, respectively. The stoichiometries of SOM pools, however, are a prognostic feature of

Formatted: Font: (Default) +Headings (Times New Roman), 10 pt, Not Bold, Not Italic

190 ~~the model that reflect litter chemistry, microbial necromass inputs, and the relative abundance of different SOM pools. The~~
~~stoichiometries of litter and SOM pools, however, are a prognostic feature of the model, influenced by various factors including~~
~~litter stoichiometry and the response of the microbial community composition.~~ For this study, ~~it the testbed~~ was run at the
single point encompassing the study site, Fernow Forest.

2.2.2 Model forcing and initialization

195 The CASA-CNP model consists of coupled vegetation and soil models (Randerson et al., 1996; Wang et al., 2010). In the
testbed used for this study, both the CASA-CN soil component and the MIMICS-CN soil model are coupled to the CASA-
CNP vegetation model component (although here we only represent coupled C-N biogeochemistry above and belowground).
The vegetation component of CASA-CNP requires daily meteorological inputs, including air temperature, precipitation, and
GPP. Both soil models (CASA-CN & MIMICS-CN) also need inputs for depth-weighted means of soil temperature and liquid
200 and frozen soil moisture. The CASA-CNP vegetation model calculates net primary productivity, allocation to leaves, wood
and roots, vegetation N demand and uptake, and litterfall fluxes. For this study, input data used to run the model were generated
from simulations by the Community Land Model, version 5.0, with satellite phenology (CLM 5.0-SP), forced with GSWP3
climate reanalysis for the period 1900-2014 (Lawrence et al., 2019). In contrast, previous work with the testbed used input
data from an older version of CLM (CLM 4.5-SP) forced with Cru-NCEP climate reanalysis data (Wieder et al. 2018; 2019).
205 In the present study, input data beyond 2014 were generated by extending the CLM 5.0-SP simulation with an anomaly forcing
(2015-2019) of atmospheric fields from projections made with the Community Earth System Model version 2 (CESM2, see
Danabasoglu et al., 2020; for methods, see also Wieder et al., 2015a, 2019b, who used a similar approach with previous
versions of CLM and CESM). Briefly, this anomaly forcing cycles over the last decade of the GSWP3 input and applies an
anomaly based on a 3-member ensemble mean from CESM2 simulations that have been archived for the Coupled Model
210 Intercomparison Project Phase 6 (CMIP6) experiment. This experiment was run under the “high” emissions pathway, SPP3-
70, climate change scenario to generate data from 2015-2100 (<http://www.earthsystemgrid.org>). For this study we only present
results through 2019.

From these global simulations we extracted data for the grid cell capturing the Fernow Forest, and the daily CLM 5.0-SP
output were then used as input boundary conditions for all simulations presented here. Because we ran the testbed in single-
215 point mode, the CASA-CNP vegetation model was assigned one plant functional type (PFT) for our experiment: temperate
deciduous forest. Some of the CASA-CNP vegetation parameters were modified to better represent observations at the Fernow
Forest when appropriate empirical observations were available (Table A1). The CASA-CNP vegetation model simulated NPP
and plant litterfall inputs that become inputs to both soil biogeochemical models (CASA-CN & MIMICS-CN). In the carbon-
only version of the testbed, litterfall fluxes seen by CASA-CN and MIMICS-CN biogeochemical models are identical, but
220 nitrogen limitation reduces NPP in the CASA-CNP vegetation model (Wang et al. 2010), thus providing a feedback between

soil biogeochemical representations and simulated vegetation pools. In all simulations, soil depth was set to 45 cm to allow for comparison with observations of [total](#) soil C and N stocks.

Models were spun-up by cycling over meteorological input data (1900-1919) until C and N pools equilibrated. This took a spin-up period of 6,000 years for MIMICS-CN and 8,000 years for CASA-CN to ensure that soil stocks reached steady state.

225 We also ran all simulations through a historic period (1900-1988) using transient GSWP3 climate, N deposition taken from CLM5 simulation (Lawrence et al., 2019), and atmospheric CO₂ data from the same period. Results from historic simulations were compared with observational data from the Fernow Forest and used to complete the site-specific configuration of the testbed models.

2.3 Site-specific configuration of historic simulations

230 Based on preliminary results, we modified several parameters in the vegetation and soil model components so that historic simulations (through 1988) better matched observed ecosystem C and N stocks and fluxes at the Fernow Forest (Sect. 2.1; based on Eastman *et al.* 2021). All vegetation and soil parameter modifications for site-specific configuration are detailed in Tables A1, A2, and A3, and these modifications are supported by observational data from the long-term experimental data (Eastman et al., 2021). Briefly, changes in the CASA-CNP vegetation parameters were made to decrease vegetation C stocks and increase the baseline N limitation in the model, which was defined by a positive NPP response to N additions (Table A1).

240 Modifications to CASA soil component parameters reduced the [total litter +](#) soil C:N ratio and total [litter +](#) soil C stocks, again better capturing observed values (Table A2; Eastman et al., 2021, 2022). In contrast, modifications to the MIMICS-CN soil parameters were needed to increase total [litter +](#) soil C:N ratios and total [litter + soil](#) C stocks, to better reflect observed values and reduce model-to-model differences (Table A3; Eastman et al., 2021, 2022). After both CASA-CN and MIMICS-CN soil model parameters were calibrated to the Fernow Forest site for the end of the historic period, the models with these calibrated parameters became the “default” models that were used in experimental simulations (1989-2019) that are the focus of this study.

2.4 Experimental design: N enrichment experimental simulations

245 We performed three soil model testbed experiments that simulated the experimental N additions at the Fernow Forest (1989-2019). Similar to historic simulations, experimental simulations used GSWP3 climate and atmospheric CO₂ data that was extended with an anomaly forcing for years 2015-2019. Each experiment consisted of a control simulation with ambient N deposition rates used in CLM 5.0, and a “+N” simulation that received an additional 3.5 g N m⁻² y⁻¹ distributed evenly across every day of the year (Table 1). This annual rate of additional N deposition matched the annual rate of experimental N additions at the Fernow Forest whole-watershed fertilization experiment (Adams et al., 2006). In the first experiment, “default +N,” the 250 N perturbations were the only modifications made to the site-calibrated models (Table 1).

The “default +N” simulation did not capture observed responses to N fertilization that included increases in wood biomass, increases in total litter + soil C:N ratio, and a reduction in soil heterotrophic respiration (Fig. 2). In the second experiment, “allocation shift +N,” we modified the CASA-CNP vegetation model to address assumptions about plant C allocation. It is well established that more nutrient availability leads to less belowground C flux, and thus increases aboveground NPP (Fernández-Martínez et al., 2017; Litton et al., 2007; Vicca et al., 2012), but this dynamic allocation pattern in response to nutrient enrichment is one that many models do not capture, including CASA-CNP (Thomas et al., 2015; Wieder et al., 2019a). To improve model representation of observed ecosystem responses at the Fernow, and to test our second hypothesis that reduced soil heterotrophic respiration resulted from shifts in plant allocation away from belowground C inputs, we adjusted carbon allocation of vegetation in CASA-CNP (Table 1). We adjusted the parameters of the fixed allocation scheme in the CASA-CNP vegetation model to shift 10% of GPP C away from roots and to wards wood production under conditions of +N. This 10% shift is a conservative estimate of the observed response, where total belowground carbon flux (estimated using a mass balance approach) was ~13% lower in the fertilized watershed (Eastman et al., 2021). Results from the adjusted allocation scheme experiment are presented here and referred to as “allocation shift + N” models and simulations hereafter.

In the third experiment, “enzyme inhibition +N,” we built on the “allocation shift +N” parameterization to test the additional effect of direct enzyme inhibition: the hypothesis that reduced microbial enzyme activity from elevated soil N led to an accumulation of POM and subsequent increase in the mineral soil C:N ratio. In the MIMICS-CN model, this could be approached multiple ways (see Wieder et al., 2015a), but here we focus on the direct effects that N additions may have by suppressing ligninolytic enzyme activity, which is supported by observations at the Fernow Forest and other sites (Carrara et al., 2018; Carreiro et al., 2000; Tan et al., 2020; Xia et al., 2017). MIMICS-CN includes a transition of chemically protected SOM (SOM_c which we equate with POM) to microbially available SOM (SOM_a). This transition from SOM_c to SOM_a in MIMICS-CN follows reverse Michaelis-Menten kinetics but is not parameterized as a function of soil N availability. To represent potential nitrogen inhibition on POM decomposition, therefore, we increased the half saturation constant for the oxidation of the chemically protected SOM pool during experimental N additions, essentially reducing rates of decomposition of this pool (Table 1). In CASA-CN, we adjusted the turnover time of the SLOW pool, increasing it by 30%. These reductions in the turnover time of the SOM_c/SLOW pool were intended to reflect observed declines in decomposition and increases in POM (Eastman et al., 2022). These declines, a conservative estimate based on observed reductions in decomposition were, in part, a result of a 25-57% in ligninolytic enzyme activity in the fertilized watershed, the primary agent of decomposition of POM (Table 1; Carrara et al., 2018). Results from this experiment are presented here and referred to as “enzyme inhibition + N” models and simulations hereafter.

2.5 Model-data comparisons

To compare the sensitivity of observed and modelled responses to N enrichment we calculated response ratios for different C and N pools and fluxes following 30 years of N additions. Response ratios were calculated for key observations and model

outputs, using the most recent observed values and the annual mean value from the last 10 years of the experimental simulations. Response ratios were estimated by dividing ~~the ambient (control) observed or modelled value by the the~~ +N watershed ~~observed or modelled value by the ambient (control) observed or modelled value~~. Thus, a response ratio of 1 indicated that there was no effect of N additions on the pool/flux, whereas a response ratio greater than or less than one indicated an increase or decrease in that flux/pool with N additions.

~~Modeled total soil C and N stocks were estimated as the sum of C in both litter pools, the three SOM pools, and the microbial biomass pools (in MIMICS-CN only) unless otherwise noted. Observed total litter + soil C and N stocks included the litter layer, organic horizon, and 0-45 cm of the mineral soil horizon, unless otherwise noted. Because of limitations in measuring total NPP, we compare ANPP between models and observations. ANPP is calculated as the sum of wood C production and leaf C production (measured as litter C flux in observational data).~~

Formatted: Space Before: 12 pt

3 Results

3.1 Comparison of baseline calibrated models to observations

Baseline models calibrated to the Fernow Forest had overall good agreement of key carbon and nitrogen pools and fluxes in comparison to observations. Table 2 summarizes baseline calibrated model output from the last ten years of the historic transient simulations (1979-1988) with comparisons to observations. We compare baseline models to the recent measurements from the reference watershed 7 because this was the watershed and time period with the most complete observational data at the site (see Eastman *et al.* 2021). Because of higher-than observed vegetation nitrogen concentrations (especially in wood) represented in the CASA-CNP vegetation model, models had greater aboveground NPP (ANPP) and plant N uptake fluxes than observations, but slightly lower wood C pools. CASA-CNP vegetation model also simulates much larger fine root C pools than observed (Table 2). -The discrepancy in fine root C pools is in part due to the depth difference in modeled (45 cm) versus observed (15 cm) values, but CASA-CNP still likely ~~is~~ overestimates this total pool (over 3 times observed; Table 2) that is typically concentrated in the first 20 cm of soil (Jobbágy and Jackson, 2000). As intended, calibrated soil pools, mineral soil C:N ratios, and simulated soil respiration- by baseline models were very similar to observations (Table 2). The CASA-CN soil model attributes more of the total soil C to the ~~organic horizon~~ (litter layers) than MIMICS-CN and observations, and MIMICS-CN predicted slightly lower soil respiration fluxes (Table 2).

3.2 Experiment 1: Default model responses to N additions

Both default versions of the models exhibited a positive response in aboveground plant productivity but were not as sensitive to nitrogen additions as observations, as shown by relatively small increases in ~~aboveground ANPP (ANPP;~~ (Fig. 2a; Table A4). Because the default version of CASA-CNP uses fixed plant allocation, changes in leaf, wood and root C pools were all positive, reflecting increases in NPP that were associated with N fertilization. Overall, the vegetation response to N addition

was stronger with the MIMICS-CN soil model than with the CASA-CN soil model. Belowground, both soil models predicted little to no change in soil C stocks, a slight increase in heterotrophic soil respiration, and very slight decreases in soil C:N ratios (Fig. 2b). These ~~modeled~~ ~~modelled~~, ~~positive~~ -soil responses were opposite to ~~what was~~ ~~mean~~ ~~negative~~ observed responses (Fig. 2b). ~~The modelled responses and~~ were due to the overall positive response of ~~root and leaf production~~ ~~NPP~~ and, thus, plant matter inputs to the soil ~~without a reduction in decomposition~~. ~~However, even with no change in the total soil C stock, this response fell within the wide range variability of the observed response. Observed increases in soil C stocks were found in the surface mineral soil (0-10 cm), but not at greater depths (Eastman et al., 2021). Therefore, we targeted the plant allocation scheme for the vegetation allocation shift +N experiment.~~

3.3 Experiment 2: Plant allocation shifts with N additions

To elicit a vegetation response in CASA-CNP that reflected the observed shift in plant C allocation, we modified allocation parameters for fertilized experiments in the CASA-CNP vegetation model. As intended, this “plant allocation shift” modification to ~~the~~ CASA-CNP vegetation model ~~parameterization~~ improved model-observation agreement through a more positive ANPP response, enhanced woody biomass C stocks, and reduced fine root production with N additions in both coupled vegetation-soil models (Fig. 2a; [Table A4](#)). This change in the vegetation response influenced soil biogeochemical responses by both models, as well.

Notably, the significant (~20%) reduction in root C inputs to the soil ~~with N additions~~ lead to a small reduction in soil respiration (~6%) ~~with N additions~~ in both soil models (Fig. 2b). However, the combination of large reductions in soil C inputs and small reductions in soil C outputs (respiration), resulted in an overall 3–4% reduction – rather than the observed stimulation – in the total soil C pool with both models (Fig 2b). Soil models diverged in soil stoichiometric response to N additions, with a slight decrease in ~~total~~ soil C:N simulated in the CASA-CN “plant allocation shift” experiment — similar to the default experiment — but a very slight increase in ~~total~~ soil C:N resulting from the MIMICS-CN “plant allocation shift ~~+N~~” experiment, which was more similar to the mean observed response (Fig. 2b). These increases in soil C:N ratio resulting from the plant allocation shift and N additions in MIMICS-CN coincided with a subtle accumulation of POM (SOM_c; Fig. 3).

3.4 Experiment 3: Enzyme inhibition of decomposition with N additions

Based on observed increases in light particulate organic matter (POM) and soil C:N ratios with N additions in the surface soil at the Fernow Forest (Eastman et al., 2022), we examined whether the distinct soil models could capture this pattern with an additional ~~parameter~~ modification that reflected a reduction in soil enzyme activity with the elevated N perturbation (Fig. 1; [Table 1](#)). These “enzyme inhibition +N” experiments generated similar plant productivity responses as in the “plant allocation shift +N” simulations (Fig. 2a). By increasing the turnover time of the CASA-CN SLOW pools and reducing the oxidation rate of SOM_c in MIMICS-CN, both models simulated increases in the total soil C stocks, ~~that are more~~ consistent with observations (5% and 8%, respectively) and, particularly, in the POM pools (SLOW and SOM_c; Figs. 2b, 3). ~~While both~~

models captured total soil C:N responses within the range of observations. ~~Only in MIMICS-CN, however, did this lead to a~~
345 ~~more captured an positive response, or~~ increase in; the total soil C:N ratio that closely approximated the observed mean value
(Fig. 2b, Table A4). Similar to observations, the positive response of the bulk soil C:N ratio (not including litter pools) that
occurred with N additions was concurrent to an increase in the relative abundance of the POM pools in “enzyme inhibition
+N” simulations (Fig. 3). However, the relationship between the fraction of soil C in POM and bulk soil C:N ratios captured
by the models were weak compared to the actual relationship found in surface mineral soil (0-15 cm) samples collected from
350 both watersheds at the Fernow Forest (Fig. 3). The weak relationship between POM abundance and bulk soil C:N ratios was
due to the low C:N ratios of the POM pools in CASA-CN and MIMICS-CN models.

4 Discussion

Using a soil model testbed to evaluate model responses to N additions, we found that modifying plant C allocation and soil
POM decomposition ~~rates-parameterizations~~ under conditions of elevated N deposition most improved model-observation
355 agreement (Fig. 2). Coupled to a vegetation model with a static allocation scheme, both CASA-CN and MIMICS-CN models
captured general observations of key ecosystem pools and fluxes in the reference watershed (Table 1). However, without
modification to ~~the some key model parameters~~, they failed to capture some key observed responses to N additions: increased
woody biomass production, reduced belowground C allocation, reduced soil respiration, and POM accumulation in surface
mineral soil (Fig. 2, default models; Fig. 3). With our model experiments, we show that modifications to plant C allocation
360 parameters that increased the overall turnover time of vegetation C created the greatest improvement of model-observation
agreement to N additions (Fig. 2). However, this modification still failed to adequately capture two important observed
responses: an increase the total litter + soil C:N ratio, and an increase in the pool of total litter + soil C.

Further refinement of the model parameterizations to simulate a direct inhibition of microbial activity moved the soil model
predictions closer to mean observed increases in soil C stocks and improved the predicted decreases in soil respiration with N
365 additions (Eastman et al., 2021; Fig. 2b). Furthermore, this modification to one of the models (MIMICS-CN) resulted in
elevated soil C:N ratios (not including litter layers) that matched observed surface mineral soil values. Given the widespread
occurrence of reduced soil respiration and microbial activity with N additions (Janssens et al., 2010), as well as the importance
of this C flux for the future of the land C sink (Bond-Lamberty et al., 2018), validating model assumptions against long-term
experimental data is a necessary step to improve our predictions of the land C sink to global change. We recognize that the
370 same parameter modifications may not lead to the same model-observation improvements at other sites with different
ecosystem properties or climate. Nonetheless, this exercise allowed us to identify the potential mechanisms and processes that
could be better developed in models to more broadly apply across ecosystems and climates under conditions of elevated N
deposition.

4.1 Implications of a fixed allocation vegetation model

375 Our model efforts suggest that capturing the shifts in plant C allocation in response to N additions is the most impactful way
to improve the modeled N fertilization response. The default parameterizations with static plant C allocation were not sensitive
to N additions, suggesting that the models underestimate N limitation by plants (Fig. 2). ~~When we~~ We modified the fixed
allocation ~~scheme parameterization~~ in the CASA-CNP vegetation model under elevated N inputs, so that both models captured
380 the often observed increase in wood production and reduction in belowground carbon flux (root inputs) with N additions (de
Vries et al., 2014; Fernández-Martínez et al., 2014; Frey et al., 2014; Zak et al., 2008). We note this model experiment was a
post-hoc modification to the CASA-CNP allocation parameters for fertilized simulations, but it allowed us to test the soil
model responses to shifts in plant C allocation and underscores the importance of future work to develop more robust
~~parameterizations-model processes~~ that moderate plant C allocation as a function of ecosystem fertility status (e.g., Parton et
al. 2010, Shi et al. 2016). Such developments in models that do not already account for dynamic allocation shifts are critical
385 for making more accurate projections of plant NPP responses to global change drivers, and the role of terrestrial ecosystem in
sequestering atmospheric CO₂ (Shi et al., 2019). Notably, with improved vegetation responses to fertilization in our “plant
allocation shift +N” simulations, reduced soil heterotrophic respiration rates followed from reductions to belowground C inputs
in both the model and experimental results (Fig. 2b). The ability of the “plant allocation shift +N” model experiment to capture
the observed responses at the Fernow mirrors other recent model-experiment integration efforts. For example, a recent model-
390 data synthesis of forest responses to elevated CO₂ showed that the models that performed best had dynamic representations of
C allocation that were responsive to water and nutrient availability (De Kauwe et al., 2014). As such, there remains a clear
need to prioritize models that employ dynamic allocation approaches ~~and parameterizations~~ based on data syntheses.

~~One shortcoming of our model efforts was the inability to represent a meaningful rhizosphere priming response in the control
simulation that would lead to reduced priming in the elevated N simulations.~~ High soil N availability encourages shifts in plant
395 nutrient acquisition strategies by reducing belowground C flux to mycorrhizae that is typically required for nutrient acquisition
(Eastman et al., 2021; Gill and Finzi, 2016). At our study site, shifts in nutrient acquisition strategy and C allocation led to
reduced mycorrhizal colonization, reduced rates of SOM decomposition, and an accumulation of POM. When we shifted in
the overall C allocation of plants (through a parameter change in the second “allocation shift +N” experiment) to increase
wood production and reduce root production, this parameter change did reduce soil respiration relative to the control run, but
400 does not account for all mechanisms that reduce soil respiration. Rather than an overall reduction in decomposition and
accumulation of POM (as observed), this allocation shift reduced litter inputs from roots to the soil, and thus a relative decrease
in total soil C (Fig. 2). ~~One shortcoming of our model efforts was the inability to represent a meaningful rhizosphere priming~~
~~response in the control simulation that would lead to reduced priming in the elevated N simulations.~~ Neither the CASA-CN
nor MIMICS-CN represent mycorrhizae and the plant-soil interactions that occur in the rhizosphere and with priming of soil
405 microbes. Though MIMICS-CN does represent a K-type microbial pool, it does not distinguish between mycorrhizae that
closely interact with plants versus free-living saprotrophs.

Future modelling attempts could implement a root exudate flux in a way that reflects C allocated to ~~the rhizosphere and mycorrhizal~~ a microbial community ~~that targets POM and may mobilize plant-available N~~ (e.g., K-type microbes, or a new pools of microbes ~~that more closely resemble mycorrhize~~), ~~and also incorporates~~ a N component of the exudate flux ~~that stimulates~~ microbial growth and activity ~~may also be necessary to avoid microbial N limitation and increase plant-available N in the models~~. Some ecosystem models do consider plant exudate inputs to the soil that prime the rhizosphere community for N acquisition (e.g., FUN-CORPSE; Sulman et al. 2017). Because N acquisition comes with a C cost, such a transactional representation of N acquisition and uptake may better predict the plant C allocation response to elevated N inputs (Thomas et al., 2015). As we were not able to address this shortcoming in this study, we directly targeted a parameter controlling decomposition rates and simulated the direct inhibition to decomposition by N additions instead.

4.2 Enzyme inhibition and soil C accumulation

~~Despite significant improvements brought forth by the modified plant allocation scheme, the strong reductions in soil C inputs (by fine roots) with N additions outweighed the more subtle reductions in soil C outputs (heterotrophic respiration) and led to an overall reduction in soil C stocks, contrary to observations (Fig. 2). Subsequently,~~ We tested the enzyme inhibition hypothesis, ~~by reducing/modifying parameters that control the~~ decomposition rates of POM pools with N addition. Augmented N likely increases the turnover time of the POM pool through reduced oxidative enzyme activity and less microbial priming (Chen et al., 2018; Craine et al., 2007; Eastman et al., 2022; Von Lützow et al., 2008). While our modelling efforts did successfully increase the litter + soil C stocks in both CASA-CN and MIMICS-CN, it only led to an increase in total litter + soil C:N ratio response in the MIMICS-CN model (Fig. 2b). The ~8% increase in soil C with N addition predicted by the MIMICS-CN “enzyme inhibition +N” model was similar to the mean enhancement in surface mineral soil (0-15 cm) at the Fernow Forest (~11%; Eastman et al., 2021), as well as increases in surface soil C stocks at other long-term N addition experiments (Frey et al., 2014; Zak et al., 2008). The CASA-CN model predicted a more moderate enhancement in soil C stocks (5%) with N additions and these parameter modifications, which still fell within the range of observation. The first order decay dynamics in models like CASA-CN more closely links soil C input fluxes to soil C stocks (see Friend et al., 2014; Koven et al., 2015), so a stronger decrease in fine root production in CASA-CN likely resulted in a weaker soil C stock response to N additions.

Beyond accurately predicting changes in the *total* soil C stocks and fluxes, the *distribution* of SOM among POM and MAOM pools is of high importance to the future land C sink (Lavallee et al., 2020; Whalen et al., 2022). Changes in the distribution of these SOM pools may impact overall soil stoichiometry (Mikutta et al., 2019, Eastman et al., 2022), which drives important soil C and nutrient cycling processes, such as net N mineralization rates (Aber et al., 2003; Venterea et al., 2004). An increase in the relative proportion of POM constituting SOM stocks in the fertilized watershed at the Fernow Forest raises compelling questions about the future of C and N accumulations due to chronic N additions in a changing world. For example, how will N-induced increases in the relative importance of POM impact forest recovery from N deposition and progressive N limitation

under elevated CO₂ conditions (Craine et al., 2018; Groffman et al., 2018; Norby et al., 2010)? Indeed, a recent global analysis
440 by Hartley et al. (2021) found evidence for greater vulnerability of POM decomposition under conditions of soil warming
compared to MAOM.

MIMICS-CN offers a potential advantage over CASA-CN because of the diagnostic soil stoichiometry and more mechanistic
decomposition dynamics, which allowed for greater shifts in soil organic matter composition (i.e., POM accumulation) and
soil C:N ratios compared to CASA-CN. Capturing shifts in bulk soil C:N (not including litter layer) requires representation of
445 multiple pathways of SOM formation, which MIMICS-CN includes, such as microbial biomass turnover *and* the direct
physical transfer of litter-derived organic matter that has bypassed microbial decomposition (Cotrufo et al. 2019; Cotrufo et
al. 2015). Observed C:N ratios of POM at the Fernow study site were ~25, but the C:N ratios in CASA-CN and MIMICS-CN
were between ~14-20. In CASA-CN, the prescribed C:N ratio of POM is lower than observed, leading to very small changes
in total bulk soil C:N even as the fraction of SOM in the POM pool increases. Thus, even if the POM turnover time in CASA-
450 CN was further increased, it would still not capture the mean observed increase in soil C:N with POM accumulation (Fig. 3;
Table A4). In MIMICS-CN, the increase in total soil C:N was mainly driven by the relative increase in the fraction of POM
and decrease in low C:N MAOM fraction (Table A4 not shown). Still, the increase in bulk soil C:N (not including litter layer)
with POM accumulation in MIMICS-CN was not as strong as observations suggest (Fig. 3). This was likely due to the
mechanism targeted in the “enzyme inhibition +N” experiment: reducing the oxidation of SOM_c to SOM_a. In MIMICS-CN,
455 most litter inputs pass through a microbial pool, and SOM pools are mostly made up of microbial necromass—with a lower
C:N ratio—though a small amount of litter inputs bypass microbial pools (Fig. 1). This underscores challenges in assessing
plant vs. microbial contributions to SOM formation and persistence (Whalen et al., 2022). Under conditions of elevated N
inputs, it is thought that more litter inputs bypass microbial decomposition. Therefore, the direct transfer of litter inputs to soil
pools is a key pathway that may better achieve observed responses of the SOM stocks and composition to N amendments in
460 MIMICS-CN.

While the microbial explicit foundation of MIMICS-CN holds promise, there still appears to be uncertainties in how plant-soil
interactions and their responses to environmental change should be presented and parameterized in the models. For example,
our post-hoc adjustment of plant C allocation and microbial decomposition decay rates with N enrichment were intended to
represent ecosystem responses that are commonly observed in nitrogen enrichment studies (Janssens et al., 2010), emphasize
465 the need to develop model parameterizations that capture phenomena in real-world ecosystems; This experiment allowed us
to identify certain mechanisms and processes in the models that exert strong control over the of the formation and stabilization
of SOM and that are influenced by N deposition. However, our results cannot necessarily be generalized to other ecosystems
or environmental changes. Future model developments, therefore, should focus on constructing more process-based
representations of these mechanisms (i.e. dynamic plant carbon allocation and reduced ligninolytic enzyme activity with N

470 ~~addition) to better predict the often observed reductions in decomposition and soil respiration under N addition that are currently hard to capture with most soil biogeochemical models.~~

Given the widespread empirical evidence for a reduction in lignin-degrading enzyme activity with elevated N inputs (Carrara et al., 2018; Frey et al., 2014; Pregitzer et al., 2008; Treseder, 2004), and the resulting impacts on soil stoichiometry (Chen et al., 2018), additional efforts to improve mechanistic representations of decomposition parameterizations with available data should be a focus area for future model improvement. Such responses, however, are nuanced across ecosystems. ~~a~~As such, Rocci *et al.* (2022) found no consistent changes in soil stoichiometry with nutrient additions in grassland ecosystems, despite an increase in the relative fraction of POM compared to MAOM. Additionally, the microbial community composition, as approximated by the relative abundance of $MIC_{i,j}$: MIC_k simulate by MIMICS-CN, was not sensitive to N additions or shifts in plant allocation and inputs (not shown). By contrast, N addition experiments in forests ecosystems have found reductions in fungal decomposer biomass, reduced ligninolytic enzyme activity, (Argiroff et al., 2019; Frey et al., 2014), and a shift in community function with reduced ability to decompose recalcitrant SOM (Ramirez et al., 2012)—including at our study site (Carrara et al., 2018; Moore et al., 2021). In these studies, this shift in microbial community and function results in accumulation of SOM. Microbially-explicit M~~m~~odels like MIMICS-CN need further development to accurately represent these changes in community composition as resource availability and stoichiometry shift to simulate the downstream effects on soil biogeochemistry. Currently, microbial communities in the model may have too great of access to SOM and litter inputs, resulting in more rapid decomposition rates and lower C:N ratios of SOM pools than is often observed (see also Kyker-Snowman et al. 2020). Specifically, constraining carbon use efficiencies (CUE), nitrogen use efficiencies (NUE), and C:N ratios for microbial communities against data and observations is warranted to capture their responses to environmental changes.

490 **Conclusions**

The two models tested in this study showed that targeted parameter modifications, informed by results from a long-term experiment, significantly improved ~~their-the models'~~ abilities to capture some key ecosystem responses to N additions: notably, a shift in plant C allocation to favor wood biomass over belowground allocation, decreased soil respiration, and an accumulation of POM with high C:N ratios (Eastman et al., 2021, 2022). Our results also suggest that ~~a-morewhile a~~ microbially explicit model has a-greater-potential to capture-theseincorporate additional plant-microbe processes or better parameter existing processes, expanding model experiments to additional sites and data is required to represent the complex responses to N enrichment and predict ecosystem recovery from N additions-compared-to first-order-relationships that have been-commonly-used-in-the-past. HoweverSpecifically, there-are-still key mechanisms driving the observed responses of the forest soil C cycle to N additions – such as direct enzyme inhibition, reduced rhizosphere priming, and shifts in microbial

505 **Table A1.** Parameter modifications made to CASA-CNP vegetation model for site-specific configuration during spin-up and
 historical runs.

CASA-CNP Vegetation Model				
Parameter	Default	Modified	Source	Description
Fine root mean age (years)	10	1.45	Eastman & Peterjohn, <i>unpublished data</i>	reduce fine root biomass to better match observations
Allocation of GPP C (leaf, wood, froot)	0.3, 0.2, 0.5	0.3, 0.3, 0.4	Eastman <i>et al.</i> , 2021	Increase wood C stocks and decrease fine root C stocks
Wood respiration (year ⁻¹)	6	3	Eastman <i>et al.</i> , 2021	Adjust NPP and wood C stocks to match observed
Leaf C:N	50	42	Eastman <i>et al.</i> , 2021	Match observed
Leaf N:C (min, max)	0.02, 0.024	0.0222, 0.02439		Capture modified target leaf C:N
Fine root C:N	41	35	Adams, 1991	Match observed
Fine root N:C (min, max)	0.02439, 0.029268	0.025, 0.032258		Capture modified target fine root C:N
N:C ratio CWD (max)	0.006857	0.00625	Eastman <i>et al.</i> , 2021	Increase C:N of CWD, decrease N availability
N leach rate (g N m ⁻² y ⁻¹)	0.01	0.15	Adams <i>et al.</i> , 2006	Closer to observed rates;

				Increase N limitation under ambient N deposition
Max fine litter pool ($g\ C\ m^{-2}$)	887	1527	Greatest value of all CASA PFTs	Increases N limitation
Max CWD pool ($g\ C\ m^{-2}$)	1164	1918	Greatest value of all CASA PFTs	Increases N limitation
xkNlimiting (min, max)	0.5, 2	3.4, 5.6 (CASA only)		Increases N limitation in CASA model, to be more similarly N limited as the MIMICS-CN model, by increasing the amount of soil N needed to maintain plant N uptake rates.

Table A2. Soil parameter modifications made to CASA-CN for site-specific configuration during spin-up and historical runs. Soil C and N stocks and C:N ratios were compared against observations from Eastman *et al.* (2021, 2022).

CASA-CN			
Parameter	Default	Modified	Justification
MIC soil pool mean age (<i>years</i>)	0.137	0.30688	Decrease total soil C:N ratio
SLOW soil pool mean age (<i>years</i>)	5	3	Decrease SLOW soil pool, total soil C:N ratio, and soil C and N stocks
PASSIVE soil pool mean age (<i>years</i>)	222.22	621	Increase PASSIVE soil pool; decrease total soil C:N ratio
MIC pool C:N (target, min, max)	8, 6.69, 8	7, 6, 10	Decrease total soil C:N ratio
SLOW pool C:N	30, 16.2, 30	14, 12, 16	Decrease total soil C:N ratio

(target, min, max)			510
PASSIVE pool C:N (target, min, max)	30, 16.2, 30	13, 10, 15	Decrease total soil C:N ratio

Table A3. Soil parameter modifications made to MIMICS-CN for site-specific configuration during spin-up and historical runs. Default values are those used by Kyker-Snowman *et al.* (2020). Some parameters used were sourced from the C-only global simulation of the tesbed (Wieder *et al.*, 2015), and denoted as such. Soil C and N stocks and C:N ratios were compared against observations from Eastman *et al.* (2021, 2022).

MIMICS-CN				
Parameter	Default	Modified	Description	Justification
a_V	4.8×10^{-7}	8×10^{-8}	Tuning coefficient	Increases decomposition rates of all pools; Wieder <i>et al.</i> , 2015
K_{slope} $\ln(\text{mg C cm}^{-3}) \cdot \text{C}^{-1}$	0.017-0.027	0.025	Regression coefficient	Wieder <i>et al.</i> , 2015
a_K	0.5	10	Tuning coefficient	Wieder <i>et al.</i> , 2015
$V_{\text{mod}} (\text{k2})$	2.25	2.5	Modifies V_{max} for fluxes from LITs to MICK	Increases decomposition of structural litter
τ_r (h^{-1})	0.00024, 0.3	0.000624, 0.6	Controls r-type microbial biomass turnover rate	Increases turnover of r-type microbial biomass
τ_k (h^{-1})	0.00011, 0.1	0.000288, 0.1	Controls k-type microbial biomass turnover rate	Increases turnover of K-type microbial biomass
τ Mod (min, max)	0.6, 1.3	1, 1	Modifies microbial biomass turnover rate	Wieder <i>et al.</i> , 2015; (no modification)
$f_p (r)$	0.015, 1.3	0.2, 1.3	Fraction of $\tau (r)$ partitioned to SOMp $0.2 \times e^{1.3(\text{clay})}$	Increases fraction of r-type microbial biomass partitioned to SOMp
$f_p (k)$	0.01, 0.8	0.2, 0.8	Fraction of $\tau (k)$ partitioned to SOMp $0.2 \times e^{0.8(\text{clay})}$	Increases fraction of K-type microbial biomass partitioned to SOMp (Wieder <i>et al.</i> , 2015)

D (h^{-1})	1.0×10^{-6} , -4.5	1.0×10^{-6} , -1.5	Desorption rate from SOMp to SOMa $10^{-6} \times e^{-1.5(f_{clay})}$	Increase desorption rate from SOMp to SOMa (Wieder <i>et al.</i> , 2015)
f_i (met)	0.05	0.3	Fraction of metabolic litter inputs transferred to SOMp	Increase total soil C stocks, increase SOMp
f_i (struc)	0.3	0.35	Fraction of structural litter inputs transferred to SOMc	Increase SOMc, increase total soil C:N ratio
f_{met}	0.85— 0.013	0.65—0.013	Partitioning of plant litter inputs to metabolic pool	Reduce fraction of inputs partitioned to metabolic pool (Wieder <i>et al.</i> , 2015)
NUE (1, 2, 3, 4) ($mg\ mg^{-1}$)	0.85, 0.85, 0.85, 0.85	0.8, 0.7, 0.8, 0.7	Proportion of mineralized N captured by microbes (1) LITmN or SOMaN to MICrN; (2) LITsN to MICrN; (3) LITmN or SOMaN to MICKN; (4) LITsN to MICKN	By reducing NUE, we reduced the microbial competitive advantage over plants for N and N limitation. Reducing NUE more for structural litter fluxes increased soil C:N
CN_r, CN_k	6 10	8 12	C:N ratio of r-type microbes C:N ratio of k-type microbes	Increase soil C:N; reduce microbial N demand & N limitation
fracDINavailMIC	0.5	0.2	Fraction of dissolved inorganic N available to microbes	Reduce N limitation by decreasing microbial N uptake
Soil Depth (cm)	100	45	Total soil depth	Observed values are measured to a depth of 45 cm

[§]Aboveground net primary productivity (ANPP) reported for observations.

[†]In 520es litter layer and soil organic horizon.

Code and data availability

Model code is available at <https://doi.org/10.5281/zenodo.7636494>. Model code, results, analysis code can also be accessed at https://github.com/wwieder/biogeochem_testbed. Model output was analyzed and figures were produced in R (R Core

525 Team, 2020), using packages tidyverse (Wickham et al., 2019), data.table (Dowle and Srinivasan, 2020), stringr (Wickham, 2019), and scales (Wickham and Seidel, 2020).

[Model output data is available at https://doi.org/10.5065/kjas-jn19.](https://doi.org/10.5065/kjas-jn19)

Author contribution

530 All authors contributed to the conceptualization of the project and experimental design. WRW and MDH developed the model code and BE performed the model simulations and analyzed model output with key input from WRW. BAE prepared the manuscript with contributions from all co-authors.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

535 This research was funded by a National Science Foundation Long-Term Research and Environmental Biology awards [Grant nos. DEB-0417678, DEB-1019522, and DEB-1455785]. B.E. also received support from National Center for Atmospheric Research Center Advanced Study Program's Graduate Student Fellowship, NCAR is a major facility sponsored by the NSF under Cooperative Agreement No. 1852977. W.R.W. acknowledges support from the NSF (Awards 1926413 and 2031238) and USDA-NIFA (2020-67019-31395).

Tables and Figures

Figure Legends

- Figure 1.** Conceptual diagram of the soil biogeochemical model testbed which includes the (a) CASA-CN vegetation model, 765 (b) CASA-CN soil model, and (c) MIMICS-CN soil model. All pools (boxes) and fluxes (arrows) represent both C and N processes, except for the Inorganic N pools and the fluxes into and out of these pools. Highlighted in yellow are processes that

were modified to test two key hypotheses: (1) modifying C allocation to plant tissues to increase wood production with N additions; and (2) decreasing the turnover time (CASA) or increasing the half-saturation constant (MIMICS) of the slow (CASA) or chemically protected (MIMICS) soil pools under conditions of elevated N (See Table 1).

770

Figure 2. Observed and modelled response ratios of select vegetation (left) and soil (right) pools and fluxes to the three nitrogen addition experiments. Observations (black circles) show the mean (+/- se) values across 10 plots per watershed from the watershed fertilization study at the Fernow Forest (Eastman *et al.*, 2021). Modelled responses include the annual mean from the last ten years of experimental N additions for CASA-CN (brown) and MIMICS-CN (blue) default models (triangles), modified vegetation allocation models (allocation shift; square), and the modified vegetation allocation and soil decay models (enzyme inhibition; asterisk). The vertical dashed line represents no effect of N additions. Vegetation fluxes include aboveground net primary productivity (ANPP) as is the sum of leaf C flux to soil and annual wood C increment (modelled estimates, only, include coarse roots). Vegetation pools include the leaf, wood, and fine root C pools. Total soil pools include organic and mineral horizons, to a depth of 45 cm for both modelled and observed values. Soil fluxes include soil respiration and root C inputs to soil (modelled)/total belowground carbon flux (observation estimated with mass balance approach). †Observed soil respiration includes autotrophic + heterotrophic, whereas modelled soil respiration includes only heterotrophic. The total soil C pool is the sum of C in litter layer, organic horizon, mineral horizon, and (for MIMICS-CN only) microbial biomass. Root flux/TBCF is the total belowground carbon flux of inputs to the soil (modeled values are root turnover inputs and observed values are a mass balance of soil respiration minus leaf C flux). †Observed soil respiration includes autotrophic + heterotrophic, whereas modelled soil respiration includes only heterotrophic.

780

785

Figure 3. Relationship between the relative proportion of light particulate organic matter (POM; named SLOW and SOMc pools in CASA and MIMICS, respectively) and the C:N ratio of bulk mineral soil in observed (black circles) and modelled (brown=CASA, blue=MIMICS) ambient and +N conditions. Figure adapted from Eastman *et al.* (2022). Observed points represent the mean of four soil samples from the top 10 cm of mineral soil per plot (from 10 plots per watershed). Modelled estimates are from the entire mineral soil profile (0-45 cm). Linear regression (standard error in gray shading) for observed (solid black) and modelled (dashed) values.

Tables

Table 1. Description of model experiments, including model parameter modifications made to test plant C allocation shift and enzyme inhibition hypotheses. Bold text indicates parameter modification.

Experiment	Model	Control or +N	Plant C allocation (leaf:root:wood)	SLOW pool decay dynamics
<i>Experiment 1</i> “Default +N”	CASA-CN	Control	0.3 : 0.4 : 0.3	turnover = 4 y
	CASA-CN	+N	0.3 : 0.4 : 0.3	turnover = 4 y
	MIMICS-CN	Control	0.3 : 0.4 : 0.3	KO [†] = 6
	MIMICS-CN	+N	0.3 : 0.4 : 0.3	KO [†] = 6
<i>Experiment 2</i> “Allocation shift +N”	CASA-CN	Control	0.3 : 0.4 : 0.3	turnover = 4 y
	CASA-CN	+N	0.3 : 0.3 : 0.4	turnover = 4 y
	MIMICS-CN	Control	0.3 : 0.4 : 0.3	KO [†] = 6
	MIMICS-CN	+N	0.3 : 0.3 : 0.4	KO [†] = 6
<i>Experiment 3</i> “Enzyme inhibition +N”	CASA-CN	Control	0.3 : 0.4 : 0.3	turnover = 4 y
	CASA-CN	+N	0.3 : 0.3 : 0.4	turnover = 5.33 y
	MIMICS-CN	Control	0.3 : 0.4 : 0.3	KO [†] = 6
	MIMICS-CN	+N	0.3 : 0.3 : 0.4	KO[†] = 9

[†]KO is a scalar to modify Km in the Michaelis-Menten equation for the oxidation of SOMc to SOMa, where MIC is microbial biomass C; Vmax is maximum velocity; SOMc is the SOMc C pool; Km is the half saturation constant.

$$SOMc \rightarrow SOMa = \frac{MIC \times Vmax \times SOMc}{KO \times Km + SOMc}$$

Table 2. Baseline model simulations and observations of the ecosystem pools and fluxes. Model mean (se) values are from the last ten years of the historic transient simulations (1907-1988). Observed mean (se) values are recent measurements (2009-2018) from the reference watershed 7, for which the most complete data were available.

Ecosystem Pool/Flux	MIMICS-CN model	CASA-CN model	Observation
<i>Vegetation</i>			
GPP ($\text{g C m}^{-2} \text{ y}^{-1}$)	1342 (68)	1342 (68)	--
ANPP ($\text{g C m}^{-2} \text{ y}^{-1}$)	772 (8.2)	805 (10)	565 (25)
Woody biomass C (g C m^{-2})	9,300 (5)	9,605 (8)	11,475 (634)
Fine root C (g C m^{-2})	497 (1.6)	521 (2.5)	152 (31)
Plant N uptake ($\text{g N m}^{-2} \text{ y}^{-1}$)	13.5 (0.2)	13.8 (0.2)	7.6 (2.4)
<i>Soil</i>			
Leaf litter inputs ($\text{g C m}^{-2} \text{ y}^{-1}$)	198 (0.8)	204 (0.7)	162 (2)
<u>Leaf litter C:N</u>	<u>53</u>	<u>45</u>	<u>43 (2)</u>
Mineral soil C (g C m^{-2})	8,220 (6)	6,641 (4)	8,299 (566)
Organic horizon C_a (g C m^{-2})	505 (2.2)	1,322 (1.6)	539 (2448)
Total soil C pool (g C m^{-2})	8,725 (11)	7,963 (0.3)	8,838 (513)
Mineral soil C:N ratio	13.6 (0.3)	13.4 (0.3)	14.42 (1.67)
<u>Total soil C:N ratio</u>	<u>14.0</u>	<u>15.6</u>	<u>14.3 (1.2)</u>
Soil respiration ($\text{g C m}^{-2} \text{ y}^{-1}$)	754 (7)	906 (4)	982 (63)
N leaching ($\text{g N m}^{-2} \text{ y}^{-1}$)	2.1 (0.06)	1.5 (0.09)	1.1 (0.06)

Includes litter layer and soil organic horizon for observed values; structural and metabolic litter for modelled values.
