Abstract. Estimations of methane (CH₄) emissions are often based on point measurements using either flux chambers or a transfer coefficient method which may lead to strong underestimation of the total CH₄ fluxes. In order to demonstrate more precise measurements of the CH₄ fluxes from an aquaculture pond, using higher resolution sampling approach we examined the spatiotemporal variability of CH₄ concentration in the water, related fluxes (diffusive and ebullitive) and relevant environmental conditions (temperature, oxygen, chlorophyll-a) during three diurnal campaigns in a hyper-eutrophic fishpond. Our data show remarkable variance spanning several orders of magnitude while diffusive fluxes accounted for only a minor fraction of total CH₄ fluxes (4.1–18.5 %). Linear mixed-effects models identified water depth as the only significant predictor of CH₄ fluxes. Our findings necessitate complex sampling strategies involving temporal and spatial variability for reliable estimates of the role of fishponds in a global methane budget.

Keywords: aquaculture, emissions, fishpond, freshwater, heterogeneity, methane

23 1 Introduction

24 Freshwater aquaculture ponds (fishponds) represent man-made counterparts to natural shallow lakes (Scheffer,
25 2004) which are mainly used for fish production (mostly of common carp, *Cyprinus carpio* L.) and water retention
26 in the landscape. Fishponds serve also as secondary biotope for various organisms (Kolar et al., 2021), supporting
27 noteworthy animal and plant diversity (Pokorný and Hauser, 2002). However, most fishponds suffer from high
28 fish stock densities, excessive carbon and nutrient loading from supplemental fish feeding, sewage pollution, and
29 fertiliser runoffs from agricultural catchments or nutrient mobilisation from the anoxic sediment layers (Pechar,
30 2000). As a result, the trophic structure of plankton communities has shifted towards a reduction of large
31 zooplankton and massive development of phytoplankton, especially cyanobacterial blooms (Potužák et al., 2007),
32 limiting light penetration in the water column. Rapid changes in the intensity of biological processes such as
33 photosynthesis and respiration often result in pronounced daily or seasonal fluctuations in dissolved oxygen (Baxa
34 et al., 2021), signalling decreasing ecosystem stability. The extent of anoxia, accumulation of organic biomass,
35 and rapid heating of the shallow water during summer result in enhanced production of greenhouse gases (Grasset
36 et al., 2018, Zhang et al., 2021; Bartosiewicz et al., 2021).

37 Most concerning are CH₄ emissions as freshwater aquaculture systems release more than 6 Tg CH₄ yr⁻¹ (Yuan et
38 al., 2019). Methane can be emitted via several pathways: simple molecular diffusion, ebullition (in the form of
39 bubbles released from oversaturated sediments), plant-mediated flux (Bastviken et al., 2004), but also through so
40 far neglected pathways including aeration, emissions from dry/drying sediments, or dredged organic material
41 (Kosten et al., 2020). Among all, ebullition is considered the dominant pathway (van Bergen et al., 2019; Kosten
42 et al., 2020), which can contribute 50–96 % (Casper et al., 2000; Xiao et al., 2017; van Bergen et al., 2019; Yang
43 et al., 2020; Zhao et al., 2021) to the total CH₄ flux. Along with the second important pathway – molecular
44 diffusion, both exhibit high spatiotemporal variability due to various physical and biological factors acting on very
45 short time scales, for instance, temperature (van Bergen et al., 2019), nutrient loading (Zhang et al., 2021), CH₄
46 production rates (Zhou et al., 2019), CH₄ oxidation rates (Sanseverino et al., 2012), dissolved oxygen concentration
47 (Xiao et al., 2017), management regime (Yang et al., 2019), or the quality of organic matter in the sediment
48 (Schmiedeskamp et al., 2021). Recently, the ~~direct-potential~~ involvement of phytoplankton in CH₄ production and
49 emissions has been ~~emphasised-suggested~~ (Yan et al., 2019; Bižić et al., 2020; Bartosiewicz et al., 2021). The
50 complex interactions between physical and biological factors lead to a dynamic and ever-changing environment,
51 characterised by high spatial and temporal variability of methane fluxes in ponds.

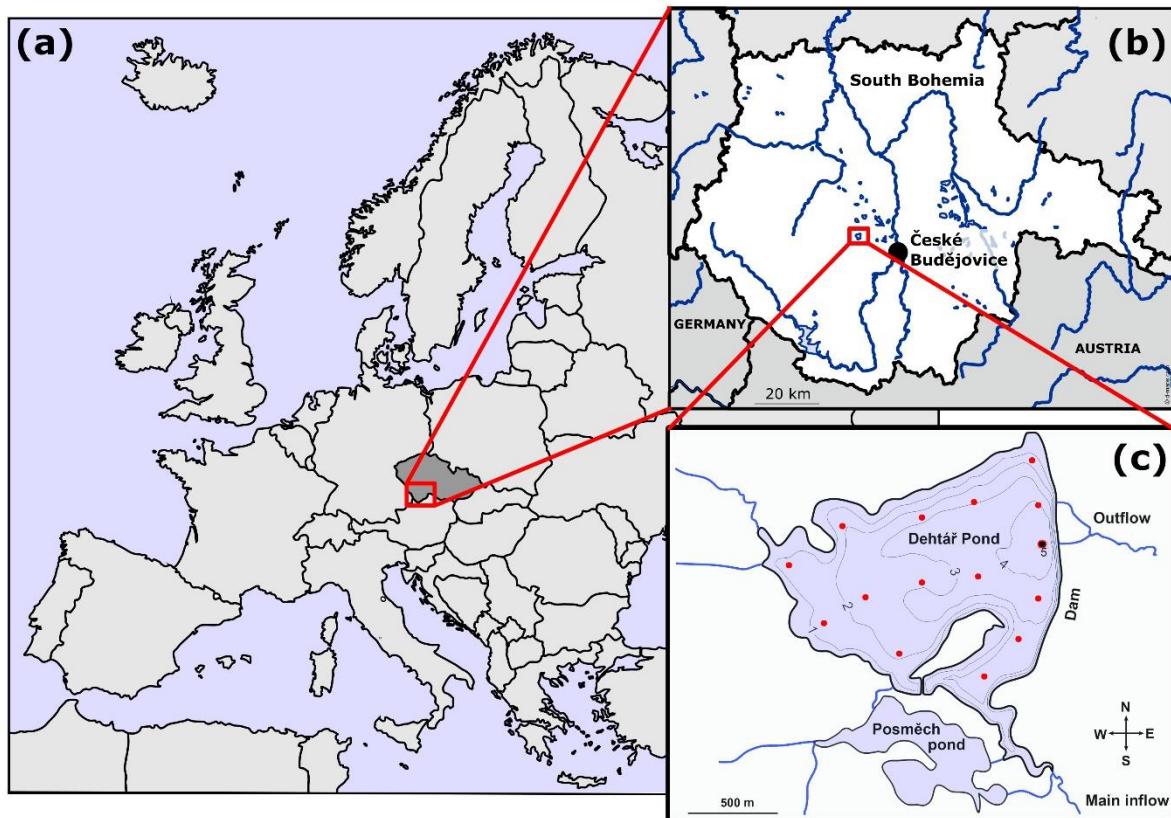

52 Although fishponds are recognised as powerful model systems for studies in ecology and evolutionary or
53 conservation biology (De Meester et al., 2005; Céréghino et al., 2008), the extent of environmental heterogeneity
54 in fishponds and shallow inland small waterbodies remains poorly understood (Ortiz and Wilkinson, 2021), largely
55 because the driving factors are either system-specific or highly variable on short time scales (Laas et al., 2012).
56 Most of current information on lentic ecosystem structure and function comes from single-site sampling, in which
57 measurements are taken over time at the deepest point in the lake, which does not sufficiently account for within-
58 lake spatial variation (Stanley et al., 2019). The motivation for our study was the growing concern about the role
59 of fishponds as important sources of CH₄ fluxes to the atmosphere (Wik et al., 2016). Unfortunately, the majority
60 of global CH₄ flux estimates rely on upscaling methods (DelSontro et al., 2018a) based on a limited number of
61 measurements that do not account for diurnal and seasonal variability or ecosystem spatial heterogeneity. Yang et
62 al. (2019) indicates that a larger number of spatial replicates over a number of months is mandatory to improve
63 the accuracy of whole-pond CH₄ flux estimates. The published research from other aquaculture studies have been
64 performed mainly in tropical and subtropical zones in fish or crab aquacultures (e.g.; Hu et al., 2016; Ma et al.,
65 2018; Yang et al., 2019, 2020; Yuan et al., 2019, 2021). To better understand the spatial dynamics of CH₄ fluxes
66 and environmental heterogeneity in temperate freshwater shallow lake, we conducted a spatial sampling of the
67 hyper-eutrophic Dehtář fishpond (Czech Republic, Europe). Since the seasonal CH₄ production is strongly affected
68 by temperature, we focused on warm summer months where the total CH₄ fluxes were expected to be the highest
69 (Jansen et al., 2019). The objectives of our study were (i) to determine the spatial heterogeneity of CH₄ diffusive
70 and total fluxes and fundamental limnological variables (oxygen, temperature, chlorophyll-a) and their change
71 daily and monthly in the hyper-eutrophic pond, and (ii) to identify the factors that influence CH₄ fluxes to improve
72 our understanding of the importance of spatiotemporal variability for global estimates of CH₄ efflux to the
73 atmosphere.

74 **2 Material and Methods**

75 **2.1 Study site description**

76 The Dehtář fishpond ([49°00'24.4"N 14°17'39.3"E](#)~~49°N, 14°E~~) is a shallow man-made lake (average and
77 maximum depth: 2.4 and 6 m) constructed in 1479 ~~and used for polycultural, semi-intensive production of common~~
78 ~~carp~~ (Potužák et al., 2016). ~~It is used for polycultural, semi-intensive production of common carp, which account~~
79 ~~for 90–95 % of the fish biomass (Rutegwa et al., 2019). The pond is stocked with two-year old carp harvested at~~

80 the end of a two-year production cycle. To increase fish production, the original management, based mainly on
81 natural processes, has been intensified, and today manuring and supplementary feeding in the form of grain or fish
82 pellets, are common practices (Pechar, 2000). ~~†~~ The pond lies in a flat agricultural landscape at 406.4 m above sea
83 level in the upper Vltava River basin in South Bohemia (Czech Republic) which is characteristic with its network
84 of fishponds (Fig. 1b). Due to the orography of the landscape, the Dehtář fishpond, surrounded by narrow belts of
85 littoral vegetation and adjacent to grassland and arable land, is exposed to wind, mainly from the northwest (for
86 aerial photograph, see Suppl. Fig 1). The catchment area is 91.4 km². The main inflow is the Dehtářský stream in
87 the south, while several smaller tributaries flow in from the west (Fig. 1c). The fishpond has a dam 234 m long
88 and 10 m high, with two outlets and a safety spillway. Covering 2.28 km², the Dehtář fishpond is among the ten
89 largest fishponds in the Czech Republic, holding a volume of 4.71×10^3 m³ and having a water residence time of
90 146–445 days (Potužák et al., 2016).

93 fishpond: [blue](#) lines indicate hydrological connections; red dots representing the sampling points. Highlighted sampling point
94 at the dam depicts the deepest site where vertical profiles were measured. Numbers indicate isobath depth.
95

96

97 2.2 Sampling design and measurement

98 To measure spatial heterogeneity and temporal changes in limnological parameters and methane fluxes, we
99 conducted three 36-hour surveys in summer 2019 (July 2–3, August 13–14, September 19–20). In the morning
100 (between 5–6 a.m.), we first measured surface values and vertical profiles of temperature, oxygen, and
101 chlorophyll-*a* concentration at the deepest point (see below for details). We subsequently installed 15 floating
102 polyethylene chambers (as shown in Fig. 1c), serving as fixed sampling sites and at the same time for accumulation
103 of CH₄ fluxes (see further), starting in the western part of the fishpond. During installation (and further during
104 each sampling), temperature, pH, and oxygen concentration were measured at 0.3 m depth using the WTW 330i
105 pH meter and Oximeter (WTW, Weilheim, Germany). Vertical chlorophyll-*a* profiles were measured at each
106 sampling site using a submersible fluorescence probe (FluoroProbe, bbe Moldaenke, Kiel, Germany). From each
107 site, the average chlorophyll-*a* concentration in the surface layer (0–1 m depth) was used to assess the
108 phytoplankton spatial heterogeneity.

109 To minimise the chance that the differences observed among sites were due to time of day, we conducted repeated
110 measurements at the deepest point at the end of each sampling. This was relevant mainly to the initial measurement,
111 when the installation of all floating chambers took a total of 3 hours and 50 minutes. All other measurements, i.e.,
112 the interval between the first and last sampling point, required approximately two hours each. If there was a change,
113 all values were corrected for the sampling time by linear interpolation:

$$114 P_{corr} = P_t + (P_{end} - P_0) \times \frac{(t-t_0)}{(t_{end}-t_0)} \quad (1)$$

115 where P_{corr} is the corrected value of a parameter, P_t is its value measured at the time t , P_0 and P_{end} are parameter
116 values measured at the deepest point at the start (time t_0) and at the end (t_{end}) of the sampling. In the evening and
117 morning of the second day (roughly at 12 h intervals), we performed additional measurements of spatial
118 heterogeneity, allowing us to assess diurnal and nocturnal changes. In addition, samples for measuring CH₄
119 concentration in the surface water were collected at each site and analysed as described below. To assess diurnal
120 variations in thermal structure and oxygen concentration in the water column, we made vertical profile
121 measurements at the deepest point (Fig. 1c) at 3–6 h intervals using the YSI EXO 2 multiparametric probe (YSI
122 Inc., Yellow Springs, USA).

123 2.3 Methane measurements

124 Water samples for determining CH₄ concentration in the surface water were collected at all 15 sampling sites in
125 triplicates into 20 ml glass bottles. The bottles were capped bubble-free under water with black butyl rubber
126 stoppers (Ochs, Germany) and sealed with aluminium crimps. Immediately after sampling, the water samples were

127 preserved by injecting 100 μL of concentrated sulfuric acid to stop the microbial activity (Bussmann et al., 2015).
128 The samples were processed within one week in the laboratory using a headspace technique according to
129 McAuliffe (1971). Methane concentration in the headspace was measured using an HP 5890 Series II gas
130 chromatograph (Agilent Technologies, USA) and calculated with the solubility coefficient given by Yamamoto et
131 al. (1976).

132 Methane diffusive fluxes (F) were then calculated for each sampling site indirectly using the 2-layer model with
133 the equation:

$$134 \quad F = k(C_{sur} - C_{eq}) \quad (2)$$

135 where C_{sur} is the CH_4 concentration in surface water in $\mu\text{mol L}^{-1}$, C_{eq} is the CH_4 concentration in surface water in
136 equilibrium with the atmosphere in $\mu\text{mol L}^{-1}$, and k is the CH_4 exchange constant (cm h^{-1}). The atmospheric partial
137 pressure of CH_4 was set to 1.8 ppm. To compute k values, we first derived k_{600} estimates using a wind speed-based
138 relationship according to Crusius and Wanninkhof (2003):

$$139 \quad k_{600} = 1.68 + (0.228 \times U_{10}^{2.3}) \quad (3)$$

140 where U_{10} represents the wind speed at 10 m height (in m s^{-1} ; obtained from the nearby gauging station)
141 approximated by $U_{10} = 1.22U$, where U is the wind speed at 1.5 m height. We then converted k_{600} to k using the
142 eq. 4 according to Crusius and Wanninkhof (2003):

$$143 \quad k = k_{600} \left(\frac{Sc}{600} \right)^n \quad (4)$$

144 where k_{600} is the gas transfer velocity for a Schmidt number (Sc) of 600; n is a wind speed-dependent conversion
145 factor, for which we used $-2/3$ for $U_{10} < 3.7 \text{ m s}^{-1}$ (Jähne et al., 1987). The Schmidt number for CH_4 was calculated
146 according to Wanninkhof (2014):

$$147 \quad Sc = 1909.4 - 120.78t + 4.1555t^2 - 0.080578t^3 + 0.000658t^4 \quad (5)$$

148 where t ($^{\circ}\text{C}$) is the water temperature at the time of CH_4 extraction. The parameter C_{eq} in Eq. (1) was determined
149 from the equation:

$$150 \quad C_{eq} = \beta \times p\text{CH}_4 \quad (6)$$

151 where β is the solubility coefficient of CH_4 as a function of temperature according to Wiesenburg and Guinasso
152 (1979), and $p\text{CH}_4$ is the partial pressure of CH_4 in the atmosphere.

153 To estimate total CH_4 fluxes from the water column to the atmosphere (i.e., diffusive and ebullitive fluxes), we
154 measured CH_4 accumulation in open-bottom floating polyethylene chambers (volume 3.1 L; area 0.024 m^2). Each
155 gas chamber was anchored at individual 15 fixed sampling sites, but allowed to float freely on the water surface.
156 Gas was accumulating for approximately 12 h (each incubation had a start and end point) during particular

157 sampling period, i.e., during the day and night periods. Afterwards, 30 ml of gas was carefully taken from each
158 chamber, after mixing the headspace in the chamber, and stored in evacuated Exetainers® (Labco Limited, UK).
159 Chambers were ventilated after each sampling period to reset the incubation conditions. Methane fluxes were
160 calculated as the difference between initial background and final concentration in the chamber headspace and
161 expressed on the 1 m² area of the surface level per day according to Bastviken et al. (2004).

162 **2.4 Background limnological parameters**

163 During each campaign, water samples for analysis of nutrient concentration and phytoplankton composition were
164 collected from the surface at the deepest point using a Friedinger sampler. Water transparency was measured using
165 a Secchi disk. Total phosphorus (TP) and soluble reactive phosphorus (SRP) were analysed spectrophotometrically
166 according to Kopáček and Hejzlar (1993) and Murphy and Riley (1962), respectively. Concentrations of NH₄⁺ and
167 NO₃⁻ were determined according to the procedure of Kopáček and Procházková (1993) and Procházková (1959),
168 respectively. Phytoplankton samples were preserved with Lugol's solution and examined for species composition
169 with an inverted microscope (Olympus IMT-2). Weather data were obtained from the gauging station at the
170 fishpond dam.

171 **2.5 Statistical analyses**

172 Two-tailed paired Student's t-tests and Two-way ANOVA with post-hoc Tukey's multiple comparison test (Prism
173 9.3, GraphPad Software Inc., La Jolla, USA) tested for differences between diffusive and total CH₄ fluxes between
174 day and night and among three sampling campaigns, respectively. The percentage of data variability explained by
175 different factors (daytime, month and site) was calculated with the Two-way RM ANOVA. Contour graphs
176 illustrating changes in spatial heterogeneity of measured parameters were constructed in Surfer 10 (Golden
177 Software, Inc., Colorado, USA) using the kriging contouring method. Spatial heterogeneity was quantified for
178 each sampling by calculating the spatial variance (i.e., coefficient of variation of values measured at 15 sampling
179 sites; see, e.g. Fig 2):

$$180 \quad CV\% = 100 \times \frac{SD}{mean} \quad (7)$$

181 Higher spatial variance indicates increasing ecosystem patchiness. Linear mixed-effects models were used to
182 analyse the effects of O₂, pH, temperature, and water depth on the CH₄ diffusive fluxes with the random effect of
183 time of day nested within the effect of sampling date. The most parsimonious model was obtained by a manual
184 backward selection, where we sequentially removed all insignificant predictors ($p > 0.05$) using likelihood ratio

185 tests implemented in the drop1 function (Zuur et al., 2009). We also compared the slopes of the month-specific
 186 regression lines produced by the model using analysis of covariance (Zar, 1984). Linear mixed-effects models
 187 were implemented in the lme4 package version 1.1-21 (Bates et al., 2015), and Kenward-Roger F-tests were
 188 computed using the ANOVA Type II function from the pbrtest package version 0.4-7 (Halekoh and Hojsgaard,
 189 2014). The prediction of the resulting final model was visualised in the package ggeffects version 0.14.1 (Lüdtke,
 190 2018). Package performance version 0.4.4 (Lüdtke et al., 2020) was used to calculate Nakagawa's R^2 of the linear
 191 model. The statistical analyses were performed using R software (v. 3.5.2, R Core Team, 2018).

192 3 Results

193 3.1 Weather and background fishpond characteristics

194 Weather parameters varied among sampling campaigns. In July, clear skies prevailed with the daily air temperature
 195 above 30 °C (Table 1). During the August and September measurements, it was very cloudy, and daily air
 196 temperatures decreased to 22 and 18 °C, respectively. The water level was stable during the whole studied period
 197 with a monthly fluctuation of ~ 10 cm. Water transparency was low (15–40 cm), with an increasing trend towards
 198 the end of summer (Table 1). Concentrations of total phosphorus and soluble reactive phosphorus were high (Table
 199 1), consistent with a hyper-eutrophic state of the fishpond. In contrast, nitrogen concentrations were rather low,
 200 with ammonium nitrogen being the predominant form of inorganic N in the water (Table 1).

201 **Table 1:** Basic characteristics of the Dehtář fishpond during the studied period, measured at the surface at the deepest point.

	July	August	September
Weather	Clear sky, windy	Partly cloudy, no wind	Partly cloudy, no wind
Air temperature (°C)	25–32	20–22	11–18
Water temperature (°C)	24–29	22–23	16–17
Maximum wind speed (m s⁻¹)	3.2	0.8	0.9
PHAR (mol m⁻² day⁻¹)	9.5	3.4	5.0
Secchi depth (cm)	15	30	40
TP (µg L⁻¹)	568	527	406
SRP (µg L⁻¹)	100	200	107
N-NH₄⁺ (µg L⁻¹)	23	783	560
N-NO₃⁻ (µg L⁻¹)	14	23	46

Chl-<i>a</i> (µg L⁻¹)	456	156	185
Phytoplankton composition	Cyanobacteria	Cyanobacteria, green algae, cryptophytes	Cryptophytes, green algae

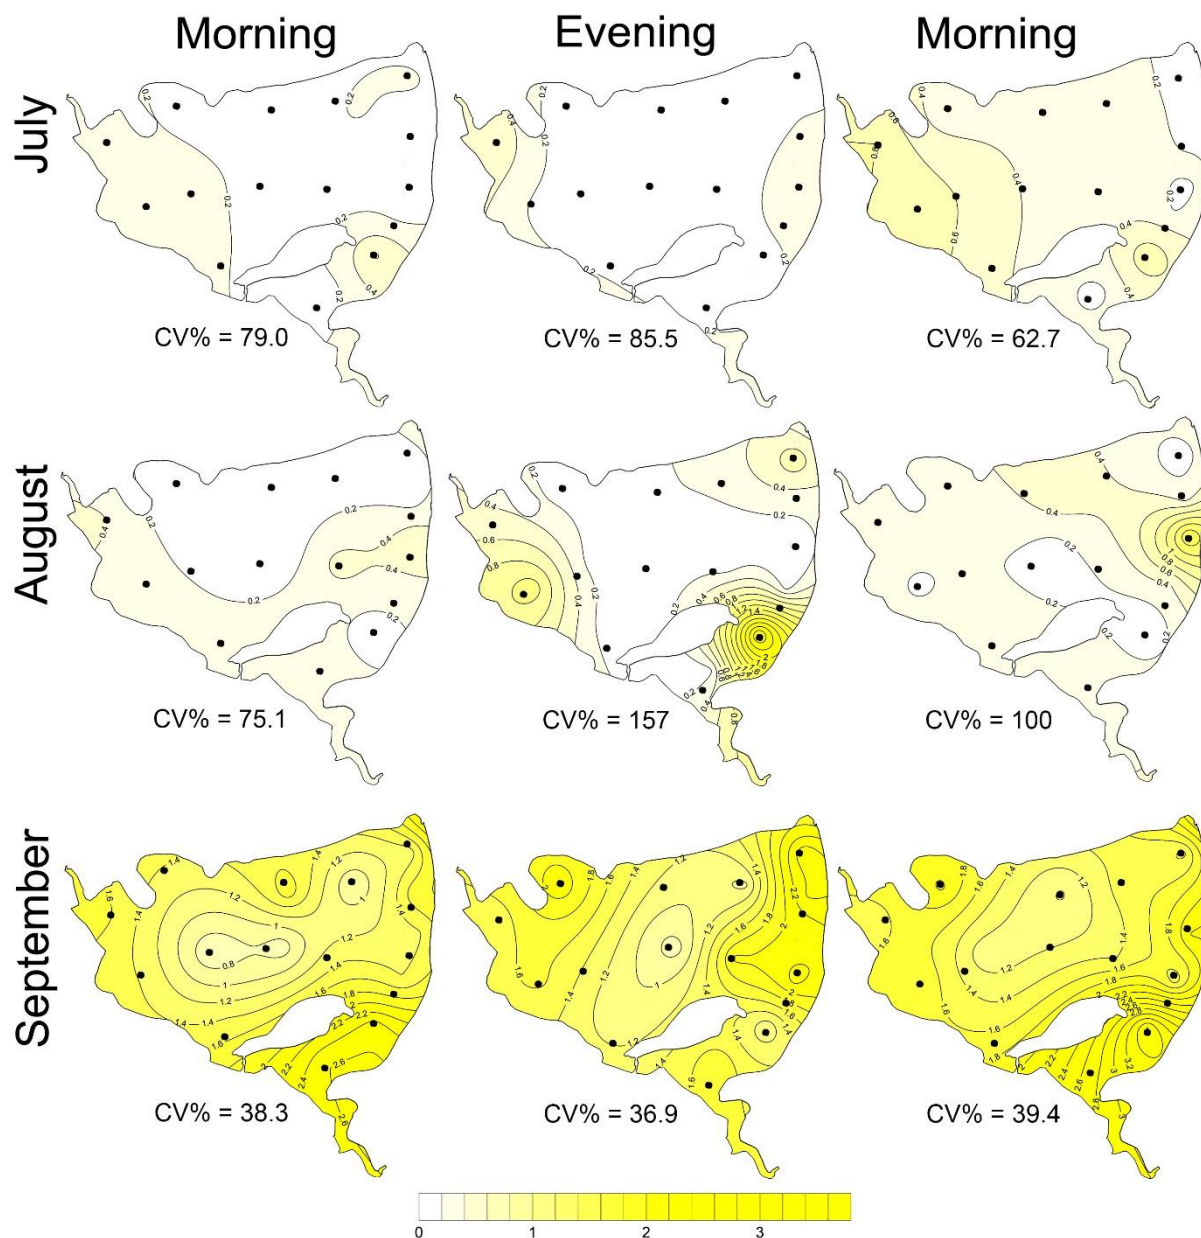

202

203 Chlorophyll-*a* concentrations were highest in July due to the dense cyanobacterial bloom accumulated at the
 204 surface (Table 1). The phytoplankton consisted of only three cyanobacterial taxa: *Dolichospermum flos-aquae*,
 205 *Planktothrix agardhii*, and *Raphidiopsis mediteranea*. In August, phytoplankton was more diverse but also
 206 dominated by cyanobacteria: *P. agardhii*, *Aphanizomenon issatschenkoi*, and *D. flos-aquae*. In September,
 207 cyanobacteria were absent and instead, cryptophytes (*Cryptomonas reflexa*), green algae (*Pediastrum*, *Coelastrum*
 208 and *Desmodesmus*) and dinoflagellates (*Ceratium hirundinella*) prevailed.

209 3.2 Methane concentration and fluxes

210 The CH₄ concentration in surface water was highly supersaturated over the whole studied period. The obtained
 211 values varied from 0.003 up to 3.75 µmol L⁻¹ (Fig. 2), which corresponded to saturation levels of 108–12 834%.
 212 It is obvious, that the obtained data show remarkable variance: the mean (± SD) values were 0.22 ± 0.18 for July,
 213 0.34 ± 0.45 for August, and 1.61 ± 0.61 µmol L⁻¹ for September (Suppl. Fig. 11).

214

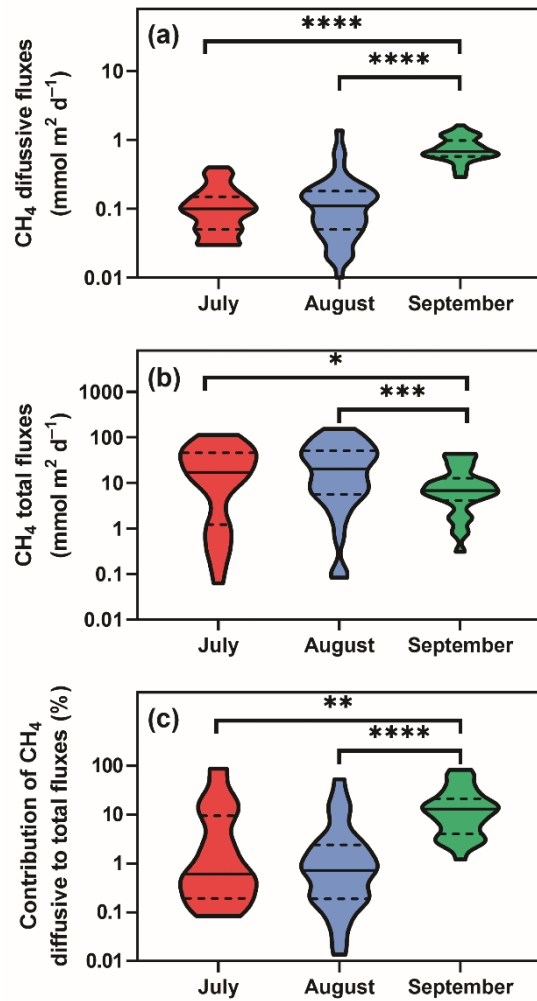

215

216 **Figure 2:** Surface methane concentrations ($\mu\text{mol L}^{-1}$). Contour graphs illustrating both seasonal and daily changes in spatial
 217 heterogeneity (indicated by the coefficient of variation, CV%) in the fishpond. Black dots representing the sampling sites.

218

219 Diffusive fluxes (*i.e.*, calculated from CH_4 concentration, see Eq. 2) showed the lowest values in July and August
 220 (average 0.12 and $0.16 \text{ mmol m}^{-2} \text{ d}^{-1}$, respectively) and pronouncedly peaked in September (average 0.78 mmol
 221 $\text{m}^{-2} \text{ d}^{-1}$, Fig. 3a). By contrast, in July and August, the average total CH_4 fluxes (obtained with floating chambers)
 222 showed the highest values (average $31.8 \text{ mmol m}^{-2} \text{ d}^{-1}$; ranging from 0.08 to $152 \text{ mmol m}^{-2} \text{ d}^{-1}$) while in
 223 September, total CH_4 fluxes were three times lower than before (average $11.8 \text{ mmol m}^{-2} \text{ d}^{-1}$, range 0.3 to 43.5
 224 $\text{mmol m}^{-2} \text{ d}^{-1}$, Fig 3b). As a result, diffusive fluxes accounted for only a minor fraction of total CH_4 fluxes to the
 225 atmosphere (on average, 9.2% in July, 4.1% in August, 18.5% in September, Fig. 3c).

226

227 **Figure 3:** Violin plots of CH₄ diffusive (a) and total fluxes (b) during the studied period. Panel (c) depicts differences in the
 228 percentage contribution of diffusive to total fluxes. Solid lines are medians, while dashed lines denote quartiles. Asterisks
 229 indicate significant differences (* p<0.05, ** p<0.01, *** p<0.001, **** p<0.0001) between sampling dates determined by
 230 two-way ANOVA with Tukey’s multiple comparison test. Note that a log scale is used here for clarity.

231

232 The total CH₄ fluxes show spatial variability within the fishpond that range four orders of magnitude (Fig. 3, 4;
 233 Suppl. Fig. 11; Suppl. Table 1). The observed spatial pattern showed high temporal variability on both daily and
 234 monthly scales (Fig. 2, 4, Suppl. Table 1). Most of the variability in CH₄ diffusive fluxes was explained by
 235 sampling date (62.4 %), while for the total CH₄ fluxes, spatial heterogeneity accounted for 87.2 % of data
 236 variability (Table 2). Using linear mixed-effects models, we identified water depth as the only significant predictor
 237 of total CH₄ fluxes (Df = 1, p < 0.0001, marginal Nakagawa’s R² = 0.348; Fig. 5).

238

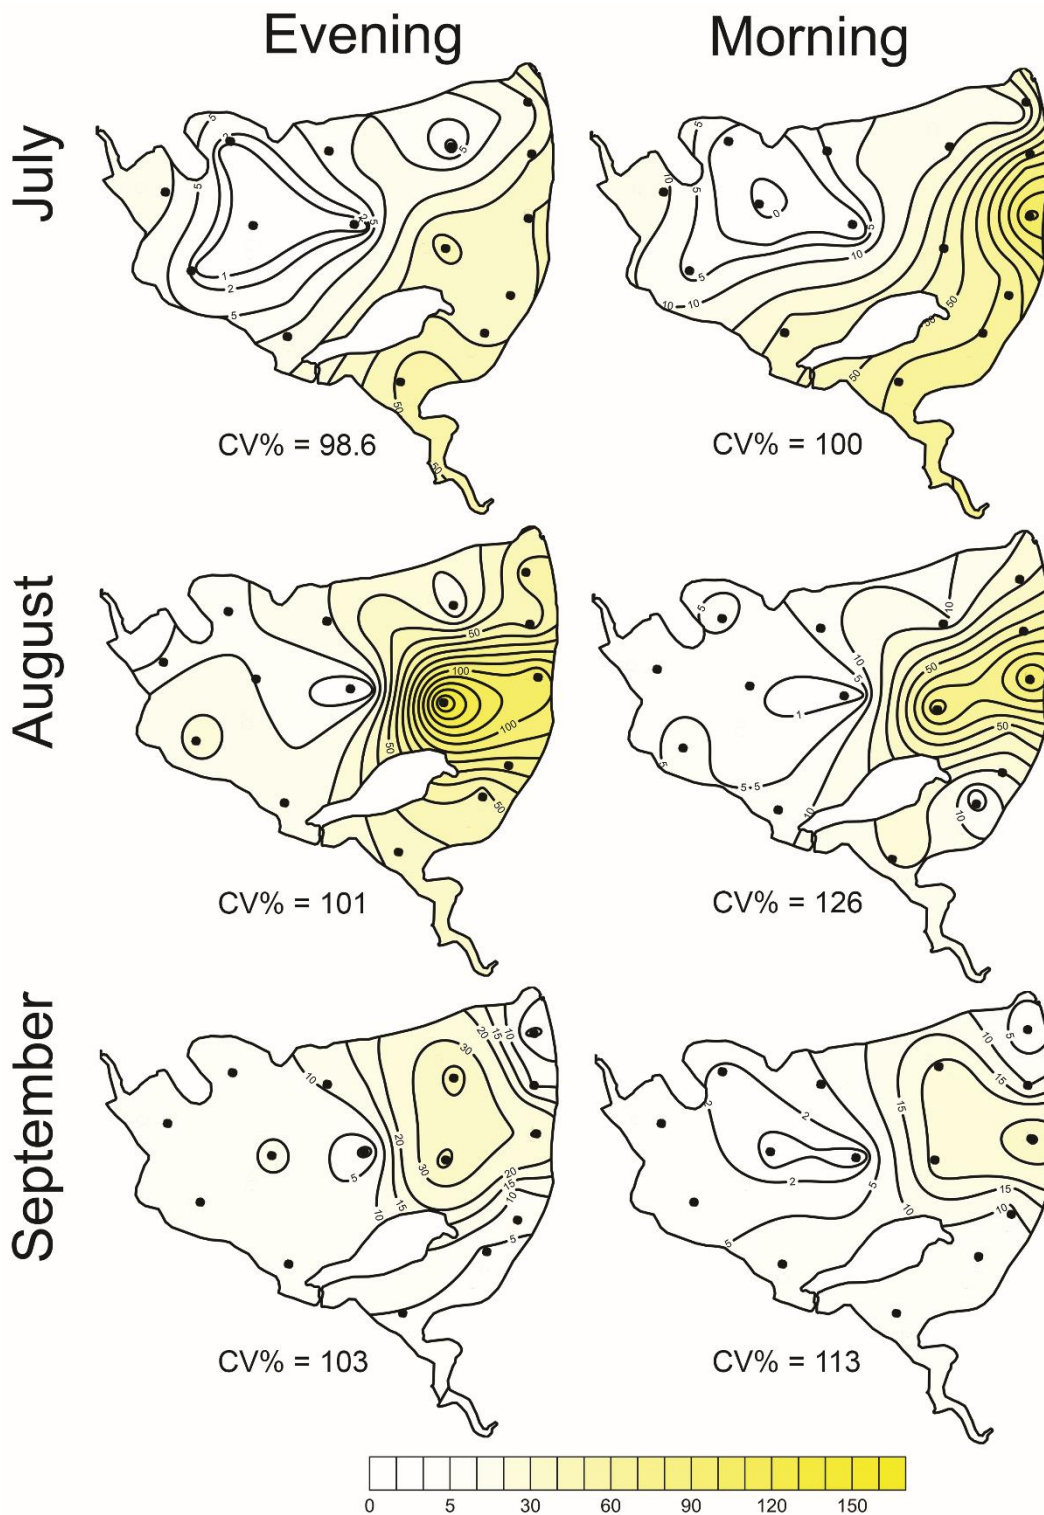

239

240

241 **Table 2:** The percentage of data variability explained by different factors (daytime, month = sampling date, and site)
 242 calculated with the Two-way RM ANOVA. Statistically significant values ($p < 0.01$) are bold.

	% of variability				Significance		
	Daytime	Month	Site	Unexplained	Daytime	Month	Site
CH₄ diffusive flux	2.3	62.4	13.2	22.1	0.0123	<0.0001	<i>n.s.</i>
CH₄ total flux	0.19	2.4	87.2	10.2	<i>n.s.</i>	<i>n.s.</i>	<0.0001
pH	4.4	64.9	11.1	19.6	0.0001	<0.0001	<i>n.s.</i>
Water temperature	3.3	92.3	2.5	1.9	<0.0001	<0.0001	<0.0001
O₂	21.7	48.1	13.8	16.4	<0.0001	<0.0001	0.0135
Chl-<i>a</i>	0.019	74.9	16.7	8.4	<i>n.s.</i>	<0.0001	<0.0001

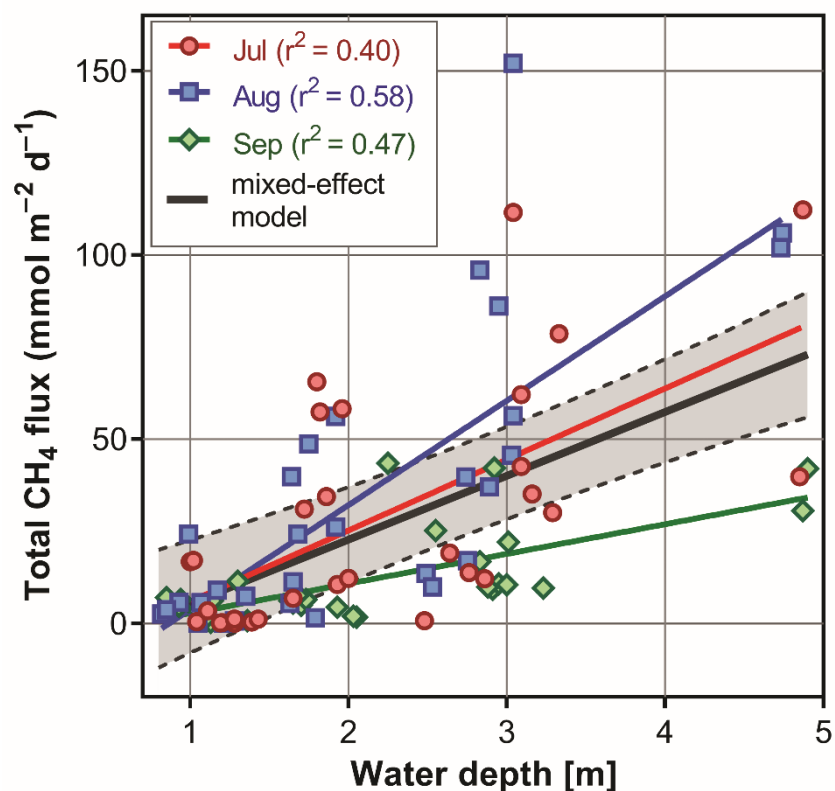

243 Interestingly, slopes of the linear regressions differed significantly among individual sampling campaigns (Fig. 5),
 244 indicating an additional season-related factor that affects CH₄ fluxes in the fishpond. Calculated CH₄ diffusive
 245 fluxes were not correlated with total fluxes. Linear mixed-effects models did not identify any significant predictor
 246 of the fluxes, indicating that factors and processes out of the study's scope are involved. We found no significant
 247 difference in either diffusive or total CH₄ fluxes between day and night.

248

249 **Figure 4:** Contour graphs of methane total fluxes in the Dehtář fishpond. Isopleths connect sites with the same value of
 250 methane fluxes ($\text{mmol m}^{-2} \text{ day}^{-1}$). CV% is a measure of spatial heterogeneity. Black dots representing the sampling sites.

251

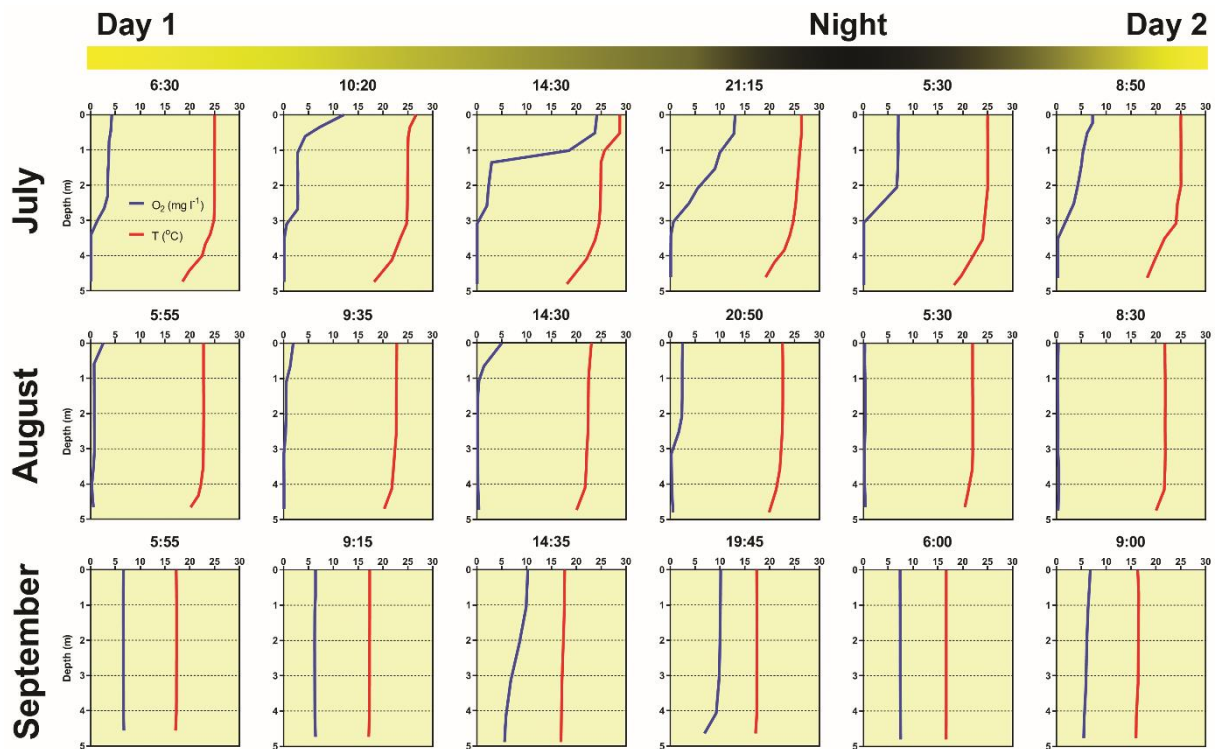

252

253 **Figure 5:** The most parsimonious linear mixed-effect model of methane total fluxes showing the water depth as the only
 254 significant predictor. Symbols are the measured values, the solid black line is the prediction, and dashed lines are 95th
 255 confidence intervals. Colours indicate month specific relation between total methane fluxes and water depth. Differences in
 256 slopes were tested using the F-test. In September, the slope of the regression line was significantly different from that in July
 257 and August.

258 3.3 Diurnal changes in vertical profiles of oxygen and temperature

259 Several contrasting patterns of vertical temperature and oxygen profiles occurred during summer 2019. Diurnal
 260 changes were most pronounced in July (Fig. 6). Surface temperatures varied from 25 °C in the morning to nearly
 261 30 °C in the afternoon. Thermal stratification of the water column was weak in the morning but became strongest
 262 at 14:30 with a thermocline at 0.5 m depth (Fig. 6). Later in the afternoon, the water column began to be mixed by
 263 wind. The morning vertical oxygen profile was characterised by a surface value of 4.3 mg L⁻¹, corresponding to
 264 51 % saturation and anoxia below 3 m.

265

266 **Figure 6:** Diurnal changes in vertical profiles of temperature and oxygen concentration measured at the deepest point of the
 267 fishpond. Numbers above each graph indicate the time of measurement.

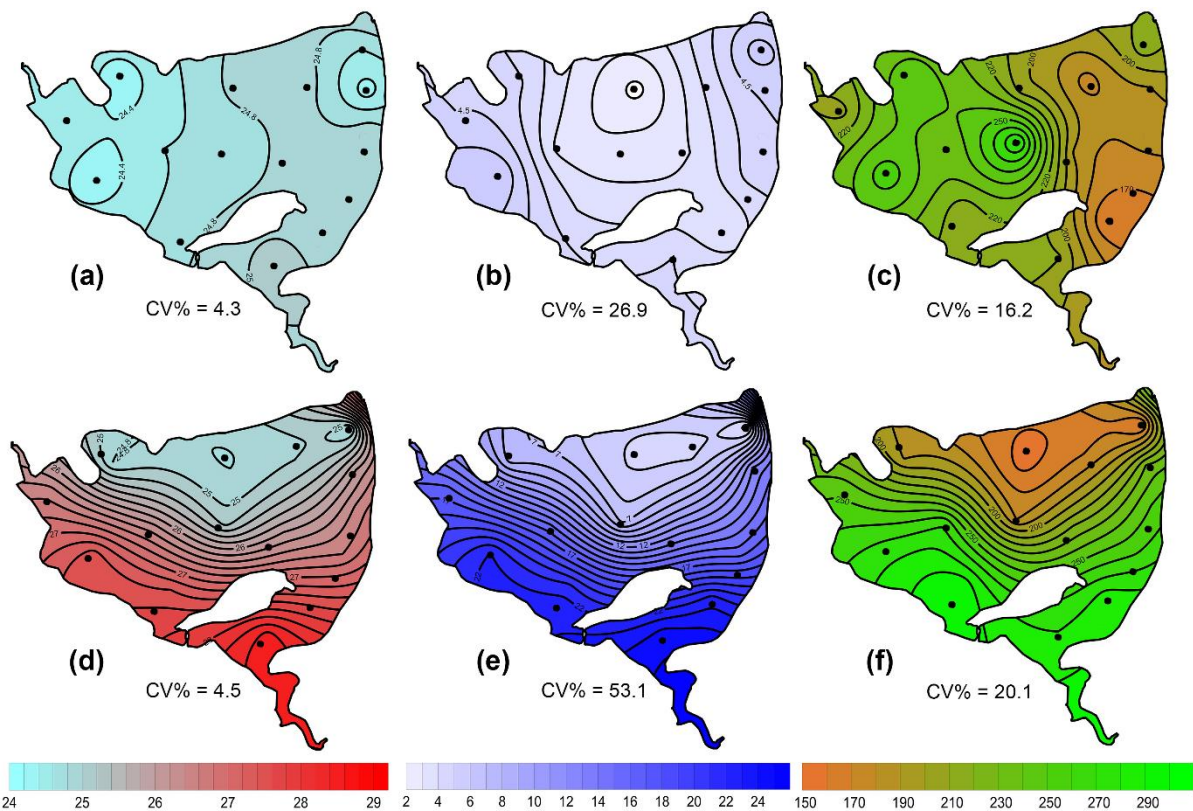

268 Due to the high photosynthetic activity of cyanobacteria, the surface oxygen concentration increased to 24 mg L^{-1}
 269 1 (320 % saturation, Fig. 6), and a steep oxycline was established at a depth of $0.5\text{--}1.5 \text{ m}$ with no effect on the
 270 anoxic conditions at the deeper layers. Wind action eroded both the oxy- and thermoclines in the evening, and by
 271 the next morning, the vertical profiles were similar to those at the beginning.

272 In August, the water column was almost entirely mixed and low in oxygen in the morning, with only 2.6 mg L^{-1}
 273 (30 % saturation) of oxygen at the surface. Due to cloudy weather, the daily photosynthetic activity of
 274 phytoplankton resulted in only a slight increase in oxygen concentration at $0\text{--}1.5 \text{ m}$ depth (4 mg L^{-1} , 47 %
 275 saturation). By the morning of the next day, the entire water column turned very close to anoxic (0.4 mg L^{-1} , 4 %
 276 saturation; Fig. 6), which in turn affected the spatial distribution of zooplankton, as evidenced by the formation of
 277 dense zooplankton clouds accumulated in the thin layer just at the surface (see Suppl. Fig. 3). In September, the
 278 water column was completely mixed, and we observed only weak daily changes in thermal and oxygen vertical
 279 structures (Fig. 6).

280 3.4 Effect of wind on spatial heterogeneity of temperature, oxygen and chlorophyll-*a*

281 During the summer, all measured parameters showed remarkable within-lake spatial heterogeneity (Suppl. Fig. 5–
 282 8). In July, meteorological conditions allowed for demonstrating the effect of wind on fishpond spatial

283 heterogeneity. In the morning, there were no substantial differences in the surface temperature and oxygen
 284 concentrations (Fig. 7ab). Phytoplankton biomass was accumulated mostly in the shallow western part, with the
 285 maximum in the centre (Fig. 7c). At 14:00, a light breeze started to blow from the northwest, achieving a maximum
 286 of 3.2 m s^{-1} (Suppl. Fig. 9). This episode lasted till the evening measurement, and the wind ceased by 21:00. The
 287 wind was strong enough to change spatial distribution substantially (Fig. 7d–f, Suppl. Fig. 4). In the evening, the
 288 surface water temperature on the windward (south) side of the fishpond was $\sim 4 \text{ }^\circ\text{C}$ higher than in the north (Fig.
 289 7d). The wind also induced order of magnitude differences in oxygen concentration along the north-south axis of
 290 the fishpond (3 mg L^{-1} of O_2 at the north, 24 mg L^{-1} of O_2 at the south; Fig. 7e) and affected phytoplankton
 291 distribution in the fishpond, resulting in remarkable bloom accumulation in the south (Fig. 7f, Suppl. Fig. 8).
 292 During the calm night after the disturbance, the north-south gradient substantially weakened. In August and
 293 September, the thermal heterogeneity of the pond was rather low, but the spatial distribution of oxygen and
 294 chlorophyll-*a* remained highly variable (Suppl. Fig. 5–8, Suppl. Table 1).

295
 296 **Figure 7:** Contour graphs of surface temperature (a, d; $^\circ\text{C}$), oxygen concentration (b, e; mg L^{-1}) and chlorophyll-*a*
 297 concentration (c, f; $\mu\text{g L}^{-1}$) measured on July 2 at different times of day: a, b and c are the morning measurements; d, e and f
 298 are evening measurements following a wind disturbance. Coefficient of variation (CV %) is a measure of spatial heterogeneity
 299 of measured parameters. Black dots representing the sampling sites.

300 **4 Discussion**

301 **4.1 Methane fluxes**

302 Assessing spatial heterogeneity of the CH₄ fluxes within a fishpond is critical for a reliable estimate of its
303 contribution to the global CH₄ budget. In our study, the variability in total CH₄ fluxes spanned several orders of
304 magnitude (ranging from 0.06 up to 1 121.3 mmol m⁻² d⁻¹), which is in agreement with similar studies (Casper et
305 al., 2000; DelSontro et al., 2016; Natchimuthu et al., 2016). However, most system-specific CH₄ flux estimates rely
306 on upscaling from a limited number of sites (Bastviken et al., 2004; Rasilo et al., 2015; Wik et al., 2016) because
307 obtaining spatial variability in CH₄ emission is methodologically challenging. In general, spatial heterogeneity
308 may reflect differences in water sources, physical mixing, local transformations and biogeochemical processes and
309 rates among lake habitats (Loken et al., 2019). In deep lakes, littoral areas can contribute disproportionately to
310 total lake CH₄ fluxes (Hofmann et al., 2010; Hofmann 2013, Natchimuthu et al., 2016; Schilder et al., 2013) and
311 are often missed by traditional sampling approaches (Wik et al., 2016). According to Wik et al. (2016), low
312 temporal and spatial resolutions are unlikely to cause overestimates. On the other hand, DelSontro et al. (2018b)
313 suggested that horizontal transport of CH₄ produced in littoral zones and the interaction between physical and
314 biological processes (e.g. air-water gas exchange, water column mixing, the interplay between CH₄ production
315 and microbial oxidation) may result in an underestimation of whole-lake CH₄ fluxes based on centre samples.
316 Similarly, Natchimuthu et al. (2016) found that up to 78 % underestimation would occur if samples obtained only
317 from the lake [centre](#) are used to extrapolate the total CH₄ flux. However, extrapolating our data from the deepest
318 point of the Dehtář fishpond would lead to an overestimation of the CH₄ fluxes by a factor of 2.9 (Suppl. Fig. 12).
319 The bias introduced by the deepest point measurement appears to be highly variable among systems with different
320 morphology, geographical location, mixing regimes or trophic states. For instance, analysis of 22 European lakes
321 during late summer has shown that spatially resolved CH₄ diffusive fluxes were highly variable for individual
322 lakes, yielding 55–300 % differences in the whole-lake estimates (Schilder et al., 2013). Schmiedeskamp et al.
323 (2021) observed an increase in CH₄ fluxes from the shore towards the centre in response to increasing sediment
324 C-content in two shallow German lakes. In line with these findings, our results provide further evidence that
325 spatially resolved data are needed to validate the uncertainties that come from using single-point samples to
326 represent whole-lake processes in hyper-eutrophic systems. As stated by Loken et al. (2019), rather than assuming
327 spatial homogeneity, scaling-up exercises of global carbon budgets should acknowledge the uncertainty that comes
328 from extrapolating from spatially limited data sets.

329 In the Dehtář fishpond, the total CH₄ fluxes increased with water depth, and this relationship was month specific.
330 The highest CH₄ fluxes at the deepest points may seem contradictory to previous studies, in which the highest
331 fluxes were typically observed in littoral areas (e.g., DelSontro et al., 2018b; Hofman et al., 2010; Natchimuthu et
332 al., 2016; Schilder et al., 2013). However, these findings are based on studying mostly large, shallow to medium-
333 deep oligotrophic lakes whose morphology, trophic state or oxygen regime sharply contrast with the hyper-
334 eutrophic Dehtář fishpond, where the upper two meters of the water column were oxygen-saturated while the
335 deepest strata were mostly anoxic, i.e., the extent and duration of bottom anoxia could be the most influential
336 factor contributing to the highest methane fluxes at the deepest point of the pond. In ~~such~~ hyper-eutrophic systems,
337 high nutrient loading increases autochthonous primary production (Potužák et al., 2007; Rutegwa et al., 2019) and
338 promotes oxygen consumption and anaerobic decomposition in the sediments (Baxa et al., 2020), leading to
339 enhanced CH₄ production (Bastviken et al., 2004; Grasset et al., 2018). In aquaculture ponds in Southeast China,
340 CH₄ fluxes exhibited considerable spatial variations and peaked in the relatively deep feeding zone, where the
341 large loads of sediment organic matter ~~fuelled~~fuelled CH₄ production (Yang et al., 2020). Furthermore, sediment
342 temperature was the strongest predictor of CH₄ fluxes in shallow ponds with anoxic hypolimnion (DelSontro et
343 al., 2016; Yang et al., 2020). It is, therefore, reasonable to assume that both temperature and oxygen concentration
344 in the sediment likely contributed to changes in observed CH₄ fluxes during the studied period in our study.
345 Although both parameters were not directly measured in the sediment, it can be deduced from their vertical profiles
346 that the probability of sediment anoxia was highest in August and lowest in September, and the sediment
347 temperature was lowest in September (see Fig. 5).

348 Our results agree with the generally accepted view that processes other than diffusive fluxes, ~~—~~ most likely
349 ebullition, ~~—~~ represent the major CH₄ pathway to the atmosphere in hyper-eutrophic ponds used for intensive fish
350 production (Kosten et al., 2020). Although freshwaters with high primary production are more likely to have high
351 CH₄ ebullition rates (DelSontro et al., 2016), the dominant role of ebullition was also found across lentic systems
352 differing in size, trophic status or geographical location (Aben et al., 2017). Ebullition accounted on average for
353 56 % of total CH₄ fluxes in northern ponds in Canada (DelSontro et al., 2016), 49 and 71 % in two different zones
354 of Lake Taihu (Xiao et al., 2017) and 48-83 % in three Swedish lakes (Natchimuthu et al., 2016; Jansen et al.,
355 2019). The highest contribution was found in the small hyper-eutrophic Priest Pot (UK), where ebullition
356 represented 96 % of the total CH₄ flux from the pond (Casper et al., 2000). Apparently, the contribution of
357 ebullition can vary among systems and will remain uncertain until measurement designs cover enough
358 spatiotemporal variability to yield representative values for the whole ecosystem.

359 In shallow water bodies, a semi-stable flux of microbubbles was suggested to account for a significant portion of
360 the total CH₄ flux (Prairie and del Giorgio, 2013). When CH₄ concentration in the water column is above a certain
361 threshold of microbubble density, these microbubbles likely aggregate, fuse, and escape to the atmosphere from
362 buoyancy (Prairie and del Giorgio, 2013). Even a small fluctuation in hydrostatic pressure ([e.g.](#), due to changes in
363 atmospheric pressure) or lake water level was shown to trigger enhanced CH₄ ebullition (Bastviken et al., 2004;
364 Casper et al., 2000; Varadharajan and Hemond, 2012). Since ebullition rates increase exponentially with
365 temperature, CH₄ fluxes tend to peak in warm summer months (van Bergen et al., 2019). In our study, 1 % lower
366 air pressure in July and August than in September, along with bottom anoxia and higher water temperature, could
367 account for the enhanced release of CH₄ bubbles from the sediment (31.7 mmol m⁻²d⁻¹, >90 % of total CH₄ fluxes;
368 Suppl. Fig. 2). In September, when we observed the lowest water temperatures from the studied period and the
369 oxygen profile was rather uniform, ebullition accounted for 81 % (11 mmol m⁻²d⁻¹) of the total CH₄ fluxes. The
370 spatially pooled data of the total CH₄ fluxes measured in the Dehtář fishpond varied from 11.8 to 34.5 mmol m⁻²
371 d⁻¹, which is comparable with similar systems elsewhere ([e.g.](#), Bastviken et al., 2010; van Bergen et al., 2019;
372 Baron et al., 2022). To sum up, both diffusive fluxes and ebullition must be addressed to understand the magnitude
373 of total aquatic CH₄ fluxes and how their relative contributions vary across and within aquatic systems (Kosten et
374 al., 2020). Moreover, with an improved determination of CH₄ hot-spots and its causes, the management of ponds
375 could be changed accordingly and so the overall emissions reduced for example by decreasing P-availability and
376 dredging (Nijman et al., 2022).

377 **4.2 Effect of wind event on ecosystem spatial structure**

378 Sudden changes in ecosystem spatial structure in response to meteorological forcing have rarely been documented
379 (Loken et al., 2019) since they are hard to predict. Research into them using traditional methods requires intensive
380 effort or expensive instrumentation (Ortiz and Wilkinson, 2021), and it remains a matter of luck to obtain a relevant
381 dataset. In the July sampling campaign, we observed a strong impact of the wind on environmental heterogeneity
382 in the fishpond, which was apparent at a sub-daily time scale. Due to the methodological constraints, i.e., lack of
383 initial measurement, we can only speculate about the effect of wind on the total CH₄ fluxes. The northwest wind
384 during the day advected warmed surface water with cyanobacterial bloom from the north basin to the south. In the
385 evening, it resulted in bloom accumulation on the upward side and a north-south gradient of more than 4 °C and
386 [4-2420](#) mg L⁻¹ oxygen. After the winds fell off, the observed gradients declined during cooling at night. We assume
387 that the wind blowing across the pond surface drove buoyant cyanobacteria and surface water downwind and
388 caused an upwelling of deeper, colder, and hypoxic water on the upwind side. This wind-related circulation pattern

389 has been described as a “conveyer belt” in classical textbooks (Reynolds et al., 2006), held responsible for a
390 disruption of the thermal structure of the water column and the non-uniform spatial distribution of pH, oxygen,
391 CO₂ or CH₄ and also plankton assemblages (e.g., Loken et al., 2019; Natchimuthu et al., 2016; Rinke et al., 2009;
392 Ortiz and Wilkinson, 2021).

393 Similar to our study, mild winds (~4 m s⁻¹) were strong enough to redistribute heat and induce lake-wide
394 circulations driving upwelling and downwelling in 24 m deep Lake Pleasant (Czikowsky et al., 2018). As the wind
395 blows harder and lasts longer, the effects on ecosystem functioning may target higher trophic levels and become
396 more complex (Rinke et al., 2009). In Lake Constance, a three-day storm event with wind velocities of ~10 m s⁻¹
397 resulted in a lake-wide displacement of water masses and the formation of the 6–15 °C horizontal surface water
398 gradient, which in turn changed the spatial distribution of phytoplankton, zooplankton and juvenile fish (Rinke et
399 al., 2009). After several stormy days (wind velocities of 12–15 m s⁻¹), Čech et al. (2011) observed negative effects
400 of wind-driven changes in water temperature and wave action on perch (*Perca fluviatilis*) spawning in the Lake
401 Milada. Although wind events affect shallow and deep lakes differently, there is growing evidence that they can
402 have far-reaching consequences on the functioning of aquatic ecosystems by disrupting energy flows, nutrient
403 fluxes, productivity and reproduction, and consequently altering community composition and trophic interactions
404 in the short and long term (Stockwell et al., 2020). As the frequency, intensity, spatial extent and duration of these
405 extreme meteorological events are projected to increase due to ongoing climate change (Comou and Rahmstorf,
406 2012), there is an urgent need to better understand the mechanisms underlying their impacts on the maintenance
407 of the ecosystem services.

408 **4.3 Summer changes in the oxygen regime**

409 Our data demonstrate that shallow, hyper-eutrophic ponds have disrupted oxygen regimes (Baxa et al., 2021) with
410 anoxic hypolimnion and may experience severe whole-water column hypoxia critical for aquatic biota (Miranda
411 et al., 2001). The hypoxic periods may result, for example, from sudden weather change (Jeppesen et al., 1990)
412 and last several days, during which physical processes and phytoplankton photosynthesis cannot compensate for
413 intense community respiration (Baxa et al., 2021). This became obvious in August when severe oxygen depletion
414 was measured at the surface across the whole pond, mostly far below a critical level of 4.5 mg L⁻¹, when adverse
415 effects came into play (Banerjee et al., 2019). However, oxygen surface concentrations in shallow parts of the
416 pond were substantially higher regardless of the time of day, which contrasts with findings of Miranda et al. (2001),
417 who emphasised shallow waters as the most sensitive parts of lakes, where hypoxic events can occur due to the
418 respiration of sediment biota. The observed spatial gradients of oxygen may create temporal refugia which allow

419 fish to survive harsh conditions that occur in the deepest part of the pond. To minimise economic losses and
420 negative impacts on the ecosystem, future research should identify the interplay between meteorological forcing,
421 trophic status and anthropogenic pressures (e.g., management practices) that affect oxygen fluctuations at various
422 time scales.

423 **4.4 Study limitations**

424 Like in other research, there are some limitations in the current study. Since our measurement had only a limited
425 temporal resolution (three samplings during the summer season), it is not appropriate to extrapolate CH₄ emissions
426 for annual values. Noticeably, future research must increase the frequency of the sampling and include also
427 innovative techniques to measure CH₄ fluxes at multiple fishponds, with different management regime. In our
428 study, the 12-h deployment time of the floating chambers could have led to extensive gas accumulation, which in
429 turn might have resulted in an underestimation of the total CH₄ fluxes due to the dissolution of the CH₄ from the
430 chamber into the water once the equilibrium concentration in the chamber is overcome (Bastviken et al., 2010).
431 However, CH₄ concentrations in water corresponded to a supersaturation of several orders of magnitude, so the
432 introduced bias appears to be of minor importance. In any case, our daily spatially pooled total CH₄ fluxes (11.8–
433 34.5 mmol m⁻² d⁻¹) represent a rather conservative estimate for the global methane budget. In our study, we also
434 did not address the important processes that could shed light on the lake CH₄ budget, such as CH₄ oxidation rates
435 (Bastviken et al., 2008) or biological interaction (e.g., protistan grazing on CH₄ oxidising bacteria) in aquatic food
436 webs (Sanseverino et al., 2012) that can affect the overall CH₄ fluxes. We also lack information about spatial
437 differences in sediment microbiota and organic carbon content and compositions, which were found to affect CH₄
438 production rates (Berberich et al., 2020; Emerson et al., 2021). Despite the limitation mentioned above, our results
439 show that complementary spatial surveys help contextualise the fixed station dynamics and provide additional,
440 management-relevant information about the fishpond.

441 For improved monitoring strategies, however, a continuous measurement approach like eddy covariance would be
442 generally more efficient than traditional sampling at regular intervals. Eddy covariance accounts for temporal
443 variability and provides high temporal resolution data by continuously measuring wind speed, gas concentration,
444 and vertical turbulent fluxes to estimate methane emissions (Erkkilä et al., 2018). More importantly, it also offers
445 spatially integrated measurements, averaging emissions over a larger area and therefore accounts for pond spatial
446 heterogeneity. However, it's worth noting that the choice of monitoring approach depends on various factors,
447 including the specific objectives, available resources, and the characteristics of the emission sources. To accurately
448 capture both short-term variability and lake spatial heterogeneity of methane ebullition and diffusion fluxes, the

449 most efficient approach was found to be a combination of continuous measurements with traditional methods
450 including floating chambers, anchored funnels and boundary model calculations (Schubert et al., 2012; Podgrajsek
451 et al., 2014; Erkkilä et al., 2018). This integrated approach would provide a comprehensive understanding of
452 methane emissions, enabling better estimation and more effective mitigation efforts.

453 **5 Conclusions**

454 Many fishponds are hundreds of years old (Potužák et al., 2007), and as such, they are an integral part of our
455 cultural heritage. Nowadays, ponds face a variety of conflicting interests often leading to a focus on maximising
456 fish production that comes at the expense of other ecological services. Intensification of fish production has
457 brought a transition from the traditional management based on natural processes to practices involving
458 supplementary feeding, fertilisation, and overstocking (Pechar, 2000). These changes coupled with the impacts of
459 climate change has resulted to frequent anoxic events and cyanobacterial blooms that reduce biodiversity and limit
460 recreational activities increasingly valued by the public. Our study not only illustrates common water quality
461 problems in fishponds but also provides compelling evidence that methane emissions in these degraded ecosystems
462 further exacerbates negative climate feedbacks and should be considered in discussions to advance the
463 development of sustainable management.

464 Deciphering the mechanisms that drive spatial and temporal heterogeneity in aquatic ecosystem structure and
465 function not only expands our understanding of pond ecology but also provides insights to improve the
466 management of these ecosystems and the services they provide. Our results suggest that spatial heterogeneity needs
467 to be considered when designing experiments and monitoring programs. Without the spatially resolved sampling,
468 we introduce bias into our datasets, hampering our limnological understanding of the ecosystem's functioning and
469 impeding our ability to accurately estimate rates such as methane emissions on a global scale (DeSontro et al.,
470 2018a). In agreement with Kosten et al. (2020), we demonstrated that neglecting ebullition leads to a considerable
471 underestimating of the total CH₄ fluxes. Since there are thousands of these intensively managed fishponds, we
472 argue for changing the management practices toward sustainable use of natural resources to mitigate the overall
473 emissions of greenhouse gases from these ecosystems. Future studies are needed to characterise CH₄ fluxes over
474 a greater number and diversity of aquaculture ponds and examine the mechanisms controlling CH₄ emissions in
475 aquatic ecosystems.

476 **Acknowledgements**

477 The study was supported by the Czech Science Foundation (Research Projects No. 17-09310S, 19-23261S and
478 P504/19-16554S). We thank Martin Rulík for providing us gas chambers. We especially thank to Miloslav Šimek
479 and Linda Jiřová for enabling gas analyses. We are grateful Anna Sieczko for consultation on the calculation of
480 CH₄ fluxes. English correction was made by Anton Baer.

481 **Data availability**

482 Dataset associated with the manuscript can be found in the GitHub Repositories under
483 <https://zenodo.org/badge/latestdoi/587640213>.

484 **Author contributions**

485 All authors contributed to the study conception and design. PZ planned the campaign; PZ, AM and JN performed
486 the sampling and analyzed the data; AM performed the gas-measurements; VK performed statistical analyses and
487 modelling; PZ and AM wrote the manuscript. All authors read and approved the final manuscript.
