24 **Abstract**

25 Oxygen availability is a pivotal factor for ecosystem functioning and the resistance of organisms to the  
26 effect of climate change in aquatic habitats. Although extensive work has been made to assess the effect of  
27 oxygen on marine and freshwater biota, many studies did not capture the ecological importance of oxygen  
28 variations. Overlooking the fluctuating nature of oxygen may cause potential biases in the design and  
29 implementation of management policies [effor](#) aquatic habitats. Conceptual perspectives on the dynamic  
30 nature of oxygen fluctuations have been raised in the scientific community to enhance the understanding  
31 of the effect of oxygen on the physiology and the ecology of aquatic species and the biogeochemical  
32 functioning of the ecosystems. A growing number of empirical works are outlining a novel conceptual  
33 framework that considers the magnitude of oxygen fluctuation as a key variable that explains adaptation to  
34 stress conditions. Oxygen in productive aquatic habitats shows large fluctuations at diel scale, exposing  
35 aquatic species from conditions of extreme supersaturation to anoxia. Recent research indicates that such  
36 fluctuation tunes the physiological plasticity of the animal in response to thermal stresses. In this  
37 contribution, we provide compelling evidence based on current research that the fluctuating oxygen  
38 landscape, here defined as “*oxyscape*”, has an important role in aquatic animal physiology and adaptation  
39 and the ecosystem biogeochemistry. We propose that the oxyscape should be considered in the modelling  
40 and managing policies of aquatic ecosystems.

46 **1. Introduction to environmental dissolved oxygen variability and its ecological relevance**

47 The actual assembly of organism communities in a given habitat is determined by the specific environmental  
48 conditions that select specific sets of species. Climate anomalies and changes raise concerns on ecosystem  
49 stability and habitat preservation, with consequences ranging from species substitution to species extinction  
50 (Antão et al., 2020). To model and predict such effects on community composition and stability, it is  
51 necessary to learn about the limits of the environmental conditions that challenge the different species  
52 (Bennett et al., 2021). However, in many cases, such conditions are resumed into averaged parameters that  
53 do not capture the whole range to which organisms are exposed to (Bernhardt et al., 2020).

54 In aquatic environments, chemical and physical parameters greatly vary at different time and spatial scales,  
55 following cyclical fluctuation or stochastic variations (Shaw et al., 2013; Kerrison et al., 2011; Vargas et al.,  
56 2017, 2022; Manzello, 2010; Challener et al., 2016; Duarte et al., 2013). The lack of details on such variations  
57 in time and space challenges our understanding of how the species adapt their physiology, limiting our  
58 estimation of their resilience to ongoing environmental changes (Booth et al., 2023a). The perception of  
59 such knowledge gap is progressively moving the research interest on species' eco-physiological response to  
60 chemical and physical parameters, such as temperature, salinity or pH, and the associated biogeochemical  
61 cycles, toward more accurate assessments of their natural variability (Antão et al., 2020; Bernhardt et al.,  
62 2020). Increasing efforts are now devoted to [upgradeupgrading](#) eco-physiological approaches to integrate  
63 the relevant environmental background (Giomi et al., 2019; Marasco et al., 2023; Bitter et al., 2018, 2021;  
64 Pörtner et al., 2023).

65 Oxygen variability exerts a [deep-great](#) effect on aquatic life yet remains underestimated. Most studies dealing  
66 with oxygen variation have addressed the decline of mean oxygen availability in oceans (Breitburg et al.,  
67 2018) and the occurrence and repercussions of events of environmental hypoxia (Diaz and Rosenberg,  
68 2008; Bickler and Buck, 2007). How short-term (i.e., daily) oxygen variations shape aquatic life and  
69 biogeochemical processes remains largely overlooked. These variations are generally of greater amplitudes  
70 and more regular than seasonal ones (Limburg et al., 2020; Bates et al., 2018). We refer to deviation from  
71 the saturation of oxygen concentrations as the ratio between the actual concentration and the saturation  
72 concentration of oxygen that would be observed in water under equilibrium conditions between air and  
73 water. The fine measure of the range of variation of aquatic oxygen and its effect on organisms and

74 biogeochemical cycles has the potential to elucidate unpredicted mechanisms of resilience and tolerance to  
75 ongoing climate change.

76

## 77 **2. Oxygen trends and stochastic variations**

78 A gradual decline of the total oxygen content of about 2% since the second half of the 20<sup>th</sup> century has  
79 been recently reported, with a further reduction of up to 7% predicted for the following century (Schmidtko  
80 et al., 2017; Breitburg et al., 2018). In parallel, open-ocean oxygen minimum zones (OMZs) have largely  
81 expanded (Stramma et al., 2010) together with the increasing occurrence of severe hypoxia events whose  
82 predictability has decreased as their occurrence spreads across all oceans (Diaz and Rosenberg, 2008). The  
83 main cause of deoxygenation is attributed to global warming and is exacerbated by the discharge of nutrients  
84 and pollutants (Ito et al., 2016). ~~Topography~~The topography of water basins also affects the incidence of  
85 hypoxia events influencing the rate of mixing of oxygenated layers and the resident time of water bodies  
86 (Breitburg and Grégoire, 2018; Laffoley and Baxter, 2019). For example, in the Baltic Sea, the  
87 geomorphology of the coastline can explain up to 80% of the hypoxic phenomena (Virtanen et al., 2019).

88 The gradual decrease of total oxygen in oceans has been reported in several studies that analyse long time  
89 trends (Keeling et al., 2010; Schmidtko et al., 2017; Breitburg et al., 2018) and from reports at the global  
90 geographical scale (Laffoley and Baxter, 2016). However, unexpected oxygen profiles have also been  
91 reported in several specific habitats and at different time scales suggesting that different abiotic and biotic  
92 drivers modulate oxygen dynamics (Craig and Hayward, 1983). For instance, the alternation of oxygen  
93 biological production and consumption determines massive fluctuation of its availability in highly  
94 productive aquatic habitats, such as mangrove forests, salt marshes, coral reefs (Giomi et al., 2019; Fusi et  
95 al., 2021; Booth et al., 2021), kelp forests (Krause-Jensen et al., 2016), plankton blooms in the open oceans  
96 (Riser and Johnson, 2008; Benoiston et al., 2017), freshwater lakes (Andersen et al., 2017) or even in  
97 agricultural drainage channels (Booth et al., 2023). The seasonal variation of diel oxygen fluctuations is  
98 increasingly reported at all latitudes and habitats and ~~occurs~~ occurs in a vast range of water bodies  
99 independently of the scale, the hydrological features, and the local biotic components (Figure 1). For  
100 example, fluctuations of 150% in spring and 30% in winter occur in the Venice lagoon (Figure 1, Location  
101 5), and even more pronounced fluctuations occur in mangroves, corals and seagrasses (Figure 1, Locations

102 10-12; Giomi et al., 2019). The magnitude of oxygen fluctuations is site-specific and depends, among other  
103 factors, on the solar radiation and water temperature and their effect on primary producers' photosynthetic  
104 and respiration activity, the cycles of water column stratification and mixing, and the nutrient loads. Spatial  
105 differences in oxygen saturation also occur between surface and bottom water masses because of isolation  
106 driven by water stratification, the decrease of light penetration, and the coupling with increased oxygen  
107 demand close to the sediments at the bottom of the water column (Figure 2). In summer, enhanced benthic  
108 respiration is determined by higher water temperature, which decreases oxygen solubility and enhances  
109 oxygen demand. Lower vertical mixing, higher water residence time, and higher turbidity due to higher  
110 concentration of organic matter; further decrease oxygen concentrations down to hypoxia in the deep water  
111 layers (Figure 2; Talke et al., 2009; Schmidt et al., 2019). Conversely, dissolved oxygen increases in the  
112 euphotic part of the water column because of the enrichment of photosynthetic communities (Spietz et al.,  
113 2015).

114

### 115 **3. The oxygen variation in the day-life of aquatic organisms**

116 Marked oxygen variations occur at a diel scale, driven by temperature and light diel cycles and by the balance  
117 between photosynthesis and respiration (Winter et al., 2019). The amplitude of diel oxygen variation can  
118 exceed the average seasonal variation, thus being variable with higher explanatory power for the physiology  
119 of aquatic life (Giomi et al., 2019). While water temperature is only linked to meteorological changes, the  
120 oxygen concentration in productive aquatic environments is also regulated by the biota component  
121 (Chapman, 2021). Community composition of primary producers (Power and Cardinale, 2009), rainfall  
122 level (Mallin et al., 1993), nutrients' runoff (Kinney and Roman, 1998), biotic networks (Graham et al.,  
123 2018; Breen and Mann, 1976), and bacterial community dynamics (Guo et al., 2022), govern, at a small  
124 scale, high spatial and temporal change in the concentrations of dissolved oxygen. The interaction of all  
125 these factors strongly affects dissolved oxygen fluctuations beyond the levels that can be predicted from  
126 just the meteorological trends.

127 Oxygen availability plays an important role in the physiology of aquatic species (Pörtner, 2010; Hochachka,  
128 1991; Stillman and Somero, 2000). In the design of experiments on the physiology of aquatic animals,  
129 oxygen is frequently treated as a fixed factor and maintained around the water saturation. However,

130 organisms inhabiting aquatic environments experience ample diel oxygen fluctuations and are adapted to  
131 endure or respond to the experienced variation (Blewett et al., 2022; Morash et al., 2018). Oxygen may be  
132 systematically depleted at night and fully recovered during the day, changes that certainly have consequences  
133 on the tolerance to acute stressors such as hypoxia and warming. Dependent on the intensity of the  
134 photosynthetic activity, dissolved oxygen concentrations can reach levels far above the physical saturation  
135 (Giomi et al., 2019; McArley et al., 2020). Under such hyperoxic conditions, aquatic organisms experience  
136 oxygen availability well beyond their physiological needs, but the effects on their physiology and life history  
137 are largely unknown.

138 Hyperoxia benefits the metabolic performance of fishes and invertebrates, especially under acute warming  
139 that may be very intense in tidal ponds or shallow coastal habitats (Fusi et al., 2021; Booth et al., 2021;  
140 Giomi et al., 2019; McArley et al., 2020; Booth et al., 2023a). It extends the upper thermal tolerance of  
141 aquatic animals during acute events of daily warming and their survival to anomalous heat waves (McArley  
142 et al., 2022). Within the current trend of climate change, the beneficial effect of hyperoxia against extreme  
143 heating events can have underestimated positive consequences on the survival of the animals. For instance,  
144 an important consequence of exposure to the hyperoxic conditions experienced during the daytime under  
145 high heating regimes is the enhanced capability to extract oxygen from the poorly oxygenated water during  
146 the night and endure hypoxic or even anoxic periods (Giomi et al., 2019; Booth et al., 2021).

147 Oxygen fluctuations are also appreciated as a factor contributing to the structuring of organismal networks  
148 and in the synchronisation of life history dynamics such as spawning or larval recruitment (Garzke et al.,  
149 2019; Viaroli and Christian, 2004).

150

#### 151 **4. The role of oxygen fluctuation in coastal biogeochemical cycles**

##### 152 ***4.1 Biogeochemical cycles in the pelagic compartment in relation to oxygen fluctuation at daily scale***

153 In productive coastal ecosystems, the biogeochemical cycles of key chemical elements are strongly  
154 interconnected with oxygen dynamics. Nitrogen and phosphorus are typically key elements which limit  
155 primary production in shallow coastal-marine ecosystems, whose emissions from river basins (or other  
156 sources, such as previously enriched sediments) can lead to eutrophication with detrimental effects on  
157 biodiversity and human welfare (Palmeri et al., 2013). The biogeochemical cycles of nitrogen and

158 phosphorus are composed of multiple physical, chemical and biological processes, of which some are  
159 accelerated by oxygen availability, such as nitrification and mineralisation, while ~~some~~ others are enhanced  
160 by its absence, such as denitrification and P release from sediments. The regular daily alternation of  
161 contrasting conditions of below- and above-saturation dissolved oxygen concentrations in the water  
162 column, particularly in the euphotic zone, promotes changes in the relative abundance of different nutrient  
163 forms (Figure 3). This becomes clear when looking, for example, at the nitrogen cycle in the water column  
164 and its complex relationship with oxygen availability: the presence of dissolved oxygen speeds up the  
165 mineralisation of organic nitrogen to ammonium as well as nitrification, i.e., the microbial oxidation of  
166 ammonium into nitrites and then nitrates. The absence of oxygen makes denitrification possible, i.e., the  
167 reduction of nitrates into inert gaseous nitrogen is promoted by facultative aerobic bacteria ~~which that~~, in  
168 the absence of anoxia, will prefer oxygen to nitrates as an electron acceptor (Palmeri et al., 2013).  
169 Ammonium, nitrites and nitrates are important nitrogen forms ~~which that~~ are bioavailable to primary  
170 producers, and ~~the~~ oscillating oxygen conditions in the water column at the diel scales can promote their  
171 removal via the nitrification-denitrification chain. High oxygen concentrations are also associated with high  
172 photosynthetic activity (e.g., planktonic) and, therefore, with the fast removal of dissolved inorganic  
173 nutrients from water through uptake by primary producers (Caron, 1994). The picture is made more  
174 complex by the typically non-linear dependence of biogeochemical reactions on oxygen concentration (e.g.,  
175 nitrification and denitrification) and on temperature (in the case of most biogeochemical processes), which  
176 can both change ~~strongly~~~~enormously~~ throughout the day, especially in shallow productive ecosystems,  
177 altering reaction rates at sub-daily scales in a way which cannot be appreciated if only the daily mean in  
178 dissolved oxygen is considered, but which needs to be quantified if we are to ~~mechanistically~~ predict future  
179 biogeochemical cycling ~~mechanistically~~ under climate change (Caballero-Alfonso et al., 2015). A further  
180 source of complexity is given by the ~~feedbacks~~~~feedback~~ between abiotic and biotic components of pelagic  
181 ecosystems. The growth of primary producers, both microscopic and macroscopic, is on the one hand  
182 affected by the presence of bioavailable nutrient forms, and on the other hand their biomass can reduce  
183 light availability by increasing shading or turbidity, limiting light penetration and, so, oxygen production  
184 and warming in deeper waters. These examples highlight the importance of higher frequency measurements  
185 of oxygen fluctuations, nutrient concentrations, and microbial community abundance, composition and

186 activity in the water column at sub-daily scales; to get a better, more quantitative grasp of biogeochemical  
187 cycling in coastal water bodies (Meire et al., 2013). A general framework to assess the short-term (hourly)  
188 oxygen fluctuations in relation to the movement and related physical properties of water masses, i.e., of  
189 processes such as stratification, residence time, and thermohaline flows, in addition to other processes  
190 (photosynthesis, respiration, solubility changes, etc.) is important to future oxygen modelling.

191

#### 192 *4.2 Biogeochemical cycles in the benthic compartment in relation to oxygen fluctuation at daily scale*

193 The intertwined oxygen and nutrient dynamics in the water column cannot be understood, at least in  
194 relatively shallow aquatic ecosystems, without looking also looking at the interactions between the pelagic  
195 and the benthic compartment. This takes place through the vertical transport of matter (settling,  
196 resuspension, convection, upwelling currents, etc.) and is also affected by stratification, gradient-driven  
197 diffusive fluxes, and organism movements and vertical migrations.

198 When temperature and oxygen concentration in the water column fluctuate at short daily time scale, yet  
199 with very large amplitude (from anoxia/hypoxia to hyperoxia), the impact on biogeochemical cycles and  
200 chemical transfers is mostly unknown. Based on the trends observed at seasonal “steady-state” conditions,  
201 a conceptual model on the location of the major benthic processes in the sediment and the resulting fluxes  
202 at the sediment-water interface within the diurnal temporal scale can be drawn (Figure 4).

203 As oxygen penetration depth and concentration in sediment is known to rapidly evolve in response to the  
204 oxygen concentration in the overlying water (Glud, 2008), the importance of aerobic process in surface  
205 sediment is also expected to fluctuate at the diurnal timescale, with higher contribution during the day than  
206 during the night. The fast kinetics of the reductive dissolution/oxidative precipitation of Mn and Fe oxy-  
207 hydroxides and the redox cycle of S chemical species (i.e.,  $\text{H}_2\text{S}/\text{SO}_4^{2-}$ ) suggests that those chemical species  
208 should evolve with a similar trend over daily timescales, with a reasonable short term (minutes-hours) delay  
209 (Rigaud et al., 2018). Consequently, we expect a vertical fluctuation of those biogeochemical redox  
210 processes in the sediment and related fluxes under diel oxygen fluctuation (Figure 4). The low oxygen  
211 concentration at night should induce a lower oxygen penetration depth and an upward distribution of  $\text{NO}_3^-$ ,  
212 Mn and Fe oxyhydroxides and  $\text{SO}_4^{2-}$  reductions. If the oxygen concentration is low enough, the reductive  
213 dissolution of Mn and Fe oxyhydroxides may directly occur at the sediment-water interface, inducing their

214 release to the water column with other chemical species associated with these phases (i.e.,  $\text{PO}_4^{3-}$  and most  
215 trace elements). In the specific case of anoxia, the sulfate-reduction process may occur at the sediment  
216 surface, releasing  $\text{H}_2\text{S}$  to the water column. It is expected that in such a condition, the release of dissolved  
217 metals (Fe, Mn and trace elements), which also present a rapid kinetic for metal sulfide formation in the  
218 presence of S(-II), can be reduced and likely reverted (Figure 4). In contrast, the increase of oxygen  
219 concentration during the day promotes oxygen penetration in the sediment and the oxidation of reduced  
220 species accumulated during the night, such as dissolved Mn, Fe,  $\text{NH}_4^+$  and eventually  $\text{H}_2\text{S}$ , preventing their  
221 release from the sediment. The reconstitution of the Mn/Fe oxyhydroxide reservoir in surface sediment  
222 favours the trapping of  $\text{PO}_4^{3-}$  and trace elements associated with Fe and Mn cycles. The oxidation of  $\text{NH}_4^+$   
223 induces the formation of  $\text{NO}_2^-$  and  $\text{NO}_3^-$  that may be released from the sediment.

224 In shallow coastal areas, the light radiation may also reach the sediment surface allowing the photosynthetic  
225 activity of the microphytobenthos to occur in surface sediment (Figure 4). The local source of oxygen at  
226 the sediment surface occurs because photosynthesis strongly enhances the biogeochemical processes  
227 described above (Denis et al., 2012; Rigaud et al., 2018). The oxygen released in the water column enhances  
228 the water hyperoxia and consumes nutrients and  $\text{CO}_2$  during photosynthesis. This creates a very peculiar  
229 situation that modifies the direction and intensity of chemical fluxes at the sediment-water interface and  
230 the chemical composition of water and surface sediment in coastal areas at the diurnal scale. For those rapid  
231 redox-sensitive chemical species, processes and fluxes are thus expected to evolve, between such extreme  
232 night/day fluctuations, with a transient response related to the reaction kinetics and transport within the  
233 sediment surface.

234 For OM mineralisation processes, the effects of short-term oxygen fluctuation are more challenging to  
235 predict. It will also be dependent on the capacity of heterotrophs to react/adapt to the changing oxygen  
236 concentrations and eventually shift between different metabolic processes (for microorganisms where  
237 variables metabolic pathways coexist) or to activate/cease the process in relation to physicochemical  
238 conditions and oxidant availability (for microorganisms with specialised metabolisms). Consequently, the  
239 dynamic response of the microbial community to short-term oxygen and chemical fluctuations needs to be  
240 investigated in more detail in relation to microbial communities' resilience and adaptation capacity (see  
241 section 5).

242 In productive coastal areas, the benthic organisms, including macro and meiofaunal species, adapt to ~~large~~  
243 ~~wide~~ and rapid daily oxygen variation by modifying their behaviour. The bioturbating activity may be  
244 favoured during high oxygen concentration and lowered during conditions of low oxygen availability. We  
245 expect that, during the night oxygen deficiency, the benthic organism activity is reduced, inducing a decrease  
246 in the sediment reworking intensity. This is accompanied by a reduction of the biologically-mediated solute  
247 fluxes at the sediment-water interface and oxygen penetration depth in the sediment. In contrast, during  
248 oxygen supersaturation occurring in the day, bioturbation is intensified and may induce a short-term change  
249 in the contribution of biologically-mediated reactions and transfers. Here also, a delay between the oxygen  
250 fluctuation in the water column and the biogeochemical response of the sediment, related to the biological  
251 activity, would depend on site characteristics (oxygen concentration and range of fluctuation, bioturbating  
252 species). For instance, in areas where anoxia events are recurrent, the absence of macrofauna prevents  
253 bioturbation and its influence on the benthic biogeochemistry (Nilsson and Rosenberg, 1997).

254 In response to large amplitude and diel oxygen fluctuations, the sediment' biogeochemical cycles are also  
255 expected to fluctuate (Figure 4). However, as the resulting benthic biogeochemistry cycles are associated  
256 with the dynamics of three interdependent compartments (i.e., geochemical composition, microbial  
257 communities, bioturbating-faunal communities), each presenting its kinetics and responses to oxygen  
258 fluctuations, we expect the sediment to be permanently maintained under unsteady-state conditions. This  
259 makes it difficult to quantitatively predict the resulting OM ~~mineralization~~~~mineralisation~~ rates, the  
260 proportion of involved processes, and the chemical transfers at the sediment-water interface.

261 The recent development of tools which can measure the chemical composition and sediment-water fluxes  
262 over the short-term scale (i.e., microsensors, eddy covariance technic, gradient-flux method), in addition to  
263 benthic microbial and macrofaunal activity (e.g., improved sediment profile imaging), may be beneficial to  
264 produce experimental data that will help to fill these gaps in understanding. At the same time, specific  
265 efforts should be focused on assessing the isolated response to those three different compartments. Those  
266 data should then be implemented to appropriately calibrate non-steady-state coupled pelagic-benthic  
267 biogeochemical models, which can predict the resulting biogeochemical functioning of productive coastal  
268 ecosystems and, thus, ~~to~~ predict their fate under climatic changes.

269

## 270 5. The interrelationship of oxygen fluctuation and aquatic microbial communities

271 Oxygen is a two-faced element that acts as the terminal electron acceptor in aerobic respiration (by far the  
272 most efficient energy metabolism) and as an element of toxicity because the reduction of O<sub>2</sub> molecules  
273 partly results in reactive oxygen species. For this reason, oxygen remains a strong evolutionary force  
274 dominating functional interactions and the spatial structure of many microbial communities (Fenchel and  
275 Finlay, 2008). Oxygen availability determines microbial metabolism, and many studies have been carried  
276 out to elucidate the different kinds of communities and metabolisms occurring under anaerobic or aerobic  
277 conditions (Sandrin et al., 2009). Marine microorganisms in productive coastal environments also  
278 experience [large-wide](#) oxygen diel fluctuations, especially at the boundary layer between sediment/primary  
279 producers and water (Pacherres et al., 2022).

280 Assessing the full environmental oxygen variability in aquatic habitats using high-resolution temporal and  
281 spatial scales relevant to microorganisms can reveal in detail the complexity of the patterns of community  
282 dynamics and diversity in such oxygen-variable environments (Berg et al., 2022). For example, oxygen  
283 largely varies during the day in tropical clear shallow waters because of the photosynthetic activity of  
284 seagrasses, corals and mangroves (Giomi et al., 2019). Therefore, the microbial communities in these  
285 ecosystems can experience environmental conditions ranging from hyperoxia to anoxia (see the oxygen  
286 profile in Figure 2). These fluctuations imply that the microbial communities have to shift their composition  
287 and function according to the oxygen availability (Fenchel and Finlay, 2008; Booth et al., 2023b, 2019).  
288 Microorganisms generally have a short generation time (and high turnover) that favour timely adaptation  
289 to new conditions in a changing environment (Steiner et al., 2019). During low oxygen availability at night-  
290 time, bacterial communities will shift their composition and function toward anaerobic function (Figure 5).  
291 End products of anaerobic metabolisms such as ammonium, sulphur and methane are consumed when  
292 oxygen becomes available again during the daylight and ~~photosynthesis the recovery of photosynthesis~~, re-  
293 establishing aerobic respiration as the central metabolism of the microbial communities (Fenchel and  
294 Finlay, 2008). For example, in the Bohai Sea (China), under [an](#) oxygen concentration lower than 4.2 mg/L<sub>a</sub>,  
295 the microbial communities were dominated by bacteria [belonging to the group](#) of the *Anaerolineaceae* (Guo  
296 et al., 2022). In Chilean coast ecosystems, the composition of the bacterial communities is regulated by the  
297 seasonality of the upwelling waters, with the partitioning of community composition driven by dissolved

298 oxygen. *Bacteroidetes*, SAR11, SAR86 and *Alphaproteobacteria* dominated in waters containing dissolved  
299 oxygen concentrations higher than 70  $\mu\text{M}$ . In contrast, taxonomic groups such as Arctic96BD-19, SUP05,  
300 SAR324 and *Desulfobacterales* were observed at dissolved oxygen concentrations below 70  $\mu\text{M}$  to  
301 undetectable levels (Aldunate et al., 2018). The continuous variation of oxygen concentration enhances the  
302 diel cycling of nutrients in productive coastal environments, highlighting the importance of assessing the  
303 ecologically relevant oxygen fluctuations to determine the effective microbial functionality of the marine  
304 coastal ecosystem (Trowbridge et al., 2017).

305 Incorporating methods to assess the ecologically relevant variability of oxygen availability, intensity and  
306 synchronicity in future experimental designs will generate a more accurate prediction of the response of  
307 bacterial communities and therefore their potential for biogeochemical cycling to climate change, better  
308 informing the development of management strategies to mitigate detrimental stressor impact on ecosystems  
309 effectively. The current challenge in microbial ecology is to understand the widespread temporal and spatial  
310 environmental oxygen variability and switch from the “mean conditions paradigm” often used for  
311 investigations of microbial ecological processes to a dynamic model able to capture the microbial changing  
312 and functional potential under oxygen fluctuating conditions (Fusi et al., 2022).

313

## 314 **6. Implications for marine assessment and management**

315 Oxygen production is considered an ecosystem service (<https://cices.eu/>) because of the benefits humans  
316 receive, but, to date, there is limited inclusion of the impacts of deoxygenation or oxygen fluctuation in  
317 marine environmental policies. There are only few areas whose oxygen dynamics [have](#) been extensively  
318 monitored, like in North America (i.e., Chesapeake Bay, Gulf of Mexico, Long Island Sound) and  
319 included in management plans for environmental protections (e.g.,  
320 <https://coastalscience.noaa.gov/project/operational-gulf-of-mexico-hypoxia-monitoring/>). However,  
321 globally, there has been a lack of oxygen dynamics’ integration into the computation of biodiversity  
322 indicators that assess aquatic communities (Breitburg et al., 2019; Chen et al., 2022), and in particular the  
323 oxygen dynamic at a daily scale remains largely neglected in marine assessment and management. Policies  
324 on pollution or nutrient control had a positive effect on the oxygen level in ocean water, however, there is  
325 still a clear missing link on specific policies to monitor and manage daily oxygen variability. While attention

326 has been given to ocean warming and acidification, daily oxygen dynamics have been overlooked in  
327 assessing marine habitat or species' sensitivity to climate changes and anthropogenic disturbances.  
328 Including ecologically relevant variations of oxygen availability into aquatic biodiversity indicators, in  
329 addition to continuous and high temporal resolution oxygen and chemical concentration measurements in  
330 the sediment and water column, offers a great opportunity to refine and produce more robust predictors  
331 that will be able to disentangle better the response of aquatic ecosystems to climate change and  
332 anthropogenic disturbances (Dafforn et al., 2012).

333 Current hypoxic thresholds for aquatic ecosystem management are generally calculated on averages and  
334 ~~minimum~~ oxygen concentrations in water ~~and they with the~~ risk of overlooking the effect of the  
335 oxygen fluctuation, which ~~are~~ is more relevant for communities' physiology (Tomasetti and Gobler, 2020).  
336 Enhancing monitoring programs by capturing the daily oxygen fluctuation will allow detection of when  
337 night-time low oxygen content is followed by a daytime recovery period, often reaching oxygen  
338 supersaturation. This alternation allows the aquatic communities to sustain their homeostasis in a  
339 fluctuating environment. Therefore, proper monitoring can inform a correct management to conserve,  
340 protect, and restore coastal water mosaic patterns of primary producers to ensure the ~~ecological~~ ecologically  
341 relevant fluctuations of dissolved oxygen.

342 In this contribution, based on recent research, we provide evidence that the fluctuating oxygen creates a  
343 spatial and temporal heterogeneous aquatic oxygen landscape that we have defined here as "oxyscape". The  
344 oxyscape—having an important role for aquatic animal physiology and adaptation and the ecosystem  
345 biogeochemistry—should be considered in the modelling and managing policies of aquatic ecosystems to  
346 capture the ecologically relevant oxygen fluctuation. Understanding the oxyscape can help to reconsider  
347 the dynamics of many productive aquatic ecosystems and we, therefore, call on ecologists to rethink their  
348 models and experiments in this light. This would increase understanding of variations and resilience of  
349 communities to changes in environmental conditions at the scales of space and time relevant to individual  
350 components.

351

352 **Author contributions**

353 MF and FG conceived the study and wrote sections 1 to 3. AB, GG, SR, FG wrote section 4.1 and 4.2 and  
354 provided data for the Mediterranean sites. MF, RM and DD wrote section 5 and provided data for the Red  
355 Sea. MF, LP and CVH wrote section 6. All the authors discussed and reviewed the final version.

356

#### 357 **Competing interests**

358 The contact author has declared that none of the authors have competing interests.

359

#### 360 **Financial support**

361 D.D. acknowledge the financial support of King Abdullah University of Science and Technology (KAUST)  
362 through the Circular Carbon Economy initiative (grant no. REI/1/4483-01-01). D.D also acknowledge the  
363 Competitive Research Grant (CRG-7-3739), “The role of the bacterial symbiome at the gill-water (air)  
364 interface in the evolution toward territorialisation (Microlanding),” 1 April 2019 to 31 March 2022. We are  
365 very grateful to the LabEx DRIIHM, French Programme “Investissements d’Avenir” (ANR-11-LABX-  
366 0010), which is managed by the French ANR, under the Human- Environment Observatory  
367 “Mediterranean coast” (OHM Littoral Méditerranéen) for its funding that allowed to collect data from the  
368 Prevost lagoon, the Excellence Initiative of Aix-Marseille University - A\*MIDEX, a French  
369 “Investissements d’Avenir” programme (reference number ANR-11-IDEX-0001- 02), the PACA region  
370 and the CNRS-INSU-EC2CO program (PREDHYP- O2 program) for its funding that allowed to collect  
371 data from the Berre lagoon, and the Occitanie region and the University of Nîmes for the funding of PhD  
372 Thesis of Julie Régis. We also thank all the members who allowed us to collect data from the coastal  
373 Mediterranean lagoons in France (syndicat mixte GIPREB, Mairie de Chateauf-neuf-les-Martigues,  
374 Compagnons de Maguelone). The PREDHYPO program has received funding from Excellence Initiative  
375 of Aix-Marseille University - A\*MIDEX, a French “Investissements d’Avenir” programme (reference  
376 number ANR-11-IDEX-0001- 02), the PACA region and the CNRS-INSU-EC2CO program (PREDHYP-  
377 O2 program).

598 **Figure captions**

599

600 **Figure 1.** Range of oxygen saturations in several productive aquatic habitats. The dashed line represents  
601 100% oxygen saturation. The violin plots report the densities of the frequencies of oxygen saturation  
602 measured at each ecosystem across different seasons (based on data availability). Data source is specified  
603 for each environment in the Supplementary Dataset for [Figure Figures 1 and 2](#).

604

605

606 **Figure 2.** Fluctuations of oxygen saturation measured at the bottom (4 m) and surface (30 cm) oxygen  
607 saturation of the Rove canal in France that highlight the contrast between the two depths of  
608 eutrophicated coastal environment from the winter to summer. The analysis of these case studies revealed  
609 different power to predict oxygen variation.

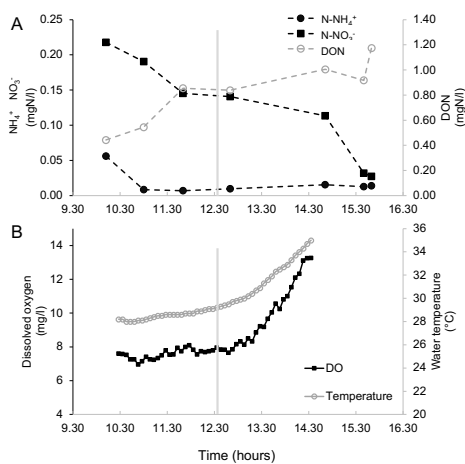

610  
611

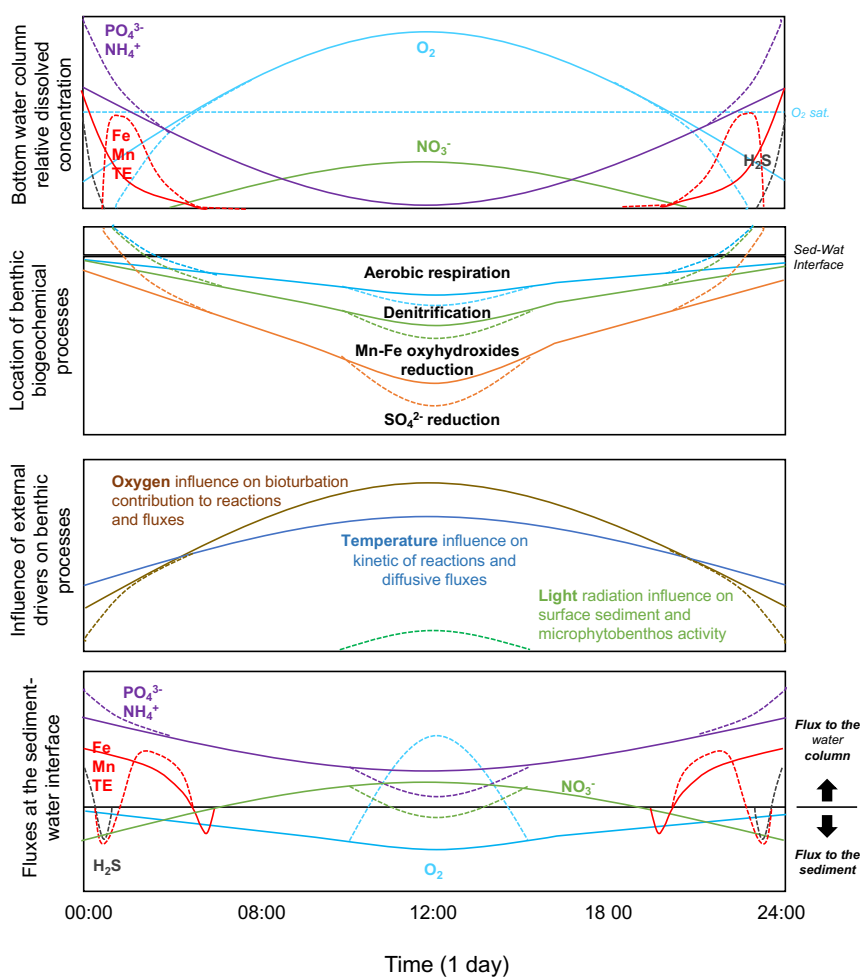

612 **Figure 3.** Nutrient concentration, dissolved oxygen and water temperature measurements made in the  
 613 water of a salt marsh of the Northern Venice Lagoon (Italy) on August 13th, 2015. **(A)** Concentration  
 614 concentration of different nitrogen forms in the marsh water (notice the two different vertical axes) over  
 615 time in the central part of the day. Measurements are made in the water entering the marsh (flood phase,  
 616 left of the vertical grey line, which indicates the tidal peak) and quitting from the salt marsh (ebb phase,  
 617 right of the vertical grey line). After some time spent in the marsh, which is flooded by tide twice per  
 618 day, water becomes depleted in inorganic nutrients, presumably due to the uptake by primary producers,  
 619 exchanges with the sediments, and (in the case of ammonium) nitrification. Concurrently, water is enriched  
 620 with dissolved organic nitrogen related to the intense biological activity within the marsh. **(B)** Dissolved  
 621 oxygen and temperature of the water entering the marsh (flood phase, left of the vertical grey line, which  
 622 indicates the tidal peak) and water quitting from the salt marsh (ebb phase, right of the vertical grey line)  
 623 over time in the central part of the day. While Notably, in the biologically productive habitat of the marsh  
 624 (space between water entering and quitting) compared to the surrounding waters, which is a biologically  
 625 productive habitat compared to the,  
 626 surrounding waters, the water becomes enriched in with dissolved oxygen the water, paralleled by  
 627 an increase in water temperature.

629  
630

631 **Figure 4.** Scheme of the benthic biogeochemical cycle in relation to diel oxygen fluctuation. (A) The  
 632 relative evolution of the bottom water chemical composition; and (B) evolution of the location of the  
 633 most important biogeochemical processes in the benthic compartment. (C) Relative influence of external  
 634 drivers on benthic processes. (D) Relative evolution of resulting flux direction and intensity. Note that the  
 635 graphs are not drawn to scale. Although concentrations of  $\text{PO}_4^{3-}$  and  $\text{NH}_4^+$  and of Mn and Fe may behave  
 636 differently, they are represented as similar in this figure for simplification.

637  
 638

639 **Figure 5.** Daily bacterial community cycle scheme in relation to diel oxygen fluctuation. Relative shift of  
 640 microbial community controlled by the oxygen availability that ~~control~~ controls the ratio between aerobic  
 641 and anaerobic taxa and their relative function. Oxygen fluctuation is important to determine the diel cycling  
 642 of the bacterial communities that, in turn, affect the biogeochemistry and the overall functioning of the  
 643 aquatic ecosystems. Note that the graphs are not drawn to scale.
