Abstract

10 The oceans are losing oxygen (O₂) and oxygen minimum zones are expanding, due to climate warming
11 (lower O₂ solubility) and artificial fertilization related to agriculture. This ongoing trend is challenging for most
12 marine taxa that are not well adapted to O₂ depletion. For other taxa this trend might be advantageous, because
13 they can withstand low O₂ concentrations or thrive under anaerobic or even anoxic conditions. Benthic
14 foraminifera are a group of protists that might benefit from ongoing ocean deoxygenation, since several
15 foraminifera species possess adaptations to O₂ depletion that are unique amongst eukaryotes. This paper reviews
16 the current state of knowledge about foraminifera from low O₂ environments. The specific survival strategies of
17 foraminifera to withstand O₂ depletion include an anaerobic metabolism, heterotrophic denitrification, symbiosis
18 with bacteria, kleptoplasty and dormancy. These adaptations, especially the ability to denitrify by some benthic
19 foraminiferal species, have a strong impact on their preferred microhabitat in the sediments, which will be
20 discussed in detail. In addition, due to their high abundances in O₂ depleted environments and their metabolic
21 adaptations, benthic foraminifera are key players in marine nutrient cycling, especially within the marine N and P
22 cycles. Studies about the ecology of benthic foraminifera are scarce but there is evidence that foraminifers have
23 the capacity of phagocytosis, even under anoxia, and some foraminiferal species, which can withstand low O₂
24 conditions, even seem to prey on meiofauna. Finally, the fact that foraminifera can calcify even under anaerobic
25 conditions makes them important archives for paleoceanographic applications. So this review will briefly
26 summarize O₂ proxies based on foraminiferal morphology, shell geochemistry and composition of foraminiferal
27 assemblages.

28

1 Introduction

29 More than two decades have passed since Bernhard and Sen Gupta (1999) provided a comprehensive
30 review about the history of research on foraminifera from O₂ depleted environments. About a decade later, Koho
31 and Piña-Ochoa (2012) provided another overview about benthic foraminifera as inhabitants in low-O₂ habitats,
32 mainly focusing on the species distribution in different environments and the different depth layers in the sediment.
33 They also summarized the early work on foraminiferal denitrification, kleptoplasty and evidence for bacterial
34 symbiosis. Nevertheless, a lot has changed in our point of view about the anaerobic metabolism of benthic
35 foraminifera and other survival strategies that help them to withstand O₂ depletion, due to advances in methods
36 that can analyze metabolic rates, intracellular nutrient storage and even DNA and RNA of microeukaryotes such
37 as foraminifera. This paper aims to summarize these developments, mainly focusing on benthic foraminifera.

38 Our knowledge about planktic foraminifera from O₂ depleted habitats is scarce compared to our
39 knowledge about benthic foraminifera. Nonetheless, at least two species *Globorotaloides hexagonus* and
40 *Hastigerina parapelagica* are known to live in pelagic oxygen minimum zones (OMZs) (Davis et al., 2021) and
41 therefore, *G. hexagonus* has proven to be a valuable paleo-indicator for the presence of pelagic OMZs during the
42 Pliocene (Davis et al., 2023). In general, also benthic foraminifera from low O₂ environments have been
43 established as an invaluable archive for paleoceanography. I will only briefly summarize some redox proxies based
44 on benthic foraminifera, since there is work in progress to give a comprehensive review about proxies for O₂
45 concentrations in paleoceanography (Hoogakker et al., in prep).

46 Within this paper, I will summarize recent advances to understand diverse survival strategies of benthic
47 foraminifera to withstand O₂ depletion. This part will mainly focus on foraminiferal denitrification, dormancy and
48 kleptoplasty. In the chapter 1.3.1 about denitrification, I will also utilize our current knowledge about foraminiferal
49 denitrification to complement the conceptual TROX model by Jorissen et al. (1995), which explains the
50 microhabitat of benthic foraminifera by an interplay in the supply of O₂ and organic matter (i.e. food). Afterwards,
51 I will briefly discuss our scarce knowledge about ecological and trophic interactions of foraminifera from O₂
52 depleted environments. Finally, I will review the role of foraminifera for marine biogeochemical cycling, focusing
53 on nitrogen and phosphorous and, as mentioned above, provide a brief overview about applications of benthic
54 foraminifera from O₂ depleted environments in paleoceanography.

55

56

2.1 Survival strategies

57 Some benthic foraminiferal species have very specific adaptations that provide the opportunity either to
58 thrive in anaerobic conditions or at least to survive periods of O₂ depletion (examples see in fig. 1). This chapter
59 will discuss the recent advances in knowledge about these survival strategies. Contemporary improvements in

60 molecular biological methods resulted in a strong increase of our understanding about the anaerobic metabolism
61 in benthic foraminifera.

62 2.1.1 Foraminiferal denitrification

63 More than a decade ago first evidence came up that some foraminifera from O₂ depleted environments
64 are able to perform complete denitrification (Risgaard-Petersen et al., 2006). Complete heterotrophic
65 denitrification describes the step-by-step reduction of nitrate (NO₃⁻) to inert N₂ gas (Fig. 2&3). Heterotrophic
66 denitrification provides energy to an organism for oxidative phosphorylation in a similar way as O₂ respiration.
67 The discovery by Risgaard-Petersen et al. (2006) was also the first evidence for complete denitrification in
68 eukaryotic cells in general. Furthermore, this study showed that denitrifying foraminifera can have a substantial
69 intracellular NO₃⁻ storage. They likely take up NO₃⁻ from the surrounding pore water and store it within
70 intracellular seawater vacuoles.

71 Four years after the study by Risgaard-Petersen et al. (2006), Pina-Ochoa et al. (2010b) documented that
72 intracellular NO₃⁻ storage and denitrification are not an exception, limited to a few specialized foraminiferal
73 species, but actually a widespread phenomenon. Within a couple of years more studies either quantified
74 denitrification rates or the intracellular NO₃⁻ storage of various foraminiferal species (Høgslund et al., 2008; Glud
75 et al., 2009; Piña-Ochoa et al., 2010b, a; Koho et al., 2011; Bernhard et al., 2012b). The intracellular NO₃⁻ storage
76 can reach concentrations up to 567 mM in gromiids (Piña-Ochoa et al., 2010b) and experiments with isotopically
77 labeled NO₃⁻ showed that *Globobulimina turgida* takes up NO₃⁻ in a similar rate, independently of presence or size
78 of the intracellular NO₃⁻ pool (Koho et al., 2011). However, not all benthic foraminifera are able to denitrify, even
79 if they live in environments that are periodically exposed to anoxia such as the intertidal species *Ammonia tepida*,
80 which neither stores NO₃⁻ nor shows any denitrification activities (Piña-Ochoa et al., 2010b). Some foraminifera
81 from the Bering Sea have been shown to store NO₃⁻ but did not denitrify in incubation experiments (Langlet et al.,
82 2020). These species include *Nonionella pulchella*, *Uvigerina peregrina* and *Bolivinelina pseudopunctata*. Also,
83 the NO₃⁻ storage in *U. peregrina* shows a high variability, depending on the environment. Individuals of *U.*
84 *peregrina* from the Bay of Biscay lack a significant NO₃⁻ storage, while *U. peregrina* from the North Sea and the
85 Bering Sea both show intracellular NO₃⁻ enrichments (Piña-Ochoa et al., 2010b, Langlet et al., 2021). Other
86 *Uvigerina* and *Nonionella* species have been shown to denitrify (Risgaard-Petersen et al., 2006; Høgslund et al.,
87 2008; Piña-Ochoa et al., 2010b; Glock et al., 2019b; Gomaa et al., 2021). Many miliolids and allogromiids, several
88 intertidal rotaliid species but also some other rotaliids and textulariids completely lack an intracellular NO₃⁻ storage
89 (Piña-Ochoa et al., 2010b).

90 For about a decade after the first discovery of foraminiferal denitrification it remained unclear if
91 foraminifera indeed denitrify themselves, or if they host bacterial symbionts that are responsible for the
92 denitrification. Evidence came up for both hypotheses. Bernhard et al. (2012a) showed that *Bolvina argentea* was
93 able to denitrify, even after a very harsh treatment with antibiotics, which indicates that this species can denitrify
94 even, when potential bacterial symbionts are killed. Other studies showed that bacterial endobionts likely perform
95 denitrification in some gromiid and allogromiid species (Bernhard et al., 2012a; Høgslund et al., 2017). With the
96 recent advances in molecular biology, however, it became possible to analyze the transcriptome of denitrifying
97 foraminifera and Woehle & Roy et al. (2018) showed that the enzymes responsible for denitrification in
98 *Globobulimina spp.* from a Swedish hypoxic Fjord basin are indeed transcribed by eukaryotic RNA. These
99 enzymes are homologues of enzymes that are also used by bacteria for denitrification, which indicates an ancient
100 prokaryotic origin of denitrification in foraminifera. Nevertheless, the homologues of the enzymes that catalyze
101 the first and the last step of foraminiferal denitrification (Reduction of NO₃⁻ to nitrite (NO₂⁻) and reduction of
102 nitrous oxide (N₂O) to N₂ gas; fig. 3) have not been identified, yet. This indicates either that foraminifera use other
103 enzymes to catalyze these steps, that they rely on bacterial symbionts for these steps or that they use an alternative
104 denitrification pathway in general. One hypothesis, brought up by Woehle & Roy et al. (2018) is that the
105 homologue of the nitric oxide reductase (Nor) is indeed a nitric oxide dismutase that has been proposed to catalyze
106 the enzymatic reaction 2 NO → N₂ + O₂ (alternative pathway in fig. 3) (Ettwig et al., 2012). The presence of the
107 eukaryotic denitrification pathway found in foraminifera (Woehle et al., 2018) has been confirmed through other
108 analyses of foraminiferal genomes (Orsi et al., 2020; Gomaa et al., 2021). Gomaa et al. (2021) also identified an
109 enzyme of yet unknown functionality that might be responsible for the first step in the foraminiferal denitrification
110 pathway. Recent metagenomics and transcriptomics results of denitrifying foraminifera indicate that bacterial
111 symbionts might perform the missing steps in the foraminiferal denitrification pathway or that they at least partly
112 contribute to the amount of NO₃⁻ that is denitrified within foraminiferal cells (Woehle et al., 2022). The study by
113 Woehle & Roy et al. (2022) also reconstructed that the last common ancestor of denitrifying foraminifera likely
114 has its origin during the Cretaceous, likely related to the occurrence of the Cretaceous Anoxic Events. The fact

115 that the foraminiferal denitrification pathway is incomplete and the first and last steps are likely performed by
116 Desulfobacteraceae in their microbiome suggests that the acquisition of denitrification ability in foraminifera
117 occurred in multiple stages (starting during the Cretaceous) but is not yet complete (Woehle et al., 2022).

118 It is noteworthy that denitrifying foraminifera from the Peruvian OMZ show a metabolic preference of
119 NO_3^- over O_2 as an electron acceptor (Glock et al., 2019c). This might explain, why some infaunal denitrifying
120 foraminifera follow the oxycline within sediments (Linke and Lutze, 1993; Duijnsteet et al., 2003). We have to
121 keep in mind that O_2 can be quite harmful for organisms that are not adapted to higher O_2 concentrations, due to
122 its strong reactivity. In addition, even trace amounts of O_2 can inhibit denitrification and O_2 can repress the
123 denitrifying enzyme synthesis (Smith and Tiedje, 1979; Knowles, 1981; Tiedje, 1988; Mckenney et al., 1994).
124 Thus, if denitrifying foraminifera are exposed to small amounts of O_2 they cannot denitrify but also do not have
125 enough O_2 to supply their demands for electron acceptors. Larger amounts of O_2 might supply this demand but
126 also harm the cell. Furthermore, foraminifera can store NO_3^- within vacuoles, due to its lower reactivity and still
127 have an electron acceptor reservoir if NO_3^- is depleted in their microhabitat. This is not possible for O_2 due to its
128 high reactivity. Finally, a review by Zimorski et al. (2019) addresses the common misconception that the presence
129 of O_2 improves the overall energetic state of the cell. It is a fact that the energy yield from remineralizing glucose
130 or amino acids is higher in the presence of O_2 (“ O_2 respiration”) but it is also a fact that the synthesis of
131 biomass consumes thirteen times more energy per cell, if oxygen is present, compared to anoxic conditions. This
132 is related to the chemical equilibrium between organic matter and CO_2 , which strongly shifts to the side of CO_2
133 in the presence of O_2 (Zimorski et al., 2019). All this might explain, why the metabolism of at least some denitrifying
134 foraminifera is better adapted to denitrification than to O_2 respiration.

135 Furthermore, the fact that some foraminifera prefer NO_3^- over O_2 as electron acceptor (Glock et al., 2019c)
136 and other species like *U. peregrina* denitrify in some environments but completely lack an intracellular NO_3^-
137 storage in others (Piña-Ochoa et al., 2010b) might explain the microhabitat selection of benthic foraminifera in the
138 sediment. According to the conceptual TROX model, benthic foraminifera can be divided into three groups, due
139 to their microhabitat preference: Epifauna, shallow infauna and deep infauna (Jorissen et al., 1995). These
140 microhabitats are mainly controlled by bottom water O_2 concentrations $[\text{O}_2]_{\text{BW}}$ and the supply of organic matter
141 (i.e. food, Jorissen et al., 1995). Due to our increasing understanding about the anaerobic metabolism of
142 foraminifera we can now assume that NO_3^- availability is another controlling factor and according to their
143 preference for NO_3^- or O_2 as electron acceptors the different microhabitat preferences (Epifauna, shallow infauna
144 and deep infauna) might be assigned to three different attributes (Aerobe, facultative anaerobe and facultative
145 aerobe; see also fig. 4).

146 **Deep infauna** can be considered as **facultative aerobes** that prefer NO_3^- over O_2 and try to avoid trace
147 amounts of O_2 but can withstand periods of oxygenation, since they are also able to respire O_2 . They follow the
148 oxycline in the sediments to avoid the inhibition of denitrification by trace amounts of O_2 . Taxa belonging to the
149 deep infaunal – facultative aerobe group that prefers NO_3^- over O_2 include for example *Valvulineria* spp., *Bolivina*
150 spp., *Globobulimina* and *Cassidulina* spp. (Jorissen et al., 1995; Mojtahid et al., 2010; Glock et al., 2019c).

151 **Shallow infauna** can be considered as **facultative anaerobes** that basically are well adapted to the
152 presence of low O_2 concentrations but can switch to denitrification if they are exposed to anaerobic conditions or
153 need to enter the deeper sediment parts to find food or avoid competition stress. These species have the advantage
154 that they can utilize both fresh phytodetritus from the top of the sediments and organic matter of lower quality
155 from the deeper parts of the sediments. A good example for a shallow infaunal – facultative anaerobe species is
156 *U. peregrina*, that is well known for their shallow infaunal lifestyle and has been found with or without intracellular
157 NO_3^- storage in different environments (Schmiedl and Mackensen, 2006; Piña-Ochoa et al., 2010b; Langlet et al.,
158 2020).

159 **Epifauna** can be considered as **aerobes** that are used to thrive on top of the sediments or even on elevated
160 substrates. Typical epifaunal – aerobe taxa include *Cibicides* spp. and *Planulina* spp. (Corliss and Chen, 1988;
161 Lutze and Thiel, 1989). These species have the advantage that they are well adapted to collect fresh food supply
162 from above (Wollenburg et al., 2021) but usually cannot withstand longer anaerobic periods (Mackensen et al.,
163 1995). Nevertheless, recent genetic data indicates that *Cibicoides wuellerstorfi* clusters very close to known
164 denitrifying species in the phylogenetic tree, so it cannot be excluded that some *Cibicides* spp. can denitrify under
165 certain prerequisites (Woehle et al., 2022).

166 Note that the deep infauna can even migrate deeper into the sediments below the depth of NO_3^-
167 penetration, if they have to, due to their ability to intracellularly store NO_3^- as a reservoir (Fig. 4). The deeper

168 boundary of the elevated infauna might be controlled by the zone of sulfate reduction, where free sulfide is
169 produced, which might be toxic for the foraminifers. In conclusion to this chapter it is worth to mention that
170 research still continuous to measure denitrification rates for different benthic foraminiferal species (Langlet et al.,
171 2020; Choquel et al., 2021). This is important since data for such rates is scarce for foraminifera but needed to
172 estimate their contribution to oceanic N-cycling. This topic is discussed a bit further in chapter 1.5.

173 2.1.2 Dormancy

174 Dormancy is another strategy to survive anoxia or extreme O₂ depletion for some benthic foraminifera
175 that cannot denitrify. Dormancy is defined as the reduced or suspended metabolic activity in response to exogenous
176 factors (Ross and Hallock, 2016). Observations that indicate the potential of dormancy in foraminifera have been
177 documented since the 1950s and are extensively reviewed by Ross & Hallock (2016). Nevertheless, many aspects
178 of foraminiferal dormancy, such as role in foraminiferal life cycle or its role in structuring foraminiferal
179 assemblages remained unexplored (Ross and Hallock, 2016).

180 In the 1990s some studies hypothesized about potential dormancy of foraminifera, when exposed to
181 anoxia. Bernhard and Alve (1996) observed that the ATP concentration ([ATP]) of the benthic foraminiferal
182 species *Bulimina marginata*, *Stainforthia fusiformis* and *Adercotryma glomerata* flushed with N₂ gas to drive out
183 O₂ was significantly lower than in specimens from well aerated conditions. They already interpreted this
184 observation as an indication that dormancy is a survival strategy for some foraminiferal species when they are
185 exposed to periods of anoxia. Linke & Lutze (1993) observed cysts of *Elphidium incertum* from putative anoxia
186 that might be interpreted as a sign for dormancy and Hannah and Rogerson (1997) hypothesized that foraminifera
187 transported to an anoxic sediment layer might become dormant until they return to aerated conditions by transport
188 through bioturbation.

189 Recently, dormancy of foraminifera exposed to anoxia has gained more attention again. LeKieffre et al.
190 (2017) did a feeding experiment with *Ammonia tepida* (*Ammonia sp.* phylotype T6 according to Koho et al., 2018)
191 using a ¹³C-labeled diatom film as food source. They compared the metabolic differences of *Ammonia sp.* between
192 oxic and anoxic conditions by mapping the distribution of ¹³C within the cells using coupled TEM/Nano-SIMS
193 and by analyzing the carbon concentration and stable carbon isotopic composition of the total organic matter and
194 individual fatty acids in the foraminifer. Nearly the complete diatom biofilm was consumed and the foraminiferal
195 cytoplasm was strongly enriched in ¹³C under oxic conditions. Specimens from the anoxic incubation ingested
196 only few of the diatoms and those were neither assimilated nor metabolized further. In addition, the specimens
197 from the oxic incubation produced a significant amount of specific polyunsaturated fatty acids, which has not been
198 the case under anoxic conditions. *Ammonia sp.* (T6) reacted to the induced anoxia with a severely reduced
199 metabolic rate within less than 24 hours. All these observations provide solid evidence that dormancy is a survival
200 strategy of *Ammonia sp.* (T6) under anoxia.

201 Koho et al. (2018) further analyzed cell structural changes in *Ammonia spp.* under exposure to anoxia
202 collected from the field as well as from incubations. The specimens from anoxia showed an increase in lipid
203 droplets and electron dense bodies within their cytoplasm. The cytoplasm itself was thinned out, which was
204 interpreted as metabolization of the own cytosol. In addition, while absent within the specimens from oxic
205 environments, various bacteria were present within the cytoplasm of the specimens from anoxia. These were
206 interpreted as endobionts but might also be parasites that could not be fend off, due to the drastically reduced
207 metabolism under anoxia. Considering all these studies, it is likely that dormancy is a common survival strategy
208 under anoxia for foraminiferal species that don't have an anaerobic metabolism and likely also to periods of other
209 extreme environmental conditions.

210 2.1.3 Kleptoplasty

211 Kleptoplasty describes a symbiosis between algal chloroplasts and a host organism that sequesters the
212 chloroplasts from algae (Clark et al., 1990). The word originates from the Greek word “Kleptes”, which means
213 “thief”. Kleptoplasty in foraminifera is most extensively studied for shallow *Elphidium* and *Haynesina* species that
214 often thrive within the photic zone and this research goes back until the 1970s (Lopez, 1979; Lee et al., 1988;
215 Correia and Lee, 2000, 2002b, a; Goldstein et al., 2004; Pillet et al., 2011, 2013; Cevasco et al., 2015; Jauffrais et
216 al., 2016, 2017, 2018; Cesbron et al., 2017; Goldstein and Richardson, 2018; Jesus et al., 2021). Several studies
217 showed that the sequestered chloroplasts in the intertidal species *Haynesina germanica* are still capable of
218 photosynthesis under light exposure (Lopez, 1979; Cesbron et al., 2017). In 2011 there came first proof using
219 molecular biological methods, that the kleptoplasts in foraminifera originate from diatoms (Pillet et al., 2011) but
220 this had been hypothesized before on the basis of the chloroplast shape in TEM-observations (Lopez, 1979; Lee

221 et al., 1988; Cedhagen, 1991; Lee and Anderson, 1991; Bernhard and Bowser, 1999; Goldstein et al., 2004). Austin
222 et al., (2005) hypothesized that the toothplates in *H. germanica* are morphological adaptations to crack diatom
223 frustules for access to their chloroplasts. Recently, LeKieffre et al. (2018) showed in incubation experiments with
224 $\text{H}^{13}\text{CO}_3^-$ and $^{15}\text{NH}_4^+$ during a light/dark cycle that *Haymesina germanica* is indeed able to fix inorganic carbon and
225 nitrogen under light exposure. Intertidal foraminifera are often exposed to hypoxic or even anoxic conditions,
226 when water stagnates during low tide or if they are transported to deeper anoxic sediment layers by bioturbation
227 (Rybarczyk et al., 1996; Cesbron et al., 2017). *H. germanica* is also supposed to occur in black sediments of the
228 British salt marsh tide pools (Bernhard and Bowser, 1999) which likely become anoxic during a tidal cycle
229 (Rybarczyk et al., 1996) and it was among the first recolonizers of a Fjord suffering of organic pollution (Cato et
230 al., 1980; Bernhard and Bowser, 1999). Kleptoplasty might thus be an additional adaptation of foraminifera from
231 photic environments to stay active during periods of O_2 depletion (Cesbron et al., 2017).

232 Less well understood is the phenomenon of kleptoplasty, observed in the benthic foraminifers *Nonionella*
233 *stella* and *Nonionella labradorica* that can thrive below the photic zone and often inhabit O_2 -depleted sediments
234 (Cedhagen, 1991; Bernhard and Bowser, 1999; Grzymski et al., 2002; Jauffrais et al., 2019; Gomaa et al., 2021).
235 Experiments to test, if *N. labradorica* is able to photosynthesize with its sequestered chloroplasts have been
236 inconclusive. While Cedhagen (1991) found active photosynthesis in *N. labradorica* specimens incubated with
237 ^{14}C , Jauffrais et al. (2019) showed an increased O_2 respiration rate instead of O_2 production and chloroplast
238 degradation in specimens exposed to light. Recently, Gomaa et al. (2021) found chloroplast encoded transcripts in
239 *N. stella*, indicating that the kleptoplasts in this species are still active. Genetic analyses revealed that the
240 kleptoplasts in *N. stella* and *N. labradorica* are also mainly sequestered from diatoms, most likely after ingestion
241 and selective digestion of phytodetritus (Grzymski et al., 2002; Jauffrais et al., 2019; Gomaa et al., 2021). Grymzky
242 et al. (2002) calculated that the rest amount of light for *N. stella* specimens collected from aphotic depths at the
243 Santa Barbara Basin is too low to sustain active photosynthesis. Instead, they suggested that the kleptoplasts in
244 foraminifera from aphotic environments provide the ability to fix inorganic nitrogen via the glutamine synthetase
245 and glutamate 2-oxo-glutarate amidotransferase (GOGAT) pathway. Indeed, Jauffrais et al. (2019) showed that
246 kleptoplastic *N. labradorica* are able to fix inorganic nitrogen but coupled TEM/Nano-SIMS revealed that the
247 assimilated nitrogen is associated with electron opaque bodies instead of sequestered chloroplasts. Analyses of the
248 transcriptome of *N. stella* by Gomaa et al. (2021) support these observations, since *N. stella* appears to be able to
249 fix ammonia by itself. They also found that the fucoxanthin-chlorophyll binding protein (FCP) was expressed in
250 the transcriptome of *N. stella* and speculated that the ability to synthesize FCP was derived from the kleptoplasts
251 by horizontal gene-transfer. FCP is a pigment, commonly found in chloroplasts of brown algae and allows a more
252 efficient photosynthesis with a light absorption bandwidth especially useful in aquatic environments
253 (Papagiannakis et al., 2005; Premvardhan et al., 2008). The true function of the kleptoplasts in deep-sea benthic
254 foraminifera from aphotic, often O_2 depleted, environments still remains enigmatic, though.

255 2.1.4 Other recent developments due to advances in molecular biological methods

256 The recent advances in molecular biological methods (e.g. next generation sequencing) lead to several
257 contemporary publications about metabolic adaptations of foraminifera to O_2 depletion (examples see fig. 5)
258 (Woehle et al., 2018, 2022; Orsi et al., 2020; Gomaa et al., 2021). These studies mainly focused on denitrification
259 but also brought attention to some other metabolic features of foraminifera that can thrive under anaerobic
260 conditions. Gomaa et al. (2021) found the expression of characteristic proteins for an anaerobic metabolism in
261 *N. stella* and *B. argentea*. These proteins include pyruvate-ferredoxin oxidoreductase (PFOR) and [FeFe]-
262 hydrogenase. These PFOR sequences were indeed eukaryotic and closely related to those of the facultative
263 anaerobe polychaete *Capitella teleta* and the anaerobic protistan parasite *Blastocystis*. The [FeFe]-hydrogenase is
264 very similar to those in the amoeba/flagellate *Naegleria gruberi*, which has experimentally been shown to be active
265 and to produce molecular hydrogen even under aerobic conditions (Tsaousis et al., 2014). Due to these
266 observations Gomaa et al. (2021) suggested that *N. stella* and *B. argentea* might be able to produce H_2 gas and
267 have the capacity for an anaerobic energy metabolism.

268 Another important observation has been made by Orsi et al. (2020). They used metatranscriptomics on
269 sediments from the Namibian shelf, where the foraminiferal community is dominated by *Bolivina* and *Stainforthia*
270 species. Living foraminifera were present in the sediment column up to 28 cm depth in an anoxic habitat with high
271 sulfide concentrations. The gene expression of those foraminifera increased under sulfidic conditions, which
272 indicates that they not only survive but thrive under anoxic conditions. The anaerobic energy metabolism of these
273 foraminifera seems to be sufficient enough to support calcification and phagocytosis even under anoxic conditions.
274 Evidence for foraminiferal calcification under anoxia already came up by a study from Nardelli et al. (2014). Orsi

275 et al. (2020) suggested that the Namibian foraminifera use phagocytosis to ingest prey cells even under anoxic
276 conditions. Though, this requires high bursts of energy. The authors suggested that the foraminifera use
277 dephosphorylation of an intracellular creatine phosphate storage to regenerate ATP for these energy bursts.
278 Evidence for the capacity for the dephosphorylation of creatine phosphate under anoxia was indicated by the
279 metatranskriptomes. In addition, a high intracellular dissolved inorganic phosphate storage has been found in
280 benthic foraminifera from the Peruvian OMZ, which might serve a reservoir to synthesize creatine phosphate
281 (Glock et al., 2020). Orsi et al. (2020) also found evidence for an anaerobic metabolism in foraminifera from the
282 Namibian shelf. Their data indicates that the foraminifers metabolize hydrolyzed organics to produce ATP using
283 fermentation and fumarate reduction.

284

3 Ecology

285 Studies about ecological and trophic interactions of foraminifera from O₂ depleted environments are
286 scarce. Nomaki et al. (2006) made an *in situ* feeding experiment at central Sagami Bay (1450 m), Japan, using ¹³C
287 labeled algae and bacteria. Bottom water O₂ concentration at this location is less than 60 μM (Glud et al., 2005).
288 Nomaki et al. (2006) described three different feeding strategies by benthic foraminifera in this environment.
289 *Uvigerina akitaensis*, *Bolivina spissa* and *Bolivina pacifica* selectively ingest fresh phytodetritus and thus can be
290 described as phytophagous species. The seasonal phytophagous species *Bulimina aculeata*, *Textularia*
291 *kattegatensis* and *Globobulimina affinis* ingest fresh phytodetritus selectively but feed on sedimentary organic
292 matter instead, when fresh phytodetritus is unavailable. The species *Cyclammina cancellata*, *Chilostomella*
293 *ovoides* ingest sedimentary organic matter at random and can thus be described as deposit feeders.

294 Several studies describe carnivorous behavior of benthic foraminifera (Goldstein, 1999; Lee, 1980; Lipps,
295 1983; Hallock and Talge, 1994; Dupuy et al., 2010). These observations have mainly been done on species that
296 usually live in oxygenated environments. Recently, new evidence came up indicating ingestion of nematodes by
297 *Globobulimina auriculata* from the hypoxic Alsbäck Deep in Gullmar Fjord, Sweden (Glock et al., 2019a). The
298 species *G. auriculata* denitrifies and thrives under anaerobic conditions (Woehle et al., 2018). It is inconclusive,
299 though, if the foraminifer preys on the nematode or vice versa (Glock et al., 2019a). Although predation
300 (phagotrophy) is the main type of interaction in aerobic communities, it usually plays a much smaller role in
301 anaerobic communities (Fenchel and Finlay, 1995). This is related to the low growth yields associated with the
302 anaerobic metabolism, which results in very short food chains. Thus, the decrease in energy flow along the
303 anaerobic food chains is higher than along the aerobic food chain (Fenchel and Finlay, 1995). The predatory isopod
304 *Saduria entomon* for example strongly reduces its predatory activity under hypoxia in comparison to aerobic
305 conditions (Sandberg, 1994) and the predator/prey biomass ratio has been shown to be 4 times lower in anaerobic
306 environments compared to aerobic environments (Fenchel and Finlay, 1995). Still, there is further evidence by
307 Orsi et al. (2020) that foraminifera from the Namibian shelf perform phagocytosis even under anoxic conditions
308 (schematic representations for phagocytosis and predation on meiofauna shown in fig. 6). It is remarkable that
309 there is so much evidence for phagotrophy on or by benthic foraminifera under anaerobic conditions and future
310 studies might shed more light on predator prey interactions of benthic foraminifera in O₂ depleted environments.

311

4 The role of foraminifera in benthic nutrient cycling and biogeochemistry

312 Some benthic foraminifera from O₂ depleted environments are rare examples for eukaryotes that can
313 perform complete denitrification (Risgaard-Petersen et al., 2006). In 2010, Pina-Ochoa et al. (2010b) showed that
314 NO₃⁻ storage in foraminifera as reservoir for heterotrophic denitrification is not exotic and related to some
315 foraminifera from a Swedish fjord but actually a widespread phenomenon. Pina-Ochoa et al. (2010b) also
316 pointed out the possible importance of denitrifying foraminifera for the benthic N-cycle, due to their partly high
317 abundances in O₂-depleted environments. In some environments, such as some habitats in the Peruvian OMZ,
318 foraminifera even seem to be the keyplayers in benthic denitrification (Glock et al., 2013, 2019b). Complete
319 heterotrophic denitrification produces non-reactive (i.e. not bioavailable) N₂ gas. Denitrifying benthic foraminifera
320 can thus be considered a sink for bioavailable N. The recent genetic studies on denitrifying benthic foraminifera
321 did not find transcripts for homologues of enzymes that catalyze the last step of denitrification – the reduction of
322 N₂O to N₂ (Woehle et al., 2018, 2022; Orsi et al., 2020; Gomaa et al., 2021). Some *Globobuliminids* from the
323 hypoxic Alsbäck Deep in the Swedish Gullmar Fjord have been shown to produce N₂O gas as product of
324 denitrification, although the rates were lower than their rates for complete denitrification (Piña-Ochoa et al.,
325 2010a). The NO₃⁻ storage in denitrifying foraminifera but also in some sulfur bacteria, such as *Beggiatoa*, is of
326 greater importance for benthic biogeochemical cycling, due to the potential of biological transport of these
327 intracellular reservoirs (Dale et al., 2016). Most of the diagenetic models that describe and calculate benthic N-
328 cycling are based on (and limited to) diffusive transport of the different N-species in bottom and pore water. Active

329 biological transport of different N-species can thus efficiently influence the benthic fluxes of different N-species
330 (Dale et al., 2016).

331 The estimates of total benthic foraminiferal denitrification rates are mainly based on upscaling individual
332 species specific denitrification rates by the living abundances of benthic foraminifera in different environments
333 (Piña-Ochoa et al., 2010b; Glock et al., 2013, 2019b). This approach is limited by the availability of species
334 specific denitrification rates, although, various approximations can be used to estimate denitrification rates for
335 species with unknown denitrification rates (Glock et al., 2013). In addition, Glock et al. (2019b) provided an
336 equation to calculate an estimate for the denitrification rate, using the cell volume of the species of interest. A
337 summary of all published benthic foraminiferal denitrification rates can be found in tab. 1. Further Data about
338 species specific foraminiferal denitrification rates will improve our estimates about the role of foraminifera in
339 benthic N-cycling and, thus, also models for benthic biogeochemical cycling.

340 Recently, it has been found that some benthic foraminifera are not only storing NO_3^- for denitrification
341 but also store larger amounts phosphate (Glock et al., 2020). The intracellular phosphate concentration can exceed
342 the concentration in the surrounding pore waters by a factor of 10 to 100. The use of this intracellular phosphate
343 storage is still under debate. Hypotheses about the use of the stored phosphate include the synthesis of
344 polyphosphates or a reservoir for the synthesis of phospholipids for the cell membranes (Glock et al., 2020). In
345 addition, there is evidence that the intracellular phosphate storage in foraminifera facilitates phosphogenesis in
346 some environments, similar to the intracellular polyphosphate enrichments in some sulfur bacteria (Schulz and
347 Schulz, 2005). Sediments at the lower boundary of the Peruvian OMZ bear small phosphorite grains that show a
348 step by step transition from pristine foraminifer shells via shells that are filled with phosphorites until small
349 phosphorite grains that only retain the size and coarse shape of a foraminifer. The recent evidence for the potential
350 of benthic foraminifera to use dephosphorylation of an intracellular creatine phosphate storage to regenerate ATP
351 under anoxic conditions might be another explanation for the high intracellular phosphate storage (Orsi et al.,
352 2020). It might be that this is an adaptation of foraminifera to enable phagocytosis even under anaerobic conditions.

353 4.1 Estimating the contribution of foraminifera to benthic nutrient budgets and fluxes

354 The intracellular NO_3^- storage in benthic foraminifera from different environments shows a relatively
355 wide concentration range (Tab.2). In addition, species that lack intracellular NO_3^- storage are relatively widespread
356 and there are species that, depending on the environment, either have or lack intracellular NO_3^- (Tabs.2&3). Most
357 of the species that have been found both with and without intracellular NO_3^- in different environments (bold species
358 in Tab.3) are species that are typically found to live shallow infaunal and belong to the group of foraminifera that
359 can be considered facultative anaerobe and likely are opportunistic species that are well adapted to transitional
360 environments with periodic O_2 depletion, since they apparently can handle oxygenated and anaerobic
361 environments (see 1.3.1).

362 Due to the strong natural variability in NO_3^- storage, it strongly depends on the data basis to estimate the
363 contribution of foraminifera to benthic NO_3^- budgets with a relative robust certainty. Nevertheless, the more data
364 is available, the better we are able to calculate foraminiferal NO_3^- budgets including species with unknown
365 denitrification rates or intracellular NO_3^- . Considering this, an analysis of published data about intracellular NO_3^-
366 content reveals a highly significant correlation between the intracellular NO_3^- and the cell volume of denitrifying
367 benthic foraminifera (Fig. 7; power regression; $R^2 = 0.59$; $F = 86$; $P = 3E-13$).

368 Thus, the intracellular NO_3^- content of a potentially denitrifying foraminifer can be estimated from its
369 biovolume according to the following equation:

$$370 \text{Eq.1: } \ln(\text{NO}_3^-)_i = 1.07(\pm 0.11) \times \ln(V_{\text{cell}}) - 11.5(\pm 1.9)$$

371 ,where $\text{NO}_3^-_i$ is the intracellular NO_3^- content in pmol ind^{-1} and V_{cell} is the cell volume in μm^3 . Note that
372 only species from table 2 with an intracellular $[\text{NO}_3^-] \geq 1 \text{ mM}$ were considered for the power regression. In
373 addition, two extreme datapoints were discarded as outliers (see supplementary note). Similar equations have been
374 published to estimate foraminiferal denitrification rates (Glock et al., 2019b; here Eq.2) and intracellular dissolved
375 inorganic phosphorous content (Glock et al., 2020, here Eq.3).

$$376 \text{Eq.2: } \ln(R_{\text{den(ind)}}) = 0.68(\pm 0.12) \times \ln(V_{\text{cell}}) - 5.57(\pm 1.9)$$

$$377 \text{Eq.3: } \ln(\text{DIP}_i) = 0.82(\pm 0.03) \times \ln(V_{\text{cell}}) - 7.65(\pm 0.52)$$

378 ,where $R_{den(ind)}$ is the individual denitrification rate in $\text{pmol ind}^{-1} \text{day}^{-1}$ and DIP_1 is the intracellular
379 dissolved inorganic phosphorous content in pmol ind^{-1} . Further equations and principles for upscaling
380 foraminiferal nitrogen- and phosphorous-budgets from abundances of living foraminifera can be found in Glock
381 et al. (2013, 2019b and 2020) and (Xu et al., 2021). Formulae to estimate the biovolume of many different common
382 shapes of foraminifera have recently been published (de Freitas et al., 2021). Due to the high uncertainties related
383 to the natural variability in metabolic rates and nutrient storage, a thorough error estimation is recommended (see
384 Appendix B in Glock et al. 2020).

385 5 Applications for paleoceanography

386 Due to their ability to precipitate their calcitic tests even under anoxic conditions, fossil benthic
387 foraminifera became routine tools in paleoceanography to reconstruct past redox conditions (Nardelli et al., 2014;
388 Orsi et al., 2020). This chapter will discuss briefly that morphological features and geochemistry of benthic
389 foraminiferal tests and the species composition of benthic foraminiferal communities can be used to reconstruct
390 redox conditions in the bottom water. Nevertheless, this chapter will be short, since a larger review paper is in
391 progress that will summarize modern O_2 proxies in general (Hoogakker et al., in prep).

392 5.1 Morphological adaptations and test porosity

393 Some morphological adaptations are very common for benthic foraminifera that thrive in O_2 depleted
394 habitats. Small, more elongated and flattened morphologies are often characteristic for O_2 depletion, while more
395 spherical forms can indicate oxygenated conditions (Bernhard, 1986; Bernhard et al., 1997). This generalization
396 has to be taken with care, though, because there are larger spherical species that live deep infaunal below or at the
397 oxycline. *Globobulimina* spp. for example are well known to thrive deep in the sediments and are model organisms
398 to study foraminiferal denitrification (Risgaard-Petersen et al., 2006; Piña-Ochoa et al., 2010b; Woehle et al.,
399 2018). Though, *Golobobuliminidae* are relatively large and have a strongly spherical shape. Also, the individual
400 size within some species can be completely decoupled from O_2 availability. The size of *Bolivina seminuda* from
401 the Peruvian OMZ is directly proportional to the $[NO_3^-]_{BW}$ concentration in their habitats, even though the
402 analyzed specimens were all from O_2 depleted conditions (Glock et al., 2019c). An inverse correlation between
403 size and $[O_2]$ has also been shown for other benthic foraminifera (Keating-Bitonti and Payne, 2017). Nevertheless,
404 small size, high porosity and thin test walls seem to be characteristic for foraminifera that live in low O_2
405 environments (Kaiho, 1994). Most of these characteristics are already quantified and summarized by Kaiho (1994)
406 and won't be further discussed here.

407 One morphological feature that recently got more attention as a possible paleoceanography tool is the
408 porosity that includes pore size and pore density of the foraminiferal tests. Research regarding foraminiferal pore
409 characteristics already ranges back till the 1950s (Arnold, 1954). Then, in the 1960s, first attempts have been made to
410 use the porosity of foraminifera as an index for (paleo-)climate (Bé, 1968). This chapter will mainly focus on
411 the latest studies on the porosity of benthic foraminifera and its potential as a paleo proxy. Different foraminiferal
412 species seem to adapt their pore characteristics in a different way to different environmental conditions. *Cibicides*
413 spp. for example mainly thrive in well oxygenated environments (Mackensen et al., 1995). Recent studies,
414 however, observed living *Cibicidoides* spp. thriving in environments of $< 2 \mu\text{mol/kg } O_2$ (Rathburn et al., 2018)
415 and fossil specimens in the paleorecord during periods of severe O_2 depletion (Hoogakker et al., 2018). It is not
416 known, if any *C. spp.* are able to denitrify but recent genetic data indicates that *Cibicidoides wuellerstorfi* clusters
417 very close to known denitrifying species in the phylogenetic tree (Woehle et al., 2022). Rathburn et al., (2018)
418 also showed that the porosity in *C. spp.* and *Planulina* spp. is significantly negatively correlated to the O_2
419 concentrations in the bottom water ($[O_2]_{BW}$). If O_2 is too depleted, the foraminifers increase their porosity to
420 optimize the O_2 uptake. A recent study tested several approaches to determine the correlation between the pore
421 density of *Planulina limbata* and bottom water oxygenation and used the pore density of *P. limbata* from the
422 Peruvian margin to quantitatively reconstruct $[O_2]_{BW}$ at the Peruvian OMZ during the Late Holocene and the Last
423 Glacial Maximum (Glock et al., 2022). More comprehensive reviews about the history of studies on the porosity
424 of foraminifera and the use of morphological features as O_2 proxy can be found in other recent review papers
425 (Glock et al., 2012; Hoogakker et al., in prep.).

426 5.2 Geochemistry of benthic foraminiferal tests

427 The unique mechanism of biomineralisation in rotaliid foraminifera preserves the chemical signature of
428 ambient seawater in their test calcite. These species precipitate their test calcite directly from vacuolized seawater
429 (Erez, 2003) and thus the chemical composition of the test calcite reflects the chemical composition of the
430 surrounding water in their habitats. Different element/Ca ratios are used as proxy for various parameters. Over the

431 past decades several redox sensitive element/Ca ratios in foraminiferal calcite were focused as potential O₂ proxies,
432 for example V/Ca (Hastings et al., 1996b, a, c), Fe/Ca (Glock et al., 2012a), Mn/Ca (Reichart et al., 2003; Hathorne
433 et al., 2003; Munsel et al., 2010; Glock et al., 2012a; Groeneveld and Filipsson, 2013; Koho et al., 2015; Petersen
434 et al., 2018; Barras et al., 2018; van Dijk et al., 2019; Ni et al., 2021; Brinkmann et al., 2021) and I/Ca (Glock et
435 al., 2014, 2016, 2019d; Zhou et al., 2014, 2022; Lu et al., 2016, 2020; Winkelbauer et al., 2021; Cook et al., 2022).
436 All these proxies have their individual advantages and disadvantages, which are discussed in detail in Hoogakker
437 et al., in prep. In addition, the offset of the stable carbon isotope fractionation ($\delta^{13}\text{C}$) between the tests of epifaunal
438 and deep infaunal benthic foraminifera can be used as a quantitative [O₂]_{BW} proxy (McCorkle and Emerson, 1988;
439 Hoogakker et al., 2014, 2018). This offset is now referred to as $\Delta\delta^{13}\text{C}$. While epifaunal benthic foraminifera
440 incorporate the $\delta^{13}\text{C}$ -signature of dissolved inorganic carbon (DIC) in the bottom water, deep infaunal foraminifera
441 incorporate the $\delta^{13}\text{C}$ -signature of DIC in the pore water (Schmiedl and Mackensen, 2006; Hoogakker et al., 2014).
442 This offset increases with the height difference in the sediment column (McCorkle and Emerson, 1988). With
443 increasing [O₂]_{BW}, deep infaunal foraminifera migrate deeper into the sediment to avoid the oxycline (Duijnsteet et
444 al., 2003) and $\Delta\delta^{13}\text{C}$ increases (Hoogakker et al., 2014). Thus, there is a significant correlation between [O₂]_{BW}
445 and $\Delta\delta^{13}\text{C}$ at the lower [O₂] range. The $\Delta\delta^{13}\text{C}$ proxy is also discussed in detail in Hoogakker et al., in prep.

446 5.3 Foraminifera assemblage compositions

447 Species compositions of benthic foraminifera assemblages are routinely used to reconstruct past
448 environmental conditions and it is not the focus of this review to summarize the history of this approach. Since
449 some benthic foraminifera species are especially well adapted to O₂ depleted conditions (see chapter 2), the use of
450 benthic foraminifera assemblages to reconstruct past [O₂] appears obvious and has a relatively long history (e.g.
451 Sen Gupta and Machain-Castillo, 1993; Kaiho, 1994; Alve and Bernhard, 1995; Bernhard et al., 1997; Baas et al.,
452 1998; Nordberg et al., 2000; Leiter and Altenbach, 2010; Erdem et al., 2020; Ovsepyan et al., 2021). Kaiho et al.
453 (1994) developed the first benthic foraminifera O₂ index (BFOI), to quantitatively reconstruct past [O₂]_{BW}. Further
454 development of this index is still going on with recent developments by Tetard et al., 2021 and Kranner et al.,
455 2022. Nevertheless, according to the conceptual TROX model (Jorissen et al., 1995), microhabitats and
456 assemblage composition of benthic foraminifera are not only controlled by [O₂]_{BW}, but the supply of organic
457 carbon to the sediments is another major controlling factor, which hampers the straightforward interpretation of
458 assemblage compositions as a pure [O₂]_{BW} proxy. History, applications and different approaches to use benthic
459 foraminifera assemblage compositions as qualitative and quantitative O₂ proxy are all summarized in Hoogakker
460 et al., in prep.

461 **6 Author contribution**

462 NG wrote the manuscript and did the data compilation and statistical analyses.

463 **7 Competing interests**

464 The authors declare that they have no conflict of interest.

465 **8 Acknowledgements**

466 I would like to thank Gerhard Schmiedl for providing constructive feedback on an early draft of this
467 manuscript. Funding was provided by the Deutsche Forschungsgemeinschaft (DFG) through my Heisenberg grant
468 GL 999/3-1. Finally, I would like to thank all the authors and co-authors that are cited in this review, because of
469 their pioneering research on benthic foraminifera from O₂ depleted environments.

843

Figure captions:

844 Figure 1: Schematic representations for three survival strategy examples performed by benthic foraminifera under
845 O₂ depleted conditions.

846 Figure 2: Stoichiometry for heterotrophic denitrification. Organic matter is oxidized using nitrate (NO₃⁻) as an
847 electron acceptor in a similar way O₂ is used for O₂ respiration. This process provides energy for the organism for
848 oxidative phosphorylation. [CH₂O] symbolizes organic matter of unspecified composition. ΔG₀ value relates to
849 PH of 7. Taken from (Jorgensen, 2006).

850 Figure 3: Schematic view of two alternative pathways suggested for foraminiferal denitrification. Abbreviations
851 above the reaction arrows indicate the enzymes that are catalyzing the respective step (see legend). Enzymes in
852 black have been found transcribed by eukaryotic (foraminiferal) RNA (Woehle et al., 2018). Enzymes in grey are
853 missing in the foraminiferal denitrification pathway and are likely performed by bacterial symbionts (Woehle et
854 al., 2022). The straight pathway above describes the normal heterotrophic denitrification pathway. The junction,
855 catalyzed by the Nod, which produces O₂, has been suggested as an alternative pathway for foraminiferal
856 denitrification (Woehle et al., 2018).

857 Figure 4: TROX model modified after Jorissen et al. (1995) and Xu et al. (2021). The supply of organic matter in
858 different environments controls the penetration depth of O₂ and NO₃⁻ into the sediment. Benthic foraminifera
859 choose their microhabitat according to their metabolic preferences for O₂ or NO₃⁻ as an electron acceptor and the
860 availability of food. **Epifaunal – aerobic** species depend purely on O₂ and live on top the sediment or elevated
861 substrate. They are well adapted to collect fresh food supply and survive even in oligotrophic environments.
862 **Shallow infaunal – facultative anaerobic** species are well adapted to switch between O₂ and NO₃⁻ respiration. If
863 they store NO₃⁻ for denitrification they can even migrate and survive below the oxycline, when they have to.
864 Though, if food supply is getting critical they can migrate close to the sediment surface and easily withstand
865 exposure to O₂. **Deep infaunal – facultative aerobes** prefer NO₃⁻ over O₂ and try to avoid O₂, because even trace
866 amounts of O₂ inhibit denitrification. Thus, they thrive below the oxycline, when there is still enough supply of
867 NO₃⁻ and usually migrate upwards, when the oxycline shallows. They are able to survive short periods in the
868 transition zone below the NO₃⁻ penetration depth, due to their high intracellular NO₃⁻ storage but are likely limited
869 in depth by the region of sulfate reduction due to the presence of free toxic sulfide. Note that they also can actively
870 transport intracellular NO₃⁻ below the NO₃⁻-penetration depth in the sediments. For further details see text.

871 Figure 5: Examples for molecules and processes that are relevant in the anaerobic metabolism of foraminifera. A:
872 Structural formula of creatine phosphate. B: The role of creatine kinase (Ck) and creatine phosphate in the
873 anaerobic metabolism. High energy creatine phosphate is produced by phosphorylation of creatine. Creatine
874 phosphate can rapidly recycle ADP to ATP to provide resources for rapid energy bursts. This pathway has been
875 described by Orsi et al.(2020). C: Fermentation has been found to be relevant in the anaerobic metabolism of
876 foraminifera by both Orsi et al.(2020) and Gomaa et al. (2021). The possibility of a H₂ producing fermentation
877 pathway, catalyzed by Fe-hydrogenase has been described by Gomaa et al. (2021).

878 Figure 6: A: Schematic representation of a *boliviniid* ingesting bacterial cells. Recent studies showed that benthic
879 foraminifera from O₂ depleted habitats have the capacity of phagocytosis even under anoxia (Orsi et al., 2020). B:
880 Schematic representation of *Ammonia* sp. preying on a nematode. Some benthic foraminifera are known to prey
881 on meiofauna (Dupuy et al., 2010) and there is evidence, that even some *globobuliminids* that usually thrive under
882 anaerobic conditions might prey on nematodes (Glock et al., 2019a).

883 Figure 7: Log-log plot and power regression of intracellular NO₃⁻ content (NO₃⁻_i) against the biovolume (V_{cell}) of
884 benthic foraminifera from diverse environments (Tab. 2). Only species with an intracellular [NO₃⁻] ≥ 1 mM,
885 where both NO₃⁻_i and V_{cell} were published were considered for the power regression.

Figures

Figure 1:

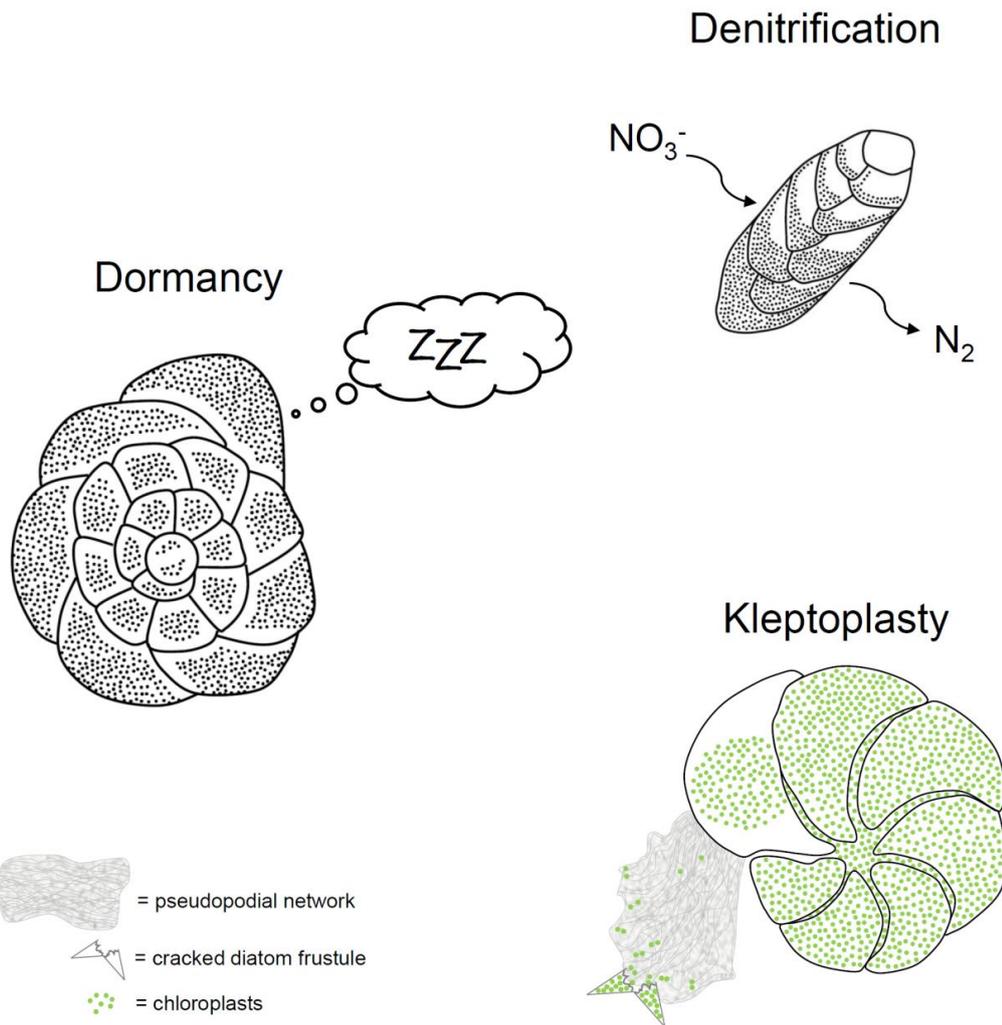

Fig. 1: Schematic representations for three survival strategy examples performed by benthic foraminifera under O_2 depleted conditions.

Figure 2:

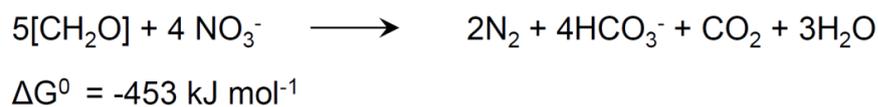

Fig. 2: Stoichiometry for heterotrophic denitrification. Organic matter is oxidized using nitrate (NO_3^-) as an electron acceptor in a similar way O_2 is used for O_2 respiration. This process provides energy for the organism for oxidative phosphorylation. $[\text{CH}_2\text{O}]$ symbolizes organic matter of unspecified composition. ΔG^0 value relates to PH of 7.
Taken from (Jorgensen, 2006).

Figure 3:

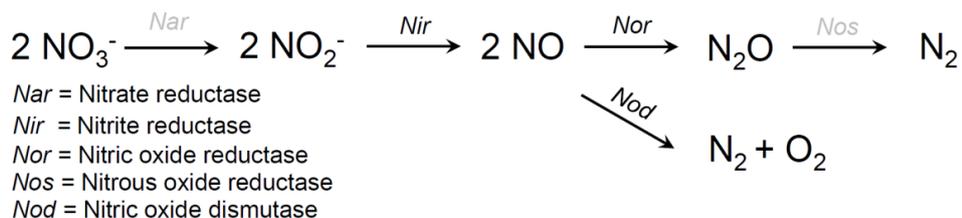

Fig. 3: Schematic view of two alternative pathways suggested for foraminiferal denitrification. Abbreviations above the reaction arrows indicate the enzymes that are catalyzing the respective step (see legend). Enzymes in black have been found transcribed by eukaryotic (foraminiferal) RNA (Woehle et al., 2018). Enzymes in grey are missing in the foraminiferal denitrification pathway and are likely performed by bacterial symbionts (Woehle et al., 2022). The straight pathway above describes the normal heterotrophic denitrification pathway. The junction, catalyzed by the *Nod*, which produces O_2 , has been suggested as an alternative pathway for foraminiferal denitrification (Woehle et al., 2018).

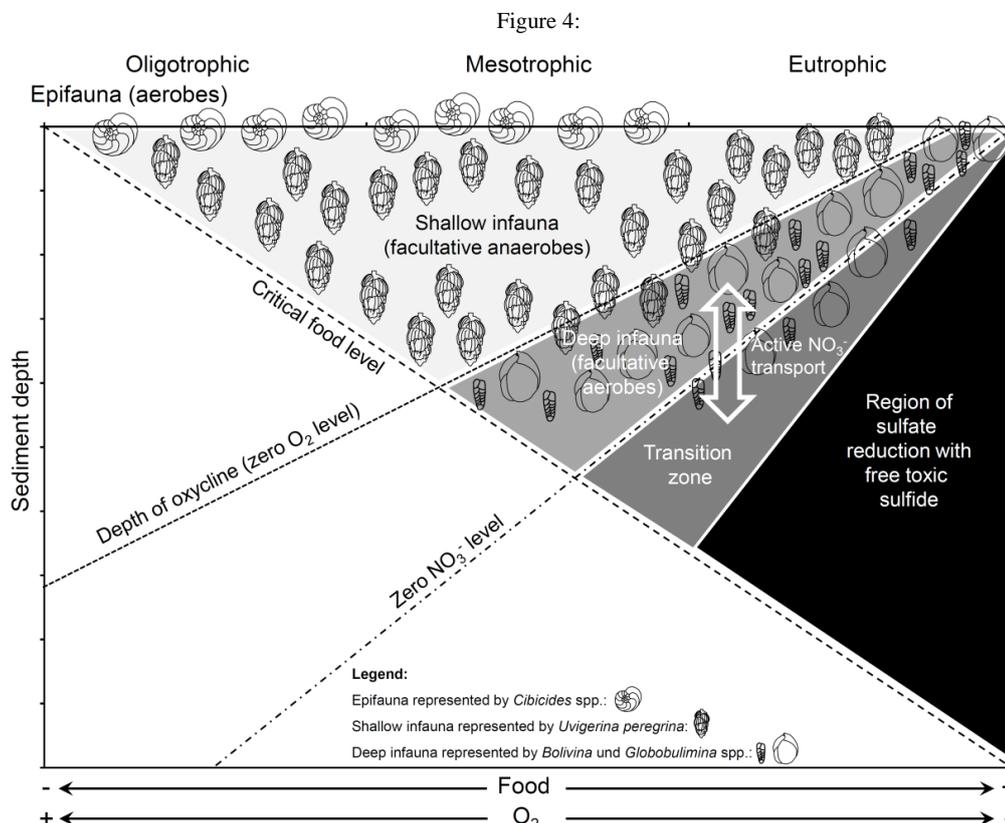

Fig.4: TROX model modified after Jorissen et al. (1995) and Xu et al. (2021). The supply of organic matter in different environments controls the penetration depth of O₂ and NO₃⁻ into the sediment. Benthic foraminifera choose their microhabitat according to their metabolic preferences for O₂ or NO₃⁻ as an electron acceptor and the availability of food. **Epifaunal – aerobic** species depend purely on O₂ and live on top the sediment or elevated substrate. They are well adapted to collect fresh food supply and survive even in oligotrophic environments. **Shallow infaunal – facultative anaerobic** species are well adapted to switch between O₂ and NO₃⁻ respiration. If they store NO₃⁻ for denitrification they can even migrate and survive below the oxycline, when they have to. Though, if food supply is getting critical they can migrate close to the sediment surface and easily withstand exposure to O₂. **Deep infaunal – facultative aerobes** prefer NO₃⁻ over O₂ and try to avoid O₂, because even trace amounts of O₂ inhibit denitrification. Thus, they thrive below the oxycline, when there is still enough supply of NO₃⁻ and usually migrate upwards, when the oxycline shallows. They are able to survive short periods in the transition zone below the NO₃⁻ penetration depth, due to their high intracellular NO₃⁻ storage but are likely limited in depth by the region of sulfate reduction due to the presence of free toxic sulfide. Note that they also can actively transport intracellular NO₃⁻ below the NO₃⁻-penetration depth in the sediments. For further details see text.

Figure 5:

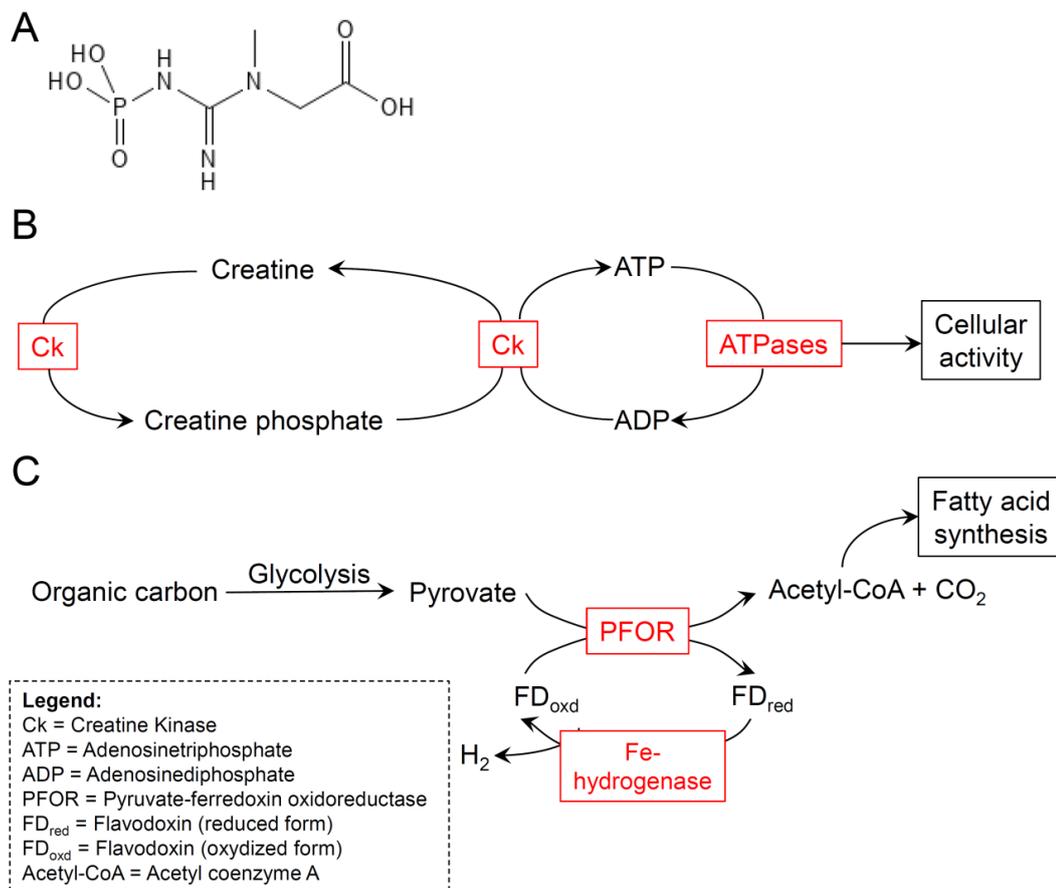

Fig. 5: Examples for molecules and processes that are relevant in the anaerobic metabolism of foraminifera. A: Structural formula of creatine phosphate. B: The role of creatine kinase (Ck) and creatine phosphate in the anaerobic metabolism. High energy creatine phosphate is produced by phosphorylation of creatine. Creatine phosphate can rapidly recycle ADP to ATP to provide resources for rapid energy bursts. This pathway has been described by Orsi et al.(2020). C: Fermentation has been found to be relevant in the anaerobic metabolism of foraminifera by both Orsi et al.(2020) and Gomaa et al. (2021). The possibility of a H₂ producing fermentation pathway, catalyzed by Fe-hydrogenase has been described by Gomaa et al. (2021).

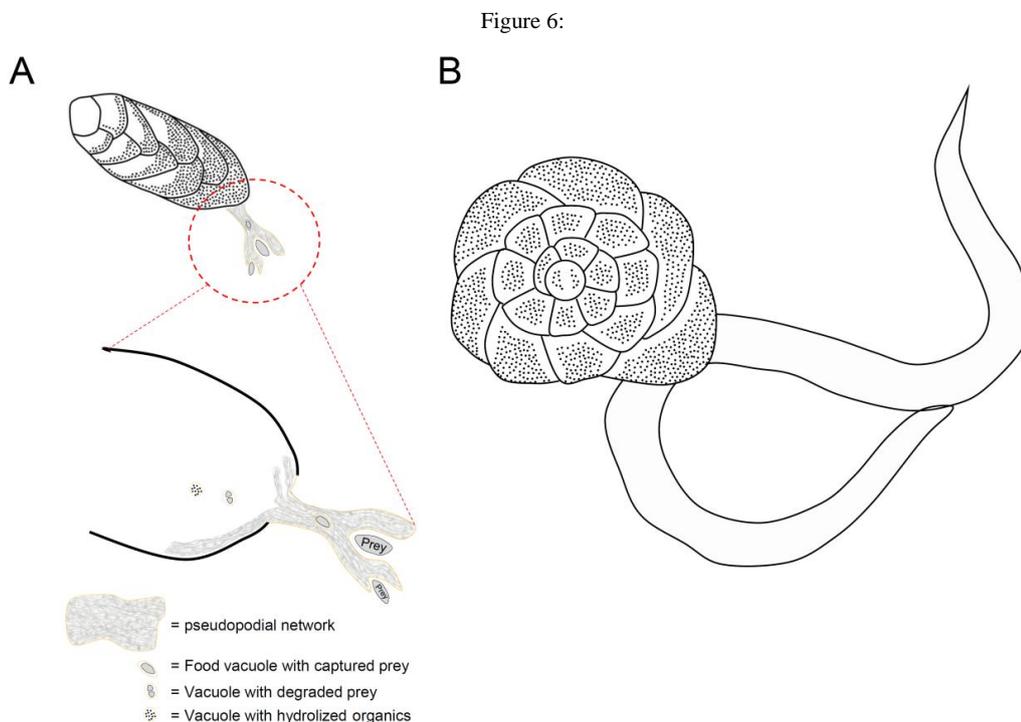

Fig. 6: A: Schematic representation of a *bolivinid* ingesting bacterial cells. Recent studies showed that benthic foraminifera from O₂ depleted habitats have the capacity of phagocytosis even under anoxia (Orsi et al., 2020). B: Schematic representation of *Ammonia* sp. preying on a nematode. Some benthic foraminifera are known to prey on meiofauna (Dupuy et al., 2010) and there is evidence, that even some *globobuliminids* that usually thrive under anaerobic conditions might prey on nematodes (Glock et al., 2019a).

Figure 7:

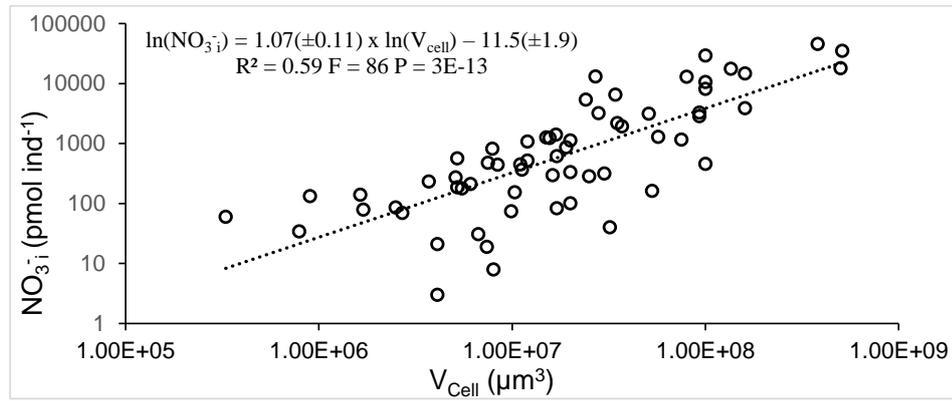

Figure 7: Log-log plot and power regression of intracellular NO_3^- content (NO_3^-) against the biovolume (V_{cell}) of benthic foraminifera from diverse environments (Tab. 2). Only species with an intracellular $[\text{NO}_3^-] \geq 1 \text{ mM}$, where both NO_3^- and V_{cell} were published were considered for the power regression.
