Extracellular polymeric substances (EPS) are an important organic carbon reservoir in many pelagic and benthic environments. The production of EPS is intimately associated with the growth of phyto- and picoplankton. EPS plays a critical role in carbonate precipitation through the binding of cations and by acting as a nucleation site for minerals. Large-scale episodes of fine-grained calcium carbonate precipitation in the water column (whiting events) have been linked to cyanobacterial blooms, including of *Synechococcus* spp. The mechanisms that trigger these precipitation events are still debated. We pose that the cyanobacterial EPS, produced during an exponential and stationary growth phases play a critical role in the formation of whitings. The aim of this study was to investigate the production of EPS during a two-month cyanobacterial growth, mimicking a bloom. We further evaluated the potential role of EPS in carbonate precipitation. The production and properties of EPS produced at different *Synechococcus* spp. growth stages were investigated and carbonate mineral formation within these EPS matrices was determined in forced precipitation experiments. EPS produced during the early and late stationary phase contained a larger amount of negatively charged groups than present in EPS produced during the exponential phase. Consequently, a higher Ca$^{2+}$ binding affinity of the stationary phase-EPS led to the formation of a larger amount of smaller carbonate minerals (<50 µm) compared to crystals formed in exponential phase-EPS, which were less and larger (>50 µm). These findings were used to establish a conceptual model for picoplankton bloom-mediated CaCO$_3$ precipitation that can explain the role of EPS in whitings (see graphical abstract).
1.2 Overview of phytoplankton blooms

Phytoplankton blooms, including those of picoplankton, are dense accumulations of cells resulting in a visible discoloration of the surface water layers (Reynolds and Walsby, 1975; Huisman et al., 2018). Their occurrence has been recorded worldwide in marine and freshwater bodies (Paerl et al., 2001; Paerl and Huisman, 2008; Plosn, 2008). Light intensity, water temperature, nutrient availability, weather conditions and hydrodynamics are key factors that determine the onset and persistence of a bloom. Blooms are typically seasonal, frequently observed during late spring or summer, and can be dominated by picoplankton (Huisman et al., 2018). Some phytoplankton organisms, notably cyanobacteria, may produce toxins and form large-scale harmful algal blooms (Paerl et al., 2001). The intensity and frequency of cyanobacterial blooms have been increasing due to anthropogenic eutrophication (Heisler et al., 2008; O’Neill et al., 2012), a trend expected to exacerbate due to climate change (Lefeling et al., 2018). Cyanobacteria comprise a diverse group of photosynthetic organisms that play a pivotal role in global primary production and are key players in the biogeochemical cycles of carbon, nitrogen and oxygen (Callieri and Stockner, 2000; Whitton and Potts, 2012; Raven et al., 2017). The unicellular cyanobacterium Synechococcus is one of the most abundant photosynthetic microorganisms on Earth (Whitton and Potts, 2012), which contribute substantially to the picoplankton community in marine (Murphy and Haugen, 1985; Coello-Camba and Agusti, 2021) and freshwater environments (Weise, 1993) that can form dense blooms (Schultze-Lam et al., 1992; Phlipps et al., 1999; Dittrich and Obst, 2008b).

1.3 Phytoplankton blooms and CaCO₃ precipitation

During the occurrence of dense phytoplankton blooms, high rates of photosynthetic activity lead to a rapid depletion of CO₂ in the surface waters, increasing alkalinity. Depending on the buffering capacity of the water, this could result in pH values ≤9 to as high as 11 (Belings and Maberly, 1998; Zepierick et al., 2021). Consequently, the inorganic carbonate equilibrium shifts towards carbonate (CO₃²⁻). Some cyanobacteria possess a carbon concentrating mechanism (CCM) that converts HCO₃⁻ to CO₂ through the action of carbonic anhydrase enzymes (Price et al., 1998; Badger et al., 2002) and produce hydroxide ions (Kapryanov and Pronina, 2011). The activity of extracellular carbonic anhydrase (eCA) may contribute to the create an alkaline microenvironment in the extracellular polymeric substances (EPS) surrounding the cyanobacterial cells (Price et al., 2002; Dupraz et al., 2009). When OH⁻ ions are released during photosynthesis it causes the pH to rise, which favors carbonate mineral precipitation, assuming there is enough calcium ions available (Kamemaya et al., 2012). Consequently, during blooms, carbonate minerals can form on EPS or precipitated in the microenvironment surrounding cyanobacterial cells.

1.4 The role of EPS

Cyanobacteria are known producers of EPS (De Philippis et al., 2001; Pereira et al., 2009; Dittrich and Sibler, 2010), especially during blooms (Pannard et al., 2016; Liu et al., 2018). EPS serve as a boundary between cells and their immediate environment (Whitton and Potts, 2012) and may act as a template for CaCO₃ nucleation (Dupraz and Visscher, 2005; Dupraz et al., 2009; Kamemaya et al., 2012). EPS are high molecular weight organic molecules composed of polysaccharides, proteins, nucleic acids and lipids (Pereira et al., 2009; Marvasi et al., 2010; Decho and Gutierrez, 2017). This complex mixture of molecules may contain specific monomers, such as uronic or silicic acids (monosaccharides), aspartic or glutamic acids (amino acids) or functions (sulfate, phosphate), which carry negative charges in physiological conditions and can therefore bind cations, such as Ca²⁺, and promote the nucleation of CaCO₃ crystals (Trichert and Defarge, 1995; Brassant et al., 2003; Dupraz et al., 2009; Dittrich and Sibler, 2010; Walker et al., 2019). Conversely, polyionic EPS in solution can inhibit crystal growth by poisoning the faces of growing nuclei by an adsorption mechanism, according to a classical and accepted view prevailing for other macromolecules of similar charge properties: synthetic peptides (Wheeler et al., 1991), skeletal proteins (Wheeler et al., 1981; Addadi and Weiner, 1985), cocolith-associated polysaccharides (Borman et al., 1982) or natural organic matter dissolved in seawater (Mitterer and Cunningham, 1985). The production and composition of EPS differ among different species of microorganisms and their type of metabolism and depend on environment in which they live and stresses (e.g., nutrient availability, pH, temperature, light, salinity) and the stage of their growth (Pereira et al., 2009; Pannard et al., 2016; Martinho de Brito et al., 2022). The deprotonation of functional groups at elevated pH enhances the binding capacity of cations such as Ca²⁺ and controls crystal nucleation and growth by reducing the interfacial energy barrier between the crystal and the EPS substrate (Dupraz et al., 2009; Dittrich and Sibler, 2010). EPS play a two-fold role in carbonate formation by initially inhibiting (through Ca²⁺ binding) and subsequently promoting carbonate precipitation by releasing calcium ions during EPS alteration and degradation (Dupraz and Visscher, 2005; Dupraz et al., 2009). Furthermore, through specific functional group composition and structural architecture, EPS may also exert control over the mineralogy, morphology and/or abundance of the minerals that are formed (Trichert and Defarge, 1995; Dupraz et al., 2009).

1.5 The goal of this study

We have previously reported that the pH of Synechococcus cultures increased when grown in a non-buffered medium (Martinho de Brito et al., 2022). In these growth conditions, the production of EPS was enhanced compared to growth in a buffered medium. Furthermore, the EPS from cells grown in non-buffered conditions contained more negatively-charged functional groups that impacted the properties of the carbonate minerals that precipitated (Martinho de Brito et al., 2022). The current study further investigates the properties of EPS produced during different growth phases of Synechococcus spp. Over an extended incubation time (mimicking a prolonged natural bloom). We aim to better understand the role of cyanobacterial blooms in carbonate precipitation through EPS production and develop a conceptual model of picoplankton-mediated organomineralization to explain the biological origin of whitening events.

2. Materials and Methods

2.1 Synechococcus PCC7942 strain and culture growth conditions

Synechococcus PCC7942 was obtained from the Centre de Ressources Biologiques de l’Institut Pasteur (Paris). Cultures were grown in a one-third-strength, non-buffered liquid BG11 medium (Allen, 1968; Ripka et al., 1979). The medium consists of (per liter): 1.5 g of NaNO₃; 0.04 g of KH₂PO₄; 0.075 g of MgSO₄·7H₂O; 0.036 g of CaCl₂·2H₂O; 6 mg of citric acid combined with 6 mg of ferric citrate; 0.001 g of Na₂EDTA·2H₂O and 0.02 g of Na₂CO₃. Trace metal solutions contained (per liter) 2.86 mg of H₂BO₃; 1.81 mg of MnCl₂·4H₂O; 0.222 mg of ZnSO₄·7H₂O; 0.39 mg of Na₂MoO₄·2H₂O; 0.079 mg of CaSO₄·H₂O and 0.0494 mg of Co(NO₃)₂·6H₂O. Cultures were incubated at room temperature (21°C±2), in a light/dark cycle of 12h/12h under 36.8 μE m⁻² s⁻¹ of photon irradiance while shaken at 200 rpm in a Cimarec i Multipoint Stirrer, 6 Position, 2000 rpm, 3L per Multipoint, 100-240 VAC rotary shaker.
2.2 Experimental design of Synechococcus-bloom formation

Two independent growth experiments were performed in 1 L glass serum bottles containing 800 mL of 1/3 BG-11 medium adjusted to pH 7.5, sealed with silicone caps to allow gas exchange. Cells used for the inoculum (pH = 9.2) were pre-cultured in a full-strength BG-11. Immediately after inoculation (30 mL/bottle), the pH increased to approximately 8.2.

2.2.1 Experiment I

In the first growth experiment, six bottles were inoculated with Synechococcus PCC 7942. Cell growth and EPS production were examined. Optical density (OD750), pH and cell counts were monitored weekly (2-3 times by week). EPS was extracted on days 14, 28 and 56 of cultivation (two bottles were harvested at each sampling time).

2.2.2 Experiment II

The second growth experiment was performed in quadruplicate. Chlorophyll a (Chla), extracellular carbonic anhydrase activity (eCA), nutrients (NO3, PO43−) and calcium concentration were analysed at 0, 14, 28 and 56 days of cultivation. pH values, OD and cell counts were also assessed at longer intervals (once per week) than in Experiment I.

2.3 Growth assessment

2.3.1 Optical density, cell counts and pH values

The pH value was measured with a CRISON GLP 21 pH meter (Crisson Instruments SA, Alella, Spain). Cell growth was monitored through cell counts and OD750 measurements. Cell counts were performed using a counting chamber (Neubauer, Mariangela, Germany) by randomly selecting five fields of view and counting approximately 100-200 cells. The OD at 750 nm of a 1 ml sample of the culture was measured in a Bio-Rad SmartSpec Plus Spectrophotometer (Bio-Rad, Hercules, CA, USA).

2.3.2 Chlorophyll-a extraction

Chla was extracted from 2 ml culture aliquots using a methanol extraction method (Stal et al., 1984). Following the extraction in the dark at 4 °C, samples were centrifuged. The Chla absorbance was measured in the supernatant at 665 nm using a Bio-Rad SmartSpec Plus Spectrophotometer (Bio-Rad, Hercules, CA, USA).

2.3.3 Extracellular carbonic anhydrase activity

The extracellular carbonic anhydrase (eCA) activity was measured using a BioVision Carbonic Anhydrase Activity Assay Kit (BioVision, Ref. K472-100, Abcam, Waltham, MA, USA) according to the manufacturer’s specifications. Aliquots of ~ 5 ml were analysed immediately after the collection. To avoid cell lysis and intracellular CA contamination, samples were not centrifuged. The cells were separated from the supernatant by using a 1 ml syringe and a 0.20 μm NALGENE® syringe filter. The absorbance was measured in a Bio-Rad Model 680 Microplate Reader at 405 nm.

2.3.4 Nitrogen, phosphorus and calcium measurements

Phosphate, nitrate, nitrite and calcium concentrations were determined in the growth medium at 0, 14, 28 and 56 days of cultivation. Cells were removed by centrifugation and filtration through a 0.20 μm Millipore filter under a mild vacuum. The samples were stored at 4°C in the dark until measured by ion chromatography and the Ca2+ concentration was determined by ICP-AES (dual axial and radial view iCAP Pro XP model with fast loop, ThermoFisher Scientific, Courtaboeuf, France) available at the University of Franche-Comté, Besançon, France.

2.4 EPS extraction and purification

EPS were extracted from the Synechococcus cultures as previously described by Martinho de Brito et al. (2022). EPS were harvested after 14, 28 and 56 days of cultivation. Cyanobacterial cells were inspected by microscopy to ensure that no cell lysis had occurred during the extraction process. The pure EPS fractions were obtained by ultrafiltration (>10 kDa + retentate) for volume reduction and the weight of the material was determined following by dialysis (using a 1 kDa Membrane) and lyophilization on a high precision analytical balance (Quintix 35-1S, Sartorius, Göttingen, Germany).

2.5 EPS characterization

2.5.1 Fourier Transform-Infrared Spectroscopy

FT-IR spectra were obtained from freeze-dried EPS on an FT-IR Bruker Alpha spectrometer (Bruker Optics SARB, Marne la Vallée, France) fitted with an Attenuated Total Reflectance (ATR) ALPHA-P device equipped with a mono-reflection diamond crystal. A total of 24 scans were performed on each sample at a spectral resolution of 4 cm−1 in the 4000–375 cm−1 wavenumber range. The qualitative assignment of absorption bands was performed by comparison with spectra available in the literature (Coates, 2009).

2.5.2 Protein, sugar and glycosaminoglycan [quantification]

The total protein content of EPS was determined using the Bicinchoninic acid assay (Pierce® BCA Protein Assay Kit) and bovine serum albumin as the standard. The total sugar content was determined by a modified phenol-sulfuric acid method (Dubois et al., 1956) and xanthan and dextran were used as standards (Sigma-Aldrich, St. Louis, MO, USA). The total glycosaminoglycan (GAGs) content was quantified using the Blyscan Assay according to the manufacturer’s protocol (Blyscan Kit B1000, Biocolor Ltd., Antrim, UK) with chondroitin sulphate as the standard. All assays were carried out in duplicate.
2.5.3 Visualization of polyanionic macromolecules on Alcian Blue stained gels

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE) followed by Alcian Blue staining (Wall and Gys, 1988) were used to separate and to stain negatively charged macromolecules (10- > 170 kDa), respectively. Alcian Blue is a dye that specifically binds to glycoconjugates with an acidic character (e.g., containing carboxylated or sulfated functional groups). Samples were analysed on one-dimensional precast gradient protein gels (TGX Gel 4-15%, 90 mm x 70 mm) on a Mini-Protean 3 cell (Bio-Rad, Hercules, CA, USA), according to the method previously described by Martinho de Brito et al. (Martinho de Brito et al., 2022).

Prior to migration, samples were heat-denatured in standard 2xLaemmli sample buffer (5 min, 99°C, ref: 1610737, Bio-Rad). A pre-stained protein ladder (Eurodex, 306P-0111; MW: 10 kDa to > 170 kDa) was used as a reference.

2.5.4 Inhibitory effect of EPS using pH-drift assay

The capacity of negatively charged functional groups in EPS to inhibit the in vitro precipitation of calcium carbonate was tested with the pH-drift assay (Wheeler et al., 1981; Marin et al., 2000; Kawaguchi and Decho, 2002). This assay was performed as previously described by Martinho de Brito et al. (2022). Briefly, the pH was recorded by a pH meter (Research Laboratory Grade Benchtop pH/mV Meter with 0.001 pH Resolution-HS5221) connected to a PC via a USB cable. Data were recorded by the HANNA HI92000 software. The pH was measured every 2 s for 15 min. The shape of the curve (after reaching its maximum, about one minute after T0) reflects directly the inhibitory capacity of the tested EPS: a fast decrease in pH (decreasing exponential) indicates ongoing precipitation, i.e. the absence of inhibition, while a delayed decrease, resulting in a plateau around pH 8, means an inhibitory effect, proportional to the length of the plateau. Between each experiment, the electrode was refreshed with dilute acid and blank tests (without EPS) were performed.

2.6 Interaction of EPS with the in vitro precipitation of CaCO₃

The potential of the EPS matrix to interact with the precipitation of calcium carbonate was tested via the diffusion method in the presence of a closed ammonia-CO₂ saturated atmosphere (Albeck et al., 1993). 200 µL of the mixture containing pre-filtered (0.22 µm) CaCO₃ solution (10 mM) and EPS at increasing concentrations (5, 18, and 36 µg mL⁻¹) were incubated in duplicate in 16-well plates (Lab-Tek, Nunc/Thermo Scientific, Rochester, NY, USA). The EPS concentrations were selected to match the EPS yields at the extraction times (14, 28 and 56 days of cultivation). The plastic covers of the well plates were perforated to allow the reaction between CaCO₃ solutions containing EPS and ammonium bicarbonate. The well plates were placed in a desiccator that was incubated at 4°C in the dark for 72 hrs. At the completion of the incubation period, the pH value was measured in each well and the overlying solutions were carefully removed to dryness and CaCO₃ crystals analysed. Blank experiments were performed without any EPS. The experiment was carried out in duplicates.

2.6.1 Morphology and mineralogy of the crystals

The 16-well plates containing crystals were used in two manners: first, the morphology of the CaCO₃ crystals was checked with a tabletop scanning electron microscope (Hitachi TM 1000, Ibaraki, Japan) in back-scattered electron mode. To this end, the glass plate base was unsealed from its plastic well part and directly observed without carbon or gold sputtering. Secondly, the polymorph of the calcium carbonate minerals was determined by FT-IR spectroscopy using an FT-IR Bruker Alpha (Bruker Optics, SARL, Champs-sur-Marne, France). Mineral phases were determined by comparison of the spectra with the reference spectra available in the RRUFF Project database (https://rruff.info, accessed on January 1st, 2022).

2.6.2 Crystal counts and size distribution

CaCO₃ crystals were counted directly in the 16-well plates using an inverted microscope (Nanut, Paris, France) equipped with Mosaic 2.2.1 image analysis software. Images were processed to obtain crystal sizes (average width and length of size classes < 50 µm and > 50 µm) and the total count of crystals in each well. A total of ten fields of view accounting for 15.5 mm² were analysed. The results are reported as the mean ± standard error of the mean.

2.7 Statistical analysis

All the data concerning Synechococcus growth and EPS production are representative of two independent experiments with two technical replicates (four replicates for EPS extraction at 56 days of culture). The results are reported as the mean ± standard error of the mean. Statistical significance was assessed by performing single-factor ANOVA tests; p-values < 0.05 were statistically different.

3. Results

3.1 Trends in Synechococcus PCC7942 growth experiments and pH evolution

Cell density and pH values increased over the Synechococcus cultivation period (Figure 1A and 1B). The growth of Synechococcus cells showed a typical pattern including a brief lag phase (~6-7 days) followed by a 7-day (experiment I) and 14-day (experiment II) exponential phase and finally a stationary phase. The stationary phase (early stationary phase) was reached after 14 and 21 days of growth in experiment I and II, respectively, and lasted until day 56 of cultivation in both experiments (late stationary phase) (Figure 1A). Growth experiments I and II started with a similar cell density of approximately 10¹⁰ cells.L⁻¹ and demonstrated reproducible growth patterns. At the time of inoculation, cell density was 9.51 × 10⁹ in experiment I and 7.11 × 10⁹ cells.L⁻¹ in experiment II (Figure 1A). Synechococcus grew exponentially over the first 19 days in experiment I and over 21 days in experiment II until reaching a maximum of 1.9 × 10¹⁵ and 1.5 × 10¹⁵ cells.L⁻¹, respectively.

At the end of the exponential growth phase, the cell numbers levelled off and achieved a stable growth stage (stationary phase). Typical evolutions of pH values in culture media during the Synechococcus growth experiments are presented in Figure 1B. As a general trend, pH is linked to the photosynthetic activity of cyanobacteria. The pH levels rose rapidly during the exponential phase in both experiments, reaching around 10, and stayed steady during the stationary phase. While experiment I experienced significant pH fluctuations during the latter part of the stationary phase, overall, the pH evolution trends for both experiments are comparable (Figure 1B).
3.2 Extracellular carbonic anhydrase

The activity of extracellular carbonic anhydrase (eCA) in solution changed slightly over the growth experiment (Figure 1S). The highest eCA activity (~1600) was detected after 14 days of culture, during the exponential phase. The lowest activity was measured after 56 days of growth, in the late stationary phase.

3.3 Nutrient concentrations during growth

Nutrient concentration during the growth experiment is shown in Table 1. High nitrate concentrations supported exponential growth and high cell density. The results show that a major decrease in nitrate and phosphate concentrations occurred during the exponential growth phase and remained slowed down progressively over the stationary phase. At the end of the stationary phase, phosphate was virtually depleted, whereas 67% of nitrate was still available compared to its initial concentration.

Ammonium concentration was below the limit of detection (0.05–40 µg.L-1). Ca²⁺ concentrations decreased gradually and accounted for the total calcium concentration of 81% in the late stationary phase.

Table 1. Concentrations of NO₃⁻, PO₄³⁻ and Ca²⁺ (µM) in the culture medium before inoculation (one-third-strength BG-11 medium) and at 0, 14, 28 and 56 days of Synechococcus growth experiment are given as mean concentrations of four replicates (n=4).

3.3 Abundance of EPS

The recovery yields of the EPS produced (mean ± SD) resulting from the applied extraction method are listed in Table 2. The EPS yields varied from 2.9±0.5 to 18.6±2.1 mg.L⁻¹ during exponential and early stationary phases and reached the highest yield of 35.4±4.2 mg.L⁻¹ at 56 days of culture, in the late stationary phase (Table 2). When the values were normalized per cell yield, data/results showed that the EPS concentration increased significantly between the exponential and late stationary phases (p-value < 0.05) (Figure 2). Synechococcus continuously produced EPS during the 56-day experiment. In the first 14 days of growth, cells grew exponentially and EPS production was deficient. Between exponential and early stationary phases, EPS production increased by a factor of five to seven, reaching a maximum in the late stationary phase, after the 56-day growth experiment.

3.4 Chemical properties of EPS

3.4.1 FT-IR spectroscopy of EPS

FT-IR spectroscopy was used to check the overall EPS properties and composition. The IR spectra of EPS harvested during the exponential, early and late stationary phases of the growth experiment are depicted in Figure 3. The three spectra show strong similarities, exhibiting characteristic absorption bands for polysaccharides and protein moieties (highlighted in Figure 3 by vertical-coloured areas). However, differences in sample composition were also revealed by the presence of additional absorptions indicated by arrows in Figure 3. Interestingly, the spectrum of the exponential phase EPS exhibits a strong band, isolated at 582 cm⁻¹, which according to the literature on EPS could be assigned to a C–X stretch of alkyl halides (Kavita et al., 2011). Bands at 1039–1128 cm⁻¹ (C–O and C–O–C stretching vibrations) could be assigned to polysaccharides and polysaccharide-like structures (Wang et al., 2012b) and were observed in all EPS samples (Figure 3, blue area). In contrast, the small shoulders observed in the early and late stationary phase EPS, at ~1242 and 1244 cm⁻¹ correspond to sulfate groups. Bands at 811-868 cm⁻¹, most likely representing the glycosidic linkage between sugar monomers, were only present in EPS extracts in the early and late stationary phases. Low-intensity bands observed in the range of 1450-1370 cm⁻¹ are assigned to CH₃ and CH₂ deformations (bends) of proteins (Kansiz et al., 1999). These absorption bands were more evident in EPS obtained during the early stationary phase. The bands present in the range of 1660 and 1540 cm⁻¹ are attributed to C=O and C=N stretching vibrations and are characteristic of Amide I and II functions (Figure 3, orange and green areas, respectively), which are typically associated with proteins (Coates, 2000). Spectra of the early stationary phase EPS showed higher peaks of protein than those observed in EPS from exponential and late stationary phases. The medium bands at 1730 and 1727 cm⁻¹, present in samples extracted from exponential and late stationary phases, can be attributed to C=O stretching vibrations resulting from lipids and fatty acids (Kansiz et al., 1999). Absorptions in the range of 2960–2850 cm⁻¹ corresponding to C–H stretching vibrations of aliphatic hydrocarbons and possibly indicative of long-chain polymers (e.g., sugars or proteins), were observable in all EPS extracts. The amide A band (3345 cm⁻¹), characteristic of the N–H vibration of peptide groups in proteins, is present in all spectra (Figure 3, yellow area), but is particularly visible on the early stationary phase EPS spectrum. In the samples at 14 and 56 days of growth, this band is included in shoulders due to the presence of OH absorptions centred at 3342 and 3351 cm⁻¹, respectively. The list of band assignments is summarized in Table 1S (Supplementary data).
3.4.2 Protein, sugar and glycosaminoglycan (GAGs) contents

Total protein and sugar contents in all EPS extracts were assessed by colorimetric assays. There were remarkable differences in the amounts of protein and these varied within the different growth phases (Table 3). The EPS produced during the exponential growth phase revealed the lowest concentration of protein (79±9 µg.mg EPS) 1/4. The highest protein concentration was measured in EPS produced during the early stationary phase (253±42 µg.mg EPS), whereas during the late stationary phase, the protein concentration decreased by ~ two-fold. When accounting for the cell yield at times of EPS extraction (Table 2), cells produced EPS with ca 11-15 times more protein in the stationary phase than in the exponential phase (Table 3). The sugar content in the EPS harvested during the three different growth stages did not vary significantly (Table 3). The EPS produced during the exponential phase contained a slightly higher sugar content (584±9 µg of xanthan and 504±78 µg of dextran equivalents/mg EPS) than that measured in EPS produced during the early and late stationary phases (1.8 times and 1.3 times lower, respectively). These results demonstrate that sugars, rather than proteins, are the major component of all EPS extracts (Table 3). Our results show that, over the cultivation time, cells enhanced the production of larger amounts of glycosaminoglycans (GAGs) which can be associated with amino sugars and glycoproteins (Table 3). The highest fraction of sulfated groups (GAGs) to total EPS (217±143 µg GAGs.mg EPS) was found in the stationary phase EPS (Table 3). These results corroborate with data obtained from FTIR analysis.

Table 3. Protein, sugar and glycosaminoglycan content of the harvested EPS at times 14, 28 and 56 days of Synechococcus PCC7942 culture. Values represent the average of two replicates (n=2).

3.4.3 SDS-PAGE

The results of gel electrophoresis after the migration of exponential, early and late stationary phase EPS samples are illustrated in Figure 4. Replicates showed similar band patterns that are distributed between 10 and >170 kDa. A sharp greenish band in the migration front is strongly stained in late stationary phase EPS (Figure 4, lanes 6 and 7) and may correspond to chlorophyll. A less pronounced smear is visible in extracts obtained from the early stationary phase (Figure 4, lanes 4 and 5). Bands of < 10 kDa were not detected in the EPS produced during the exponential phase (Figure 4, lanes 2 and 3). A marked smear pattern is evidenced in all EPS extracts between 10-26 kDa: one prominent band was individualized at 17 kDa. A discrete blue smear (> 17-43 or 55 kDa) is evidenced in exponential phase EPS samples (Figure 4, lanes 2 and 3) and is less obvious in EPS samples from the early and late stationary phase (lanes 4-5 and 6-7, respectively). No specific bands were individualized in this molecular mass range, for the three growth phases. A band at about 45-47 kDa was strongly stained in exponential phase only. It may represent an extracellular carbonic anhydrase (Kupriyanova et al., 2016) but this would need to be confirmed. Another possibility could be that the 45-47 kDa-band is chlorophyll f synthase, also referred to as CBF, which seems to migrate around 46 kDa (Shan et al., 2019). An area between 43 and 170 kDa was noted in all EPS extracts, accounting for 5-6 individualized bands that may correspond to the consecutive addition of an identical "module", because the progression is logarithmic: is clearly seen in the early and late stationary phase lanes (lanes 4-7). The individualized bands were densely stained in EPS from the late stationary phase, including a smear at ~43-55 or 72 kDa (Figure 4, lanes 6 and 7) and a prominent band at > 170 kDa (Figure 4, lanes 6 and 7).
3.4.4 pH-drift assay

Recordings of the pH-drift assay are shown in Figure 5. The pH-drift assay determined the inhibitory effect of the EPS matrix (e.g., negatively charged functional groups) on the rate of CaCO₃ precipitation. Negatively charged groups of EPS can bind calcium ions from the solution. The main phenomenon observed in this assay is mineral-binding in which small calcium carbonate nuclei (nanometric or even pre-nucleation clusters) are very rapidly formed but they can be quickly poisoned by EPS which do not allow them to grow more. We believe that in this case, their growth is simply stopped because soluble EPS molecules adsorb on mineral surfaces. This mineral-binding also occurs due to the overall negative charge of the polymer of the matrix and is a much more efficient mechanism because of the ratio between nanometric nuclei and EPS molecules in theory. In theory, one CaCO₃ mineral of few nanometres requires a great amount of Ca²⁺ ions for its formation. Thus, it is more a “one-to-one” story (or something of that magnitude) between nanometric nuclei and single EPS molecules. Complete carbonate inhibition is reached when the total Ca binding capacity is achieved. CaCO₃ minerals start to nucleate, lowering the pH of the solution. Results show that the inhibitory effect was concentration-dependent and clear differences were visible between EPS extracted in the exponential (Figure 5A), early (Figure 5B) and late (Figure 5C) growth phases. EPS matrices from the stationary phase of culture growth (Figures 5B and 5C) exhibited a stronger inhibitory effect on CaCO₃ precipitation than the EPS extracted during the exponential phase (Figure 5A). Complete inhibition was only reached in EPS from early and late stationary phases when 50 µg of EPS mL⁻¹ was tested. In this case, a drop in pH was not observed and nucleation of crystals did not occur (Figure 5B and 5C), which means that the inhibition was total. Conversely, the exponential phase EPS exhibited less inhibition of CaCO₃ precipitation (Figure 5A). The shorter plateau shows that the mineral-binding capacity of the matrix delayed CaCO₃ precipitation but that consequently the pH dropped and visible precipitates formed, showing a less powerful inhibitory effect of the EPS compared to stationary phases EPS matrices.

![Figure 5](https://doi.org/10.5194/bg-2023-51)  
*In vitro inhibition of calcium carbonate precipitation by using EPS extracted during exponential (A), early (B) and late (C) stationary phases. Each panel shows the effect of six different EPS concentrations (0, 10, 20, 30, 40 and 50 µg) on CaCO₃ precipitation using the pH-drift assay method. The drop in pH indicates nucleation of CaCO₃ (→ precipitation) and a plateau indicates inhibition of precipitation. A larger plateau indicates a higher Ca-binding capacity of the matrix and thus stronger inhibition. Complete inhibition was observed when 50 µg of EPS solution from early and late stationary phases were used (e.g., see arrows). The results in each panel represent single experiments. Replication showed identical results (see Supplementary Figure 2S).*  

3.5 Calcium carbonate crystallization in the presence of EPS

Forced CaCO₃ experiments were performed using a control solution (without EPS) and EPS solutions, at same pH, with concentrations of 3, 18 and 36 µg mL⁻¹. Each concentration corresponds to the EPS yield at different growth stages: exponential phase (= 3 µgEPS mL⁻¹), early (18 µgEPS mL⁻¹) and late (36 µgEPS mL⁻¹) stationary phases. The crystals formed in the various EPS solutions showed different morphological (Figure 6) and mineralogical (Figure 5S) features as well as distinct crystal sizes and distributions compared to those formed in control solution (Figure 7).

3.5.1 Mineral morphology

A preliminary light microscopic analysis was carried out in order to identify the most significant samples to analyse by SEM (Figure 6). The morphology of crystals precipitated in the negative controls was very homogeneous and predominantly composed of calcite rhombohedrons that sometimes formed polycrystalline aggregates of size > 50µm (Figure 6A). All control solutions tested for the various EPS harvested during exponential and stationary phases showed similar crystal characteristics.

In the EPS solutions, CaCO₃ crystals showed both rhombohedral and spheroidal morphologies (Figure 6B-D). The morphology of crystals appears to change with increasing EPS concentrations. Spherical minerals formation was observed in the exponential phase-EPS solution (Figure 6B) and were less frequent in the EPS solution from early stationary phase (Figure 6C). In the late stationary phase-EPS solution, rhombohedrons represented the prevalent crystal morphology while spherical minerals were absent (Figure 6D).
Figure 6. In vitro forced CaCO₃ precipitation assay in (A) the absence of the EPS (control solution) and in the presence of EPS extracted during the (B) exponential, (C) early and (D) late stationary phases under increasing EPS concentrations of 3, 18 and 36 µg mL⁻¹, respectively. The images show two different CaCO₃ morphologies: rhombohedral (white squares) and spheroidal (white circles), in some cases shown as polycrystalline crystals. The scale bar (black) at the bottom right of the images is 500 µm.

3.5.2 Crystal mineralogy

The crystals' mineralogy was assessed by FT-IR microscopy performed on selected individual crystals of >10 µm (Figure 3S). The results revealed that calcite was the only CaCO₃ polymorph formed in the control solution. Calcite and vaterite formed in all EPS solutions tested. The FT-IR spectra revealed that all rhombohedrons and polycrystalline aggregates with "sharp edges" represent calcite polymorphs. In contrast, spheroidal crystals revealed a vaterite signature (Figure 3S).

3.5.3 Crystal size and distribution

The results from image analysis showed that a larger quantity of crystals precipitated in the stationary phase (early and late) EPS solutions (Figure 7) and that major differences were also observed in crystal size distribution (Figure 7). A comparison of the class of small crystal sizes (<50 µm) with the large crystal size class (>50 µm) showed a clear trend of an increasing total number of small crystals in the stationary phase EPS solutions compared to those formed in the EPS solutions from the exponential phase. The size reduction of the crystals at 18 and 36 mg L⁻¹ (Figure 7, early and late stationary phases) suggests a partial inhibitory effect of the EPS on the formation of calcium carbonate.

Figure 7. Total numbers of small (<50 µm) and large (>50 µm) crystal size classes of precipitated CaCO₃ in EPS solutions obtained from exponential and stationary phases, in EPS concentrations of 3, 18 and 36 µg mL⁻¹, respectively.

4. Discussion

Our study demonstrates that the amount and properties of EPS change significantly (p-value < 0.05) at the three different stages of Synechococcus growth in an artificial bloom experiment. Cells continuously produce EPS that increases in concentration and become more negatively charged in the stationary phase. We sampled this EPS over the exponential, early and late stationary phases and studied its role in carbonate mineral precipitation. Based on this, a conceptual model was developed to correlate the findings of this investigation with the potential EPS production of the naturally occurring picoplankton blooms and its possible involvement in whitening events. Though natural blooms experience a variety of factors that are not represented in the experiments described in this paper, the first part of the discussion is focussing only on the experimental data, whereas the interaction of these basic processes with other biotic and abiotic factors acting in the environment is discussed afterwards.

4.1 Exponential growth phase

Macronutrients, such as nitrogen (N) and phosphorus (P) promote the initiation of cyanobacterial blooms (Reynolds and Walsby, 1975; Reynolds, 1987; Paerl, 1988; Phlips et al., 1999; Paerl, 2008; Xu et al., 2015). In our growth experiment, the beginning of the exponential phase (and the persistence of bloom) (Figure 1A) was positively correlated with the high initial nutrient concentration in the medium (Table 1). Environmental factors such as water temperature, light intensity, hydrodynamics and availability of dissolved inorganic carbon (DIC) are also important determinants of cyanobacteria bloom development (Clark and Flynn, 2000;
Preprint. Discussion started: 6 April 2023
© Author(s) 2023. CC BY 4.0 License.

To alleviate CO₂ limitation, cyanobacteria have developed an efficient CO₂-concentrating mechanism (CCM) (Aizawa and Miyachi, 1986; Badger and Price, 1992; Badger et al., 2002; Burnap et al., 2015) and can use bicarbonate as an inorganic carbon source for photosynthesis (Price et al., 1998, 2002; Giordano et al., 2005; Sandrin et al., 2016). By activating CCM, cyanobacteria concentrate CO₂ by a factor of up to a thousand (Badger and Andrews, 1992; Badger et al., 2002, Price, 2011). CO₂-deficient conditions experienced during the exponential phase of our growth experiment, coupled with the continuous cellular demand for inorganic carbon to support photosynthetic carbon fixation likely led the cells to activate CCM. The predicted concentrations of CO₂ and HCO₃⁻ in the growth medium (Phreeqc data) in the early and late exponential phase infer that Synechococcus cells actively transported across the membrane and accumulated DIC into the cell, where the HCO₃⁻ pool was utilized to generate elevated CO₂ levels around Rubisco (Badger et al., 2002; Price et al., 2008). The CCM of cyanobacteria accomplishes very high carbon concentrating factors (Ccmema : Ccmema) at deficient specificity factors of Rubisco (Tortell et al., 2000). CCM involves bicarbonate transporters in the cell membrane, intracellular (cCA) and extracellular (eCA) carbonic anhydrase enzymes and concentrated Rubisco CO₂ activity located in carboxysomes (Badger et al., 2006; Price et al., 2008; Rae et al., 2013). CA converts HCO₃⁻ to CO₂ (Badger and Price, 1994), which increases the external pH in close proximity to the cells. In our study, eCA activity was ~ 1.6-2.0 times higher during the exponential growth phase and reduced gradually through the stationary phase (Supplementary figure, Figure S1). Similarly, Yang et al. (2023) measured the CA anhydrase in solution over a 30-day growth experiment with Synechococcus PCC 7942 and reported an increase over the lag phase and large fluctuations over the exponential phase. During the stationary phase, CA did not vary greatly but a minor decrease was recorded in the late stationary phase (Yang et al., 2023). In our study, the higher eCA activity recorded could explain the strongly stabilized ~45-47 kDa band that was only identified in our SDS-PAGE gels of EPS production during the exponential phase (Figure 4, lanes 2-3). The molecular weight (MW) of this band is similar to a 42-43 kDa eCA previously identified by Kupriyanova et al. (2018) and discussed by Martinho de Brito et al. (2022). As explained in the Results section 3.4.3, we cannot exclude that the band is chlorophyll f synthase, which seems to show up around 46 kDa. A more substantiated demonstration of the identity of the SDS-PAGE band will require other approaches (beyond the scope of the present study), such as micro-sequencing of the purified 43 kDa band or the use of a CA-specific antibody.

In our batch experiment, cells continue to grow exponentially for ~20 days of cultivation. At this point, cultures reached the maximum cell density (Figure 1A) and pH values ranged between 10.0-11.1 (Figure 1B). Based on our calculations, under these alkaline conditions, CO₂ was completely depleited (1.7 × 10⁻⁴ M) in the growth medium, whereas HCO₃⁻ was extremely low (~ 79 μM). Thus, the dominant inorganic carbon speciation was CO₂ (421 M). Because cells cannot take up CO₂ and HCO₃⁻ concentration seems to be insufficient to cover the carbon demands of cyanobacterial growth, we assume that this may have been the cause of cell numbers starting to level off (Figure 1A, early stationary phase). Consequently, cultures entered a stationary state due to a lack of inorganic carbon availability required to increase cell population (Miller et al., 1984; Mayo et al., 1989; Verspagen et al., 2014). The excess of nutrients measured in the medium in the late exponential phase (Table 1) suggested that the specific growth rate was not limited by nutrient availability but by a rather low level of CO₂ content.
usually associated with external stress factors (Rossi and De Philippis, 2015), including high pH conditions (Martinho de Brito et al., 2022). Moreover, metabolic stress may also alter the composition of EPS (Babele et al., 2019; Martinho de Brito et al., 2022). In the present study, the negative functional group abundance increased, resulting in a higher acidity of EPS (Figure 4, lanes 4-5) due to an increase in protein and sulfated glycan (GAG) (Table 3). In the pH conditions of the early stationary phase, all the functional groups of the EPS matrix are deprotonated and are able to bind calcium ions (Figure 5B) (Dupraz and Vischer, 2005; Braissant et al., 2003, 2007; Dietrich and Sibler, 2010) and bind calcium more efficiently nonameric nuclei in formation (if their formation is thermodynamically favoured). We suggest that the increased calcium-binding capacity of the EPS probably accounts for lower the Ca²⁺ concentration measured in the medium (Table 2, see [Ca⁺²]). In our in vitro forced precipitation assay, we measure the second effect, the inhibitory one (mineral-binding effect), which results in the production of small-sized calcium carbonate crystals (< 50 µm), in comparison to what happens in the exponential phase (Figure 7).

4.3 Late stationary phase

The late stationary phase of our experiment is characterized by minor fluctuations in cell density and pH values (pH ~ 11) (Figure 1A-B). The overall trend shows that cells continued to produce more EPS, reaching a maximum concentration of one order of magnitude greater (twelve times higher) than in the exponential phase (Figure 2, Table 2). When raised to the cell-specific EPS production (in mg cells⁻¹), this ratio is about seven. As mentioned above, we assume that the continuous increase in EPS production over the late stationary phase, including an overall augmentation of negatively charged functional groups (Figure 4, lanes 6-7), including GAG content (Table 2), might be a specific response to a stress scenario. As expected, the present study shows that the greater amount of negatively charged functional groups of EPS from the late stationary phase (Figure 4, lanes 6-7) resulted in a higher Ca-binding capacity than exponential and early stationary phase-EPS (Figure 5C). Our forced precipitation experiments showed that minerals produced in the late stationary-EPS solutions are smaller and more abundant than those formed in EPS solutions from the early stationary phase (Figure 7). Under natural conditions, when the Ca²⁺ supply is continuous, the crystals may or may not continue to grow, depending on the physical space within the EPS matrix (Dupraz et al., 2009). Based on the high concentration of nitrate (4720 µM) measured in the late stationary phase (Table 1), we assume that the abundance of this nutrient supported the persistence of the stationary phase, i.e., similar to a prolonged bloom in natural conditions. The death phase was not observed in our 56-day-long experiment. Given that our cultures were continuously stirred, we can assume that light was not limiting cyanobacterial growth. Furthermore, in natural blooms, the increase in population density may affect cells at greater depth through self-shading by decreasing the light available for photosynthesis (Townsend et al., 1994). Yet, cyanobacteria (including Synechococcus) are known to be well-adapted to low-light conditions (Campbell and Carpenter, 1986; Palenik, 2001; Callieri et al., 2011). Additionally, the presence of sulfated constituents on late stationary phase-EPS contributes to a higher negative charge of the matrix and higher Ca-binding potential (Decho and Kawaguchi, 2003; Braissant et al., 2007; Dupraz et al., 2009; Skog et al., 2022), compared to EPS extracted in the exponential phase which contained significantly lower GAG (Table 2). The present study shows that the greater amount of negatively charged functional groups of EPS from the late stationary phase (Figure 4, lanes 6-7) resulted in a higher Ca-binding capacity than exponential and early stationary phase-EPS (Figure 5C). Our forced precipitation experiments showed that minerals produced in the late stationary-EPS solutions are smaller and more abundant than those formed in EPS solutions from the early stationary phase (Figure 7), suggesting an increased inhibitory ability of the late stationary-EPS.

4.4 Natural bloom and formation of whittings – Conceptual model

Our observations made during exponential and stationary phases can be applied to generate a conceptual model of EPS properties during a bloom event (Figure 8A-C). The onset of a bloom starts with an increase in cell numbers, with high values in spring-summer (exceeding 10⁵-10⁷ cells.mL⁻¹) and lower values in winter months (< 10⁵ cells.mL⁻¹) in both marine (Agawin et al., 1998; Phillips et al., 1999) and freshwater (Maeda et al., 1992; Tai and Palenik, 2009) environments. This resembles the exponential growth phase in our study (Figure 1, exponential phase). We predict that during the initial phase of a natural bloom, there is little EPS production: cells grow relatively quickly and the carbon fixed during photosynthesis is predominantly allocated to biomass production (Figure 8A). The fast growth is followed by a phase during which cell numbers level off, typically due to stress conditions, which is represented by the early stationary phase in our study. Under certain conditions, blooms can be sustained for weeks and possibly longer (Anderson et al., 2002; Havens, 2008; Zhao et al., 2013), similar to what we observed in our growth experiments (Figure 1A, early stationary phase). The maintenance of a bloom requires continuous input of nutrients, which is also the case in our experiment (Table 1) or in the case of natural systems, a turnover from lysing cells recycled by other microbes. During this phase, we did not observe a significant increase in cell density but the production of EPS continued at a disproportionately high rate (Figure 8B-C). Our findings are in agreement with the studies using diatom cultures which show that EPS production is low during exponential growth and increases in the stationary phase (Myklestad and Haug, 1972; Myklestad et al., 1989; Bhosle et al., 1995). These authors reported that nutrient-deficient conditions enhanced the production of EPS over the growth phases. If carbon fixation continues and some critically required nutrient is lacking from the growth medium, most likely the phototrophic organisms produce carbohydrate reservoirs (Cebiada et al., 2020). These include storage polymers like glycogen and the production of other carbohydrate-rich compounds, including EPS (De Philippis et al., 1996, 1998, 2001; Decho and Gutierrez, 2017). The decline of blooms in natural environments is typically associated with nutrient, low or high light intensity, grazing or viral infection. Under these stressful conditions, an increase in EPS production by the phytoplankton community may be expected.

Cyanobacterial blooms, including those of Synechococcus spp., can produce the so-called whiting events (Thompson and Ferris, 1998; Thompson et al., 1990; Robbins and Blackwellder, 1992; Schulz-Lam et al., 1992; Thompson, 2008). A whiting is defined as the occurrence of a large number of CaCO₃ minerals in surface water (Strong and Eadie, 1976). These often large-scale carbonate precipitation phenomena have been observed from space (Robbins et al., 1997; Diemont et al., 2010). The source and cause of whiting formation have been widely debated over the past decades and several biotic and physicochemical mechanisms have been proposed (Shinn and Stein, 1989; Larson and Mylroie, 2014). The most accepted mechanisms include chemical/spontaneous precipitation (Brunskill, 1969; Broecker et al., 2000), physical disturbance and resuspension of carbonate sediments (Hoss and Neumann, 1993; Broecker et al., 2000; Morse et al., 2003) and biologically-mediated CaCO₃ precipitation as a result of photophysiological activity of picoplankton and phytoplankton community (Thompson and Ferris, 1998; Robbins and Blackwellder, 1992; Schulz-Lam et al., 1992; Robbins et al., 1997; Thompson, 2000). However, the role of EPS in massive CaCO₃ production has been poorly investigated (Stanton et al., 2021). Carefully transporting the results from forced precipitation experiments to a whiting event, we suggest that early in the bloom (Figure 8A), relatively large CaCO₃ crystals form, provided sufficient Ca²⁺ is available (Figure 8D). As the bloom continues to grow, progressively the larger quantity of negatively charged
functional groups in the EPS provides more cation-binding sites and thus inhibits calcium carbonate precipitation to a greater extent. Depending on the three-dimensional structure of the EPS and surface properties (Wang et al., 2012), nucleation may yield smaller CaCO$_3$ crystals (Figure 8). If this occurs, then the production of a more negatively charged matrix (largely contributed by the enrichment in sulfated polysaccharides) may offer some selective advantage to the cyanobacteria population, by inhibiting and/or delaying mineral precipitation and by reducing crystal size formed around the cells. This might result in slow sinking rates, extending the residence time of the cyanobacterial community in the photic zone. If the bloom occurrence is short (e.g., similar to 14-28 days in our growth experiment), minerals making up the whiting will be relatively larger. Consequently, the aggregates of cyanobacteria, EPS and CaCO$_3$ minerals may sink faster because mineral precipitation in EPS increases the cyanobacterial-specific density several-fold. The Synechococcus specific density ($\rho$) is 1.040 g cm$^{-3}$ (Reynolds, 1987), near-neutrally buoyant, whereas $\rho_{\text{CaCO}_3}$ is 2.710 g cm$^{-3}$ (Lange, 1999). The production of larger amounts of more negatively charged EPS may act as a protection mechanism against carbonate formation in the vicinity of the cell wall (Martínez et al., 2010; Bundleva et al., 2012), thus allowing the organisms to reside longer in the photic zone. Interestingly, the production of EPS that contained sulfated groups among bacteria seems to be exclusive to cyanobacteria (Pereira et al., 2009; Maeda et al., 2021). Maeda et al. (2021) reported that the cyanobacterium Synechocystis 6803 produced large amounts of GAG compounds during an experimental bloom formation. The authors suggested that these constituents can be advantageous for the development of surface bloom as it may increase the buoyancy, permitting cells to migrate upward rapidly when the water column is stable (Walshby et al., 1995). Thus, GAG production may be considered as an alternative for organisms that lack gas vesicles to remain longer in the photic zone (Maeda et al., 2021). The negative charge of EPS produced containing high sulfated content also protects the community against viral infection (Matsumaga et al., 1996). Therefore, the production of GAG by pelagic cyanobacteria contributes to stress tolerance and viral infectivity, helping in the persistence of bloom. In our growth experiments, a decline in cell numbers was not observed, which would represent the end of the bloom. In the natural environment, nutrient depletion, grazing or viral lysis/infection are the most likely causes of terminating a bloom (Gons et al., 2002). The cell lysis releases organic matter, which supports the growth of heterotrophic bacteria (Kjelleberg et al., 1987; Hagiwara et al., 1988; Kieft et al., 2021). Photosynthetically derived organic carbon is one of the major carbon and energy sources for heterotrophs (Allgayer et al., 2008). These heterotrophs can degrade EPS and liberate bound Ca$^2+$ (Visscher et al. 1998; Arp et al., 2003; Duprez et al., 2004; Braissant et al. 2009; Ionescu et al., 2015; Diaz et al. 2017). In addition, microbial respiration will produce HCO$_3^-$/CO$_3^{2-}$, increasing the saturation index of CaCO$_3$, and may enhance the whiting (Figure 8). Although our model is [somewhat] largely theoretical at this stage, its merit is to focus on an overlooked actor of whiting events, the EPS. Furthermore, it provides a conceptual framework to work with, for designing novel experiments and measurements both in natural systems and at the lab bench, to validate the molecular mechanisms involved in microbial bloom associated CaCO$_3$ formation in marine and lacustrine models.
