Abstract. Uniquely long datasets, spanning 1750-2100, of daily output from two fully coupled CMIP6 Earth System Models, EC-Earth3-CC and NorESM2-LM, have been used to investigate the historical and future (under SSP5-8.5 scenario) evolution of marine net primary production and its phenology in a North Atlantic region (30-60°N). We compared the data to estimates of net primary production (NPP). Changes in the day of peak Net Primary Production in the North Atlantic (25-65°N) are here identified in daily data from two fully coupled CMIP6 Earth System Models, EC-Earth3-CC and NorESM2-LM, for the period 1750-2100 (under SSP5-8.5 scenario). The majority of the region displays the largest change point in the day of peak NPP occurring after the year 2000 indicating a shift towards earlier peak NPP with the most change occurring in the northern parts of the domain. We compared the ESM data of NPP to estimates derived from the CAFE satellite data and found significant differences between the Earth System Model simulations and the CAFE model. The low spatial resolution of the earth system models can explain much of such difference dataset. However, the two models well represent both the magnitude of peak NPP and the seasonal cycles. The daily output made it possible to detect change points in peak NPP. Two major change points in peak NPP, of an amplitude not present in the PI-Control or the historical simulation, were detected in both Earth System Models in the first decade of the 21st century. The results clearly indicate a shift towards an earlier peak NPP with a clear inflection point in the beginning of the 21st century, at the end of the historical simulation. Furthermore, the occurrence of the first day with MLD shallower than 40 m shows positive correlation with the occurrence of the day of peak NPP for most of the domain and, similar to the day of peak NPP, displays the largest change points occurring around or after the year 2000. The early timing of the detected shifts in both models suggests that similar shifts could already have been initiated or could start in the near future. This highlights the need for long term monitoring campaigns in the North Atlantic.

30 1 Introduction

31 Net Primary Production (NPP) is the [net](#) rate of photosynthetic carbon fixation. In the ocean, ~~primary production~~NPP is
32 performed by microscopic planktonic phototrophs with a turnover time of about one week. Though the individual plankton
33 are small, the total marine ~~primary production~~NPP almost equals its terrestrial counterpart with an estimated size of marine
34 NPP on the order of 50GtC/yr (eg. Kulk et al., 2020, Westberry et al., 2008, Silsbe et al., 2016, Carr et al., 2006). NPP
35 constitutes the basis of the food chain—and provides the energy for higher trophic levels. Changes in NPP thus affect the
36 entire ecosystem and ultimately fisheries and human food supply (Stock et al., 2017).—In addition, ~~primary production~~NPP
37 is the first step in the biological carbon pump, a set of processes by which carbon is exported from the surface to the deep
38 ocean through the sinking of organic matter. Understanding how the ~~primary production~~NPP and the subsequent export of
39 organic carbon from the euphotic zone will change in future climate is thus vital for evaluating future uptake of atmospheric
40 carbon dioxide (Honjo et al., 2014).

41
42 The north Atlantic is a region of particular importance for carbon sequestration in the deep ocean (Goris et al. 2018; Baker et
43 al., 2022). This region contributes about 0.55-1.94 GtC/yr (Sanders et al. 2014) to the global export production, estimated to
44 be 4-12 GtC/yr (de Vries and Weber, 2017). Moreover, here, cold water increases CO₂ solubility and deep mixing and
45 subduction—in the subpolar portion of this area result in a net transport of carbon to depth, a combination of processes
46 known as—the solubility carbon pump.—

47
48 NPP is affected by climate variability through precipitation, wind patterns, temperature and light and is thus projected to
49 change with anthropogenic climate change ([Laufkötter et al., 2015](#); [Pearl et al., 1999](#); [Myriokefalitakis et al., 2020](#)). Though
50 an increase in temperature may enhance the growth rate of phytoplankton and thereby the [net](#) primary production, global
51 NPP is projected to decrease (Behrenfeld et al., 2006; Steinacher et al., 2010; Bopp et al., 2013) though the uncertainty
52 displayed in state-of-the-art Earth system Models (ESMs) is very large (Kwiatkowski et al., 2020). A projected NPP decline
53 is often explained as being caused by increased water column stability that decreases the amount of nutrients available for
54 primary production (Behrenfeld et al., 2006; Steinacher et al., 2010) but processes such as retreat of sea ice and increased
55 stratification in high latitudes reduces the light limitation leading to NPP increases (Kwiatkowski et al., 2020).

56
57 Efforts have been made to estimate how NPP has already changed in the historical satellite record but the limited range of
58 satellite time-series makes such endeavors difficult. Estimates range from -2.1% per decade over the period 1998-2015
59 (Gregg and Rousseaux, 2019) to no significant change (Kulk et al., 2020).

60
61 ~~Apart from changes in total NPP, changes in seasonality and the timing of algae blooms can occur along with climate change~~
62 ~~with cascading effects into higher trophic levels up to fisheries and marine mammals. Depending on the onset of thermal~~

63 stratification, the spring bloom may start earlier in the year causing a shift that may change the functioning and phenology of
64 the entire ecosystem (Yamaguchi et al., 2022). The seasonal cycle of phytoplankton blooms has been explained with various
65 theories. An often cited theory is the Critical Depth Hypothesis (Sverdrup, 1953) which postulates that a bloom can occur
66 when the mixed layer has shoaled to a critical depth where the light limited gross production outweighs respiration. It does
67 not, however, give an explanation as to when a bloom starts and ends. A more recent theory, termed the Disturbance
68 Recovery Theory, of the timing of blooms was given by Behrenfeld (2010) (see also Behrenfeld and Boss, 2018). The theory
69 suggests a balance between the growth and the loss in terms of respiration, grazing and disturbances to the physical
70 environment such as the depth of the mixed layer. Other theories include Smyth et al. (2014) that relates the seasonality to
71 the shift between negative and positive net heat flux.

72 Changes in seasonality and the timing of algal blooms can occur along with climate change with cascading effects into
73 higher trophic levels up to fish and marine mammals. Changes in the phenology, or the timing of recurring biological events,
74 of phytoplankton blooms due to climate change have already been observed in the North Sea with the Continuous Plankton
75 Recorder (CPR) since 1960, with data displaying a significantly earlier onset of the spring bloom (Chivers et al. 2020). A
76 phenological change in phytoplankton blooms will affect zooplankton and larvae as the timing of available food resources
77 will change, an effect known as the match/mismatch hypothesis (Cushing, 1990, Durant et al., 2007).

78 The suggested causes of phenological shifts range from bottom up controls, including thermal stratification occurring earlier
79 in the year allowing for an earlier bloom initiation, to top down controls resulting from changes in zooplankton grazing
80 pressure (Yamaguchi et al., 2022).

81 Henson et al. (2013) used historical simulations from six ESMs covering the years 1985-2009 and a high emission future
82 scenario (RCP8.5) to study changes in the primary production NPP phenology. They found a shift towards an earlier peak
83 NPP for most areas around the globe. However, the monthly resolution of the CMIP5 data dampens the phenology signal
84 considerably. In a more recent study, Henson et al. (2018) used higher frequency model output to investigate the effect of
85 temporal resolution on results of phytoplankton phenology. They found that in order to detect long term trends in bloom
86 timing, a maximum temporal resolution of not more than 20 days is required.

87
88 However, even though a 20-day resolution may be adequate to detect long term trends, it is certainly not enough for
89 detecting the timing of a rapid change in phenology in the course of global warming. In this paper, we use a uniquely long
90 time series of daily output from two ESMs that contributed to the 6th Coupled Model Intercomparison Project (Eyring et al.,
91 2016), to investigate the evolution of oceanic net primary production and its phenology in a region 30-60° N, 67° W-9° E 25-
92 65° N in the North Atlantic in the period 1750-2100. We Furthermore, we divide the region into biogeochemical provinces
93 (Longhurst et al., 1995) in order to see how localities with similar biogeochemical functioning differ across the region. We
94 then investigate the occurrence of major changes change points in the time-series of the day of peak NPP using change point
95 analysis for the different provinces using change point analysis. Furthermore, we investigate the cross-correlation between
96 the day of mixed layer depth shallower than a certain limit (here arbitrarily taken to be 40 m) and the day of peak NPP. We

97 | also investigate the largest change points in the day of the mixed layer shoaling above the limit. The cross-correlation
98 | analysis is complementary to the change point analysis and highlights at which leads and lags, the timing of mixed layer
99 | shoaling and peak NPP are covariant in the different regions.

100 | **2 Method**

101 | Daily output of vertically integrated net primary production has been produced using NorESM2-LM and EC-Earth3-CC for
102 | 100 years pi-control, historical (1850-2014) and the very high emission scenario SSP5-8.5 (2015-2100, Kriegler et al., 2017).
103 | All runs are forced with prescribed atmospheric CO₂ concentrations (concentration driven) in accordance with Meinshausen
104 | et al., 2020. The models are described in section 2.1. Section 2.2 describes the observational data set and section 2.3 provides
105 | an overview of the change point analysis method used. The phenological indicator that we have used is the day of peak NPP
106 | which is calculated as a simple max of NPP. This is a well defined metric that is robust unless for bimodal distributions with
107 | two peaks of similar size, which was not found in our data. The metric has previously been used in eg. Nissen and Vogt
108 | (2021) and Henson et al. (2013).

109 | The mixed layer depths used for the analysis are calculated differently in the two ESMs. In EC-Earth3-CC we have used the
110 | turbocline depth as a mixed layer depth proxy calculated with a turbulent mixing coefficient criterion of 5cm²/s while in
111 | NorESM2-LM the mixed layer depth has been calculated in accordance with the criterion of de Boyer Montégut et al. (2004)
112 | and with a density difference of 0.03 kg/m³.

113 | **2.1 Models**

114 | **2.1.1 EC-Earth3-CC**

115 | EC-Earth3 is an ESM developed by a European consortium of institutes and universities (Döscher et al. 2022). It is available
116 | in several different configurations. For this work, we have used EC-Earth3-CC which consists of the Integrated Forecast
117 | System (IFS) CY36R4 of the European Centre for Medium-Range Weather Forecasts (ECMWF) for simulating physics of
118 | the atmosphere and land surface, ~~Nemo3.6~~NEMO3.6 (Madec, 2015) for ocean physics, LPJ-Guess (Smith et al., 2014) for
119 | terrestrial vegetation and PISCES (Aumont et al., 2015) for ocean biogeochemistry. In concentration driven form, PISCES is
120 | fed a spatially uniform atmospheric pCO₂ while a CO₂ mapping occurs within IFS to account for regional heterogeneities.

121 |

123 | PISCES is a mixed Monod-quota model simulating two different phytoplankton functional types, diatoms and
124 | nanophytoplankton, two size classes of zoo-plankton, micro and meso, and nutrients nitrate, ammonium, phosphate, iron and
125 | silicate. Iron and silicate are modeled using quotas in phytoplankton and the other nutrients with fixed Redfield ratios.
126 | Phytoplankton growth depends on the external concentration in nutrients, light and temperature. PISCES is suited for a wide
127 | range of spatial and temporal scales, including quasi-steady state simulations on the global scale. PISCES further simulates

128 | the carbon system, as well as dissolved and particulate organic matter. [PrimaryNet_primary](#) production is the growth of
129 | phytoplankton thus the term excludes mortality, excretion and grazing. The integrated [net](#) primary productivity used for the
130 | analysis is integrated over the water column and also summed over the two different phytoplankton functional types.

131 |

133 | PISCES has been used and validated in a number of settings (Ramirez-romero et al., 2020; Gutknecht et al., 2019;
134 | Kwiatkowski et al., 2018). Skyllas et al. (2019) validated EC-Earth3, in an offline ocean only NEMO-PISCES version, for [a](#)
135 | [north-south \(29-63oN\) transect in](#) the North-west Atlantic using cruise data of temperature, salinity and nutrients and
136 | chlorophyll-a and found a good agreement with observations. [PrimaryNet_primary](#) production has not previously been
137 | validated for EC-Earth3-CC although the air-sea CO₂ flux, which is strongly affected by [net](#) primary production, was
138 | compared to an observation based climatology in Döscher et al. (2022). Their results showed stronger uptake of CO₂ than
139 | observations in the North Atlantic, thought to be caused by too active convection in the Labrador Sea.

140 |

142 | **2.1.2 NorESM2-LM**

143 | The Norwegian Earth System Model NorESM2 (Seland et al., 2020, Tjiputra et al, 2020) is a fully coupled ESM, which is
144 | based on the Community Earth System Model version 2 (CESM2, Danabasoglu et al. 2020) but employs a different ocean
145 | component (the Bergen Layered Ocean Model, BLOM) and a modified atmosphere model (CAM6-Nor). The land surface
146 | and terrestrial biogeochemistry is represented by the Community Land Model version 5 (CLM5). BLOM uses isopycnic
147 | coordinates in the vertical (below a bulk mixed layer represented by two non-isopycnic model layers on top) and it includes
148 | the iHAMOCC model to represent ocean biogeochemistry. BLOM is coupled to the sea-ice component CICE5, which is the
149 | same as in CESM2.- The LM version of NorESM2 used in this study has an atmosphere-land resolution of **2o** and a nominal
150 | ocean model resolution of **1o**. iHAMOCC is derived from the HAMOCC model (Six and Maier-Reimer, 1996; Ilyina et al.
151 | 2013) and was adapted for the use with isopycnic coordinates by Assman et al.(2010). HAMOCC includes- a relatively
152 | simple NPZD ecosystem model with one phytoplankton and one zooplankton compartment and an implicit representation of
153 | calcifying and silicifying organisms. The model simulates nitrogen and phosphorus nutrients as well as dissolved iron with
154 | phytoplankton nutrient uptake according to Redfield molar ratios.

155 | [The growth of phytoplankton is further affected by light as well as temperature.](#)

156 |

158 | NorESM2-LM has been validated with regards to biogeochemical variables including net primary production in Tjiputra et
159 | al. (2020). The results show a seasonal cycle of marine NPP that is reasonably well captured in amplitude but with a too low
160 | annual mean.

161 | 2.2 Observations

163 | 2.2 Satellite based data - The CAFE model

164 | Direct observational data records of net primary production are scarce and in order to validate the two ESMS with respect to
165 | NPP, we have chosen to use data from a satellite based approach. There are several different methods for deriving total water
166 | column NPP estimates from satellite data. Often they are either based on ocean color (Behrenfeld and Falkowski, 1997),
167 | carbon (Westberry et al., 2008) or absorption (Smyth et al., 2005).

168 |

169 |

171 | In this work, we use data from the Carbon, Absorption and Fluorescence Euphotic-resolving (CAFE) model (Silsbe et al.
172 | 2016), freely available through the Ocean Productivity site
173 | (<http://sites.science.oregonstate.edu/ocean.productivity/index.php>). The model utilizes satellite derived properties and has
174 | been shown to compare well to in situ observations (Johnson and Bif, 2021). We here utilize the ModisMODIS-aqua dataset
175 | from 2002 to 2021.

176 | 2.3 Change point analysis

177 | ~~Change point detection is a method to identify abrupt change in a time-series.~~

179 | 2.3 Longhurst Provinces

180 | The seasonality of NPP depends on the physical characteristics of different ocean localities. In modelling the terrestrial
181 | environment, the division into regions of similar growth conditions such as boreal forest or savannah is well defined, while
182 | in the ocean, biological differences between regions exist but are more difficult to constrain (Sathyendranath et al., 1995).
183 | Division of the global ocean into biogeochemical provinces has been done in a number of references (Longhurst et al., 1995;
184 | Sathyendranath et al., 1995) with the object of determining the global or regional net primary production. Longhurst et al.
185 | (1995) made the static boundaries that we have used in this analysis (downloaded from: <https://www.marineregions.org/>).
186 | Although the boundaries in reality are shifting on seasonal and interannual time scales (Reygondeau et al., 2013), we have

187 | chosen to use the static boundaries as we then are able to compare the same localities in the two models and in the CAFE
188 | data. The North Atlantic is divided according to three main areas: Coastal, westerlies and polar which are further subdivided
189 | to give the regions shown in Fig. 1. Note that we have chosen not to include the entire Arctic basin causing the Arctic
190 | provinces to be cut off in the north. The boreal polar region (BPLR) is defined by the southward flowing Labrador current
191 | that continues northward along the Greenland coastline. The Atlantic Arctic region (ARCT) is defined by strong
192 | stratification caused by large inflow of meltwater while the Atlantic subarctic (SARC) is characterized by poleward flowing
193 | warm North Atlantic water. The west wind regions; Gulf Stream (GFST), North Atlantic Drift (NADR) and North West
194 | (NADW) and North East Atlantic sub polar gyre (NASE) are governed by westerly winds and a Sverdrup type circulation.
195 | We have also included the coastal region North west Atlantic continental shelf (NWCS).

196 | 2.4 Change point analysis

197 | Change point detection is a method to identify abrupt change in a time-series. Formally, the problem is to find the best
198 | possible segmentation of a signal according to some chosen criterion. Depending on this criterion one can look for changes
199 | in, for example, mean, variance, or a spectral characteristic of a given signal. In climate science, the method has been used to
200 | detect shifts in a wide variety of quantities (Beaulieu et al., 2012) such as AMOC strength (Smeed et al., 2018), coastal
201 | organic C sequestration (Watanabe et al., 2018), and cod stock (Möllmann et al., 2021). We have used change point
202 | detection to identify rapid change in the calendar-day of peak NPP. The calculations have been performed using the Python
203 | package Ruptures (Truong et al. 2020).

205 | Change

207 | Generally speaking, change point detection requires a search method ~~related to the number of change points, and a model~~
208 | ~~related to the type of change, a cost function and a constraint on the number of change points to detect. Search methods can~~
209 | ~~be either exact or approximate. Here we use a version of the former called optimal detection, as computational speed is not~~
210 | ~~an issue. Moreover, we use primarily the kernel based cost function and a constraint where we directly pick the number of~~
211 | ~~change points to find. Many methods of change point analysis, in fact, focus on finding a predetermined number of shifts in a~~
212 | ~~predefined quantity, such as the time series mean or variance (Truong et al., 2020). We have chosen to use the Pelt search~~
213 | ~~method developed by Killick et al. (2012). This method~~ Another option that ~~does not require the number of change points to~~
214 | be determined beforehand. ~~Instead, a penalty is defined that, is to instead use a penalty that~~ is related to the amplitude of
215 | the change of interest. A small penalty generates many change points, which may arise due to intra-annual variability or
216 | noise, while a large penalty instead only gives the largest, if any, changes in the time series. By choosing a large enough
217 | penalty, the number of change points can in this way be tuned.

218 | In the process of doing this research we have tested both approaches.

219 |

221 | Furthermore, instead of predefining the type of time series change, we have chosen to primarily use a kernel based non-
222 | parametric modelcost function developed by Arlot et al. (2013), in the following called “the kernel based modelcost
223 | function”. This model gives all can detect all sorts of changes in the probability distribution of the time-series; mean, variance
224 | and higher order changes such as skewskewness and kurtosis. The upside of this approach is that no large changes are
225 | missed. The downside is that the method does not, ~~however,~~ provide the information on which change point is related to
226 | what type of change. Therefore, we complement the method with analyses using the Least absolute deviation (L1) modelL1
227 | cost function that detects changes in the median and the Least squared deviation (L2L2) cost function that detects changes in
228 | the mean of the time-series.

229 | **3-Results and discussion**

230 | 3.1 Models vs observations Both of these are also available through the ruptures package and the search method used is the
231 | same as for the kernel based cost function.

232 | **3 Results**

233 | **3.1 ESMs vs CAFE**

234 | We have compared the daily ESM data with 8 day averaged NPP estimates from the CAFE data (Silsbe et al, 2016).
235 | Seasonal mean NPP over the MODIS-aqua period 2003-2021, for March, April, May (MAM), June, July, August (JJA) and
236 | September, October, November (SON) seasons are shown in Fig. 1. The figure shows large spatial differences between
237 | CAFE, EC-Earth3-CC and NorESM data. Most notably, EC-Earth3-CC shows a very strong primary production in MAM
238 | over the gulf stream region. We also see a tendency for stronger primary production in this region in the CAFE data,
239 | although the enhanced production is much more confined. The high resolution CAFE data show that the enhanced
240 | production occurs in the warm Gulf stream eddies. The low resolution of the ESMs gives a wider and less constrained warm
241 | water transport as a result of unresolved eddies.

242 |

243 | The NorESM results in the Gulf stream region are closer to the CAFE data, although the production in the northern part of
244 | the domain is underestimated in both ESMs. Both ESMs also fail to capture the strong JJA production in the northern part of
245 | the domain, between the Labrador current and the British Isles and do not represent the strong European coastal production
246 | seen in the CAFE data. For the the latter well compiled runoff nutrients and high resolution are required to represent coastal
247 | dynamics (Gröger et al., 2013; Sein et al., 2020).

248 |

249 Peak NPP over this period occurs in May in EC-Earth3-CC and in June in NorESM2-LM as can be seen in the seasonal
250 cycle in Fig. 2. The figure2. Note that the 2003-2021 period modelled by the ESMs is not the same period as that in the
251 observationally constrained CAFE model. The two ESMs are forced with greenhouse gas concentrations that are similar to
252 those for the period, but the internal variability of the climate system as modelled by the two ESMs is not in sync with that in
253 reality or with each other. The comparison that can be done is thus strictly climatological. Due to the smaller area seen by
254 satellites in winter, the CAFE data contains missing data over the winter months. In order to correctly compare the seasonal
255 cycles, the ESM data was bounded to the north by the maximum latitude present in the CAFE data (Fig. S1). This means that
256 not all data points to calculate a mean over the entire SON are present. The SON mean over the northern part of the domain
257 is thus biased towards September-October.

258

260 Figure 2 shows large spatial differences between CAFE, EC-Earth3-CC and NorESM2-LM data. Most notably, EC-Earth3-
261 CC shows a very strong NPP in MAM over the Gulf stream region. The high resolution CAFE data show that the enhanced
262 production occurs in the warm Gulf stream eddies while the low resolution of the ESMs gives a wider warm water transport.
263 The NorESM2-LM results in the Gulf stream region are closer to the CAFE data, although the production in the northern
264 part of the domain is underestimated in both ESMs.

265

267 Figure 3 shows the area mean seasonal cycle over the period 2003-2021 taken over all grid points in the domain, along with
268 standard deviations. Due to the smaller area seen by satellites in winter, the CAFE data contains missing data over the winter
269 months. In order to correctly compare the seasonal cycles, the ESM data was masked by the area covered by CAFE data in
270 Fig. 2.

271

272 The results indicate a reasonable agreement in the maximum and minimum size of primary production where EC-Earth3-CC
273 is closer in magnitude and NorESM2-LM closer in timing. The CAFE data does, however, show a significantly longer
274 season and the annual mean is therefore larger with $417 \text{ mgC m}^{-2} \text{ day}^{-1}$ compared to $359 \text{ mgC m}^{-2} \text{ day}^{-1}$ in EC-Earth3-CC
275 and $228 \text{ mgC m}^{-2} \text{ day}^{-1}$ in NorESM2-LM. A notable feature in Fig. 2 is the skewed shape of the EC-Earth3-CC seasonal
276 cycle. Where the observations and NorESM2-LM display a seasonality that appears almost normally distributed over the
277 year with a peak in June, EC-Earth3-CC primary production is shifted towards the earlier part of the year. It should be noted
278 that the higher resolution model version NorESM1-ME displayed a North Atlantic seasonal cycle of NPP similar to what is

279 | seen in EC-Earth3-CC (Tjiputra et al., 2020). Development targeting this behavior at high latitudes, with a too strong spring
280 | bloom and a too strong decline after the bloom, was performed in NorESM2 by generally increasing the grazing pressure
281 | during a bloom and by increasing the amount of nutrients incorporated into dissolved organic matter (Tjiputra et al., 2020 for
282 | the different provinces. Again, the data is bounded to the north by the extent of CAFE the data (Fig. S1). The size of the NPP
283 | peak is well captured by both ESMs with the notable exception of province GFST in EC-Earth3-CC. This strong GFST
284 | production in EC-Earth3-CC is clearly seen in Fig. 2. However, the CAFE data shows a flatter and wider peak which
285 | generates a higher mean NPP over the time period compared to both ESMs for all provinces except for GFST and NASW in
286 | EC-Earth3-CC (Tab. 1). It is also apparent from Fig. 3 that the timing of peak NPP differs between biogeochemical
287 | provinces and models (Tab. 1). In the CAFE data, the day of peak NPP occurs in day 164-178 (early to late June) in the
288 | northernmost provinces BPLR, ARCT, SARC and NADR while the subtropical gyres (NASW, NASE), GFST and NWCS
289 | generates an earlier peak NPP between day 114 (April 24) and day 130 (May 10). Similarly, in EC-Earth3-CC, the three
290 | arctic regions BPLR, ARCT and SARC display the latest peak NPP occurring from day 150 to day 166 (May 30 to June 15)
291 | while the peak NPP in NADR occurs earlier compared to CAFE (day 124, May 4). The earliest peak NPP occurs in NASE
292 | on day 83 (March 24). As in the CAFE data, the earliest peak NPP in NorESM2-LM occurs in NASW (April 26, day 116
293 | compared to April 24 in CAFE) while the latest occurs in NWCS (day 186, July 5). In NorESM, the three arctic regions
294 | display a day of peak NPP of 159 (June 8) for BPLR, 161 (June 10) for ARCT, and 176 (June 25) for SARC. NASE and
295 | GFST have a day of peak NPP of 138 (May 18) and 148 (May 28) respectively. In general, EC-Earth3-CC is closer to the
296 | CAFE data in size but NorESM2-LM is closer in timing (Tab. 1).

297 |

299 | **3.2 Historical and future primary production NPP**
300 | **The time-series of annual mean NPP for the different biogeochemical provinces from 100 years of pi-control, historical**
301 | **and SSP5-8.5 are shown in Fig. 34 for EC-Earth3-CC, NorESM2-LM along with the annual mean CAFE data for the**
302 | **period 2003-2021.**

303 |

304 | **The figure reveals a large interannual and multidecadal variability in EC-Earth3-CC compared to NorESM2-LM. The**
305 | **CAFE data seems to display an even larger long term variability although the limited length of the timeseries makes**
306 | **comparisons of multidecadal variability problematic. The small interannual variability in NorESM2-LM also makes it easier**
307 | **to visually discern the declining trend in NPP over the later part of SSP5-8.5**

308 For most provinces, EC-Earth3-CC generates higher annual mean NPP than NorESM2-LM, with the exception of BPLR and
309 NASE. For BPLR, the mean for the entire period (not shown) is 110 mgC/m²/day for EC-Earth3-CC and 112 mgC/m²/day
310 for NorESM2-LM and for NASE 314mgC/m²/day for EC-Earth3-CC compared to 321mgC/m²/day for NorESM2-LM. The
311 largest difference between the two models is seen in GFST, where EC-Earth3-CC generates a time-series mean of 640
312 mgC/m²/day compared to 282 mgC/m²/day in NorESM2-LM. The highest NPP in NorESM2-LM is instead found in NASE.

313

315 ~~The seasonal cycle of primary production over historical and SSP5-8.5 (1850 to 2100) for the two models are shown in Fig.~~
316 ~~4. Both models show a decline in primary production over SSP5-8.5 although the decline is concentrated around the time of~~
317 ~~the NPP peak in NorEMS2-LM while it is more pronounced and more equally distributed over the seasonal cycle in EC-~~
318 ~~Earth3-CC. Note, however, that the reduction in NPP in EC-Earth3-CC displayed in Fig 4. is not much larger than~~
319 ~~multidecadal NPP variability seen in earlier periods of the NPP time series (cf. Fig. 3) which makes it difficult to attribute~~
320 ~~the decline to climate change. Moreover, the figure reveals a shift in phenology towards an earlier~~
321 ~~entire period is in EC-Earth3-CC between 23.8 mgC/m²/day and 71.6 mgC/m²/day depending on the province (not shown).~~
322 ~~The largest standard deviation is found in NASE and the lowest in NWCS. In contrast, the standard deviation in NorESM2-~~
323 ~~LM is between 9.17 mgC/m²/day and 22.0 mgC/m²/day with, similar to EC-Earth3-CC, the largest found in NASE and the~~
324 ~~lowest in NWCS.~~

325

327 In order to find how the NPP and the timing of peak NPP has changed over the time-series, we have compared the last 30 yr
328 period of SSP5-8.5 (2070-2099) to the first 30 yr period of the historical simulation (1850-1879). The results are summarized
329 in Tab. 2. EC-Earth3-CC shows an increased NPP for most provinces with the exception of NADR and NASE where the
330 NPP is lower in the late period compared to the early historical period. In addition to those provinces, NorESM2-LM display
331 decreased NPP also for NASW and SARC. The day of the year of **peak NPP** evidentdecreases **for all regions except one in**
332 **both EC-Earth3-CC (NASE) and NorESM2-LM:**

333

334 in order to (GFST).

335

337 **To further find how the shift in phenology is distributed over the region, the spatial distribution of the day of peak**
338 **NPP averaged over the 30 year period 1850-1879 for the two ESMs is shown in Fig 5. Also shown in the figure is the**
339 **difference of the ESM results averaged over the period 1970-1999/1985-2014 and 2070-2099 from the early period**
340 **1850-1879. In the early period, 1850-1879, EC-Earth3-CC displays both ESMs displayed a pattern of later bloom in the**
341 **Labrador Sea/northern parts compared to the rest of the domain, while NorESM2-LM has a later peak NPP south of**
342 **Greenland and in the Gulf stream area compared to the rest of the domain. Both models show an earlier peak NPP in the**
343 **southernmost part compared to the rest of the region. For EC-Earth3-CC, this is most notable in the Labrador Sea while in**
344 **NorESM2-LM, the later bloom is also visible in the Gulfstream and the northwest continental shelf area (NWCS).**

345

347 **The period 1970-1979/1985-2014 shows small and scattered differences from the early period. In the late period, 2070-**
348 **2099, most of the domain experience/experienced an earlier peak NPP but with some notable exceptions. Parts of the**
349 **Gulf stream region display a markedly later peak NPP in the NorESM2-LM data compared to the early period, 1850-**
350 **1879. This corresponds to an expansion of the pattern of late peak NPP in the Gulf stream region seen in the early**
351 **period. Averaged over the entire domain, peak NPP is only one day earlier in the period 2070-2099 (day 125) compared to**
352 **1850-1879 (day 126) in NorESM2-LM. The standard deviation of the mean difference between these two periods is,**
353 **however, 30.7 days which underscores the heterogeneous pattern in the day peak NPP over the region.**

354

355 **In EC-Earth3-CC the pattern of earlier peak NPP is more robust over the domain but with the southernmost part displaying a**
356 **later peak NPP in the late period, 2070-2099. The region corresponds to data points with very early peak NPP in the period**
357 **1850-1879. A notable feature is the much later bloom west of the Strait of Gibraltar. NPP in this region is greatly reduced in**
358 **the late period compared to 1850-1879 caused by a strong reduction in winter surface nitrate concentration (not shown). The**
359 **NPP seasonality in this area shifts from a clear spring peak to an extended period of weak NPP (not shown). The peak is**
360 **therefore less well defined and located later in the year. Averaged over the entire domain, EC-Earth3-CC displays an earlier**

361 | peak NPP by 10.7 days in the period 2070-2099 (day 109) compared to the early period (day 120) with a regional standard
362 | deviation of 32.8 days which is similar in magnitude to the standard deviation of 30.7 days in the

363 |

365 | In EC-Earth3-CC, the pattern of earlier peak NPP in the final 30 yrs of SSP5-8.5 is widespread over the domain although a
366 | notable feature is the much later bloom in NASE (27 days on average, Tab. 2). The size of NPP in this region was greatly
367 | reduced in 2070-2099 compared to 1850-1879 (-86.6 mgC/m²/day, Tab. 2) caused by a strong reduction in winter surface
368 | nitrate concentration (not shown). The NPP seasonality in this area shifts from a clear spring peak to an extended period of
369 | weak NPP (not shown) with peak NPP therefore occurring later in the year. Also shown in Fig. 5 is the deviation of the late
370 | period from the 1850-1879 mean divided by the standard deviation of the PI-control in each grid cell which gives a measure
371 | of the significance of the late period change. The results show large significance in the northern parts of the domain.

372 |

374 | Averaging over the different provinces allows us to look at the mean change in the day of peak NPP as well as identify
375 | change points. Fig. 6 shows the time-series of the day of peak NPP averaged over the different provinces together with the
376 | largest (cf. Fig. S2 for the largest change points using the PELT search method). In EC-Earth3-CC, the largest change point
377 | occurs between 2002 (BPLR and ARCT) and 2066 (NASE) for all regions except NASW where the largest change point
378 | occurs the year 1900. Note also that NASW is the province with the least change over the time period (Tab. 2). In
379 | NorESM2-LM, the largest change point is in general located later, between 2010 (NASW) and 2082 (NASE). When
380 | increasing to two change points, the pattern of most change occurring after the year 2000 is maintained with few change
381 | points occurring earlier (Fig. 6). Also shown in the figure is the largest change point found by the L1 and L2 cost function
382 | that indicates changes in the median and mean respectively. The results show that the L1, L2 and the kernel based cost
383 | function gives almost the same results for almost all provinces. The most discrepancy is found in NASW in EC-Earth3-CC
384 | which is also the region displaying the least change.

385 |

387 Fig. 7 shows the first day of the year at which the spatial mean Mixed Layer Depth (MLD) shoals to 40 m or shallower in
388 each province. Similar to the results of the day of peak NPP (Fig. 6), the day of MLD shallower than 40 m occurs
389 progressively earlier over SSP5-8.5 for most provinces and for both EC-Earth3-CC and NorESM2-LM-results. The largest
390 shifts towards earlier peak NPP are seen in the Labrador sea in EC-Earth3-CC and south of Greenland in NorESM2-LM.

391 |
392 The earlier bloom displayed in our results is in agreement with Asch et al. (2019) who showed that blooms north of 40°N
393 shifted earlier under RCP8.5 using 5 daily output from GFDL ESM2M including the biogeochemical model TOPAZ2.0. In
394 contrast, Henson et al. (2018) reports, using an ocean only model (MEDUSA-2.0, NEMO), a start of bloom shifting later in
395 the year under RCP8.5 in most parts of the North Atlantic. However, both studies relate to surface chlorophyll and not NPP,
396 which makes the comparison problematic. Moreover, our temporal resolution is higher and both Henson et al. (2018) and
397 Asch et al. (2019) use the start of bloom as well as length of bloom as a phenological indicators instead of the timing of the
398 annual peak which further complicates the comparison.

399 |
400 Averaging over the entire domain allows us to look at the mean phenology change of NPP. It also allows us to identify
401 change points in the mean phenology. Fig. 6 shows the time-series of the day of peak NPP averaged over the entire region.
402 The time-series shows a decline in the day of peak NPP for both models over the 21st century under SSP5-8.5 with the start
403 of the decline occurring at the end of the historical simulation. Fig. 6 also displays the change-points of the time-series,
404 found by the kernel based model, for three different choices of penalty, which is related to the amplitude of the probability
405 distribution change. The largest penalty is tuned so that only one major change point is found. This generates the most
406 important change point in the time-series. Inchange-point in the time-series (Tab. 3) occurs between 1997 (GFST) and 2067
407 (NASW) for EC-Earth3-CC and between 2025 (ARCT, NADR) and 2092 (NWCS) for NorESM2-LM. Increasing to two
408 change points, the pattern is consistent with most points located after the year 2000 (Fig. 7). Note that the choice of 40 m is
409 arbitrary. We have tested for other cut-off depths with similar results (Figs. S3-S5).

410 |

412 But how well do change points in the spatial mean day of peak NPP of the different provinces represent the separate grid
413 points? The year during which the largest change point for every grid point occurs is shown in Fig. 8. The results broadly
414 correspond to the results seen in the spatial mean time series with a major change point occurring after the year 2000. Few
415 grid points display a change point earlier than that. Note that many of the grid cells displaying change points early in the
416 time-series correspond to cells where the PELT search method could not find only one single change point (Fig. S6). This
417 points to the fact that in these grid points, little significant change occurs (cf. Fig 5. bottom panel). Furthermore, EC-Earth3-
418 CC displays an earlier major change point for most grid points as compared to NorESM2-LM. The northern part of the
419 domain, i.e. regions where the euphotic zone is more vigorously coupled to the deep sea by vertical mixing like the Labrador
420 Sea, northern North Atlantic and the sub-polar gyre, shows the earliest change point in the EC-Earth3-CC results close to the
421 year 2000. The south-eastern part of the domain displays the latest change point in both NorESM2-LM and EC-Earth3-CC.

422

424 To elucidate on the correlation between the day of MLD shallower than 40 m and the day of max NPP, the cross correlation
425 between the area averaged time-series shown in Figs. 6 and 7 has been plotted in Fig. 9. The figure shows a notable
426 correlation, well above the 95% confidence bound, between the two indices in most provinces for both ESMs. The maximum
427 correlation occurs for zero lag in most provinces, indicating, as expected, that peaks in these variables tend to occur within
428 the same year. Note that the strongest correlation for zero lag, at least in EC-Earth3-CC this occurs is seen in the year 2010
429 and in NorESM2-LM it instead occurs in 2070. Decreasing the penalty to find two change points generates a change point
430 also in the year 2095 in the EC-Earth3-CC data and in the year 2007 in NorESM2-LM.

431

432 To shed some light on the type of change occurring at the identified times, we complement the analysis by using the l1 and
433 l2 change point models that identify respectively changes in median and mean. We use the largest penalty such that the
434 search method only picks up the most important change-point in the time-series. The results show that both models l1 and l2
435 identify the 2010 change point found by the kernel based model in the EC-Earth3-CC data, while neither l1 or l2 identifies
436 the largest change point in NorESM2-LM found by the kernel based model. l1 comes closest to the 2070 change point in
437 NorESM2-LM. The mean shift occurring first west wind provinces, GFST, NADR, NADW and NASE that have a Sverdrup-
438 like circulation. These are also open ocean regions where mixed layers can be expected to be less constrained by freshwater

439 fluxes from land. Furthermore, a striking feature is the strong negative correlations found in the BPLR and ARCT provinces
440 in EC-Earth3-CC. Looking at Fig. 8 we find that the day of MLD shallower than 40 m, at least in the BPLR province, occurs
441 so early in the year that it can hardly affect the day of peak NPP. Thus, suggesting that the anti-correlation between these
442 variables is owing to a lurking variable affecting both NPP and MLD. The similar correlation structure between BPLR and
443 ARCT strongly suggests that the same is true about the ARCT province.

444

446 4. Discussion

447 The comparison between CAFE and the two ESMs showed that the size of peak NPP was well captured by the ESMs. The
448 regional difference in NPP is larger in the ESMs compared to the CAFE data which is evident by the difference in annual
449 mean between the provinces (Tab. 1). Peak NPP occurs latest in the year for the arctic provinces; BPLR, ARCT and SARC
450 in EC-Earth3-CC which corresponds well to the CAFE data (although peak NPP in NADR occurs later than BPLR in
451 CAFE).

452

454 The results showed that the most change in the day of peak NPP occurs **after the beginning of the 21st century** which is
455 **consistent with the results of Henson et al (2009), who found no long term trend in the subpolar north Atlantic**
456 **towards earlier or later blooms in model data spanning 1959-2004. The day of peak NPP averaged over the 50 years**
457 **before and after the 2010 change point reveals a reduction in the day of peak NPP of 12 days in EC-Earth3-CC and 10 days**
458 **in NorESM2-LM. Importantly, a major change point occurs in both ESMs at the end of the historical simulation. A shift**
459 **towards an earlier peak NPP thus occurs for both models before the onset of the future scenario simulation.**

460

461 But how well do change points in the spatial mean of the region represent the separate grid points? The year during which
462 the largest change point for every grid point occurs is shown in Fig. 7. The penalty has been tuned to catch only the single
463 largest change point. The results broadly correspond to the results seen in the spatial mean time series with a major change
464 point occurring after the year 2000. Few grid points display a change point earlier than that. Furthermore, EC-Earth3-CC
465 displays an earlier major change point for most grid points as compared to NorESM2-LM. The northern part of the domain,
466 i.e. regions where the euphotic zone is more vigorously coupled to the deep sea by vertical mixing like the Labrador Sea,

31
32

467 northern North Atlantic and the sub-polar gyre, shows the earliest change point in the EC-Earth3-CC results close to the year
468 2000. The south eastern part of the domain displays the latest change point in both NorESM2-LM and EC-Earth3-CC.

469
470 The seasonal cycle of phytoplankton blooms has been explained with various theories. An often cited theory is the Critical
471 Depth Hypothesis (Sverdrup, 1953) which postulates that a bloom can occur when the mixed layer has shoaled to a critical
472 depth where the light limited gross production outweighs respiration. It does not, however, give an explanation as to when a
473 bloom starts and ends. A more recent theory, termed the Disturbance Recovery Theory, of the timing of blooms was given
474 by Behrenfeld (2010) (see also Behrenfeld and Boss, 2018). The theory suggests a balance between the growth and the loss
475 in terms of respiration, grazing and disturbances to the physical environment such as the depth of the mixed layer. In Fig. 8,
476 we have plotted the first day of the year at which the spatial mean Mixed Layer Depth (MLD) shoals to 40m or less. The
477 results show that, like the day of max NPP, the day of MLD above 40m occurs progressively earlier over SSP5-8.5 for both
478 EC-Earth3-CC and NorESM2-LM. The most important change point in the day of MLD above 40m time-series found using
479 the kernel based model, occurs in 2030 in EC-Earth3-CC and in 2031 in NorESM2-LM. However, allowing for two change
480 points generates one change point in 1995 and one in 2045 for EC-Earth3-CC, and one in 2017 and one in 2061 for
481 NorESM2-LM. Although the change points in the day of MLD above 40m are not directly corresponding to the change
482 points found in the time series of the day of peak NPP (Fig. 6), the largest change points in the time series occur in the late
483 historical simulation and in SSP5-8.5 for both models. The choice of 40m is somewhat arbitrary. We have however tested for
484 change points on cut off depths between 25 and 80m with no difference to the results of the location of change points.

485
486 To elucidate on the correlation between the day of MLD above 40m and the day of max NPP, the cross correlation between
487 the area averaged time-series shown in Figs. 6 and 7 has been plotted in Fig. 9. The figure shows a notable correlation, well
488 above the 95% confidence bound, between the two indices for both ESMs. The maximum correlation occurs for zero lag,
489 indicating, as expected, that peaks in these variables tend to occur within the same year. The clearly declining correlations
490 with longer lags may reflect the low-frequency cycles controlled by the Atlantic multi-decadal variability which controls
491 environmental parameters on time scales > 60 years (e.g. Börgel et al. 2020).

492

493 | 4 Summary and conclusions

494 | Using uniquely long datasets of 350 years of daily output earlier bloom displayed for most provinces (Tab. 2) under SSP5-8.5
495 | is in agreement with Asch et al. (2019) who showed that blooms north of 40°N shifted earlier under RCP8.5 using 5 daily
496 | output from GFDL ESM2M including the biogeochemical model TOPAZ2.0. In contrast, Henson et al. (2018) reports, using
497 | an ocean only model (MEDUSA-2.0, NEMO), a start of bloom shifting later in the year under RCP8.5 in most parts of the
498 | North Atlantic. However, both studies relate to surface chlorophyll and not to NPP, which makes the comparison
499 | problematic. Although surface chlorophyll has the benefit of being easily validated to observations, it is not, in a simple
500 | manner connected to vertically integrated NPP. The chlorophyll maxima can be found below the surface (Cornec et al.,
501 | 2021) and the relationship between the surface concentration and the subsurface profile differs between different localities
502 | (Sathyendranath et al., 1995). The seasonality of peak NPP is therefore not necessarily directly relatable to the seasonality of
503 | surface chlorophyll. Moreover, our temporal resolution is higher and both Henson et al. (2018) and Asch et al. (2019) use the
504 | start of bloom as well as length of bloom as a phenological indicator instead of the timing of the annual peak which further
505 | complicates the comparison.

506 |

508 | The change-point analysis revealed that the largest change points in the day of peak NPP occur in most provinces after the
509 | year 2000 in both ESMs (Tab. 3, Fig. 6). A noteworthy observation is that very few change points occur in the latter part of
510 | the 21st century even though it is then that the warming in the SSP5-8.5 is the greatest. In EC-Earth3-CC many change
511 | points occur already in the historical simulation, while in NorESM2-LM they tend to occur in the middle of the 21st century,
512 | at a point when the very high emission scenario SSP5-8.5 has just started to diverge from the more moderate emission
513 | scenarios in terms of global mean surface temperature (IPCC, 2022). Change points occur earlier in EC-Earth3-CC than in
514 | NorESM2-LM in all provinces, and the same change points are generally found regardless of which cost function (L1, L2 or
515 | kernel based) is chosen in both models. This indicates that the change points found are affecting multiple statistical
516 | moments.

517 |

519 | We compared the day of peak NPP with the day of MLD shallower than 40 m and the cross correlation did show the
520 | strongest correlation at zero lag. The fact that we saw significant correlations also with much longer lags likely reflected the

521 | low-frequency cycles of the Atlantic multi-decadal variability which affects many physical parameters, like SST and MLD,
522 | on multi-decadal time scales (e.g. Börgel et al. 2020). Both this type of low frequency variability and anthropogenic climate
523 | change could act as a lurking variable driving coherent changes in both NPP and MLD on a range of both positive and
524 | negative lags. Furthermore, we noted from Fig. 9 a strong anticorrelation between the MLD and NPP phenology for
525 | provinces BPLR and ARCT in EC-Earth3-CC. Given that both the provinces are far to the north and that SSP5-8.5 is a very
526 | strong warming scenario, we speculate that changes in sea-ice could be behind the observed correlation structure. This is
527 | supported by the fact that EC-Earth3 has been shown to overestimate sea ice concentrations in the Labrador Sea (Döscher et
528 | al., 2022). However, given that the timing of the MLD shallowing is unlikely to be important for the timing of peak NPP in
529 | these provinces we did not investigate further.

530 |

532 | NPP and its timing is, of course, both in the models and in reality dependent on many other factors in addition to the MLD.
533 | Some examples are light availability, nutrient concentrations and temperature. The MLD can similarly both be affected by
534 | and affect some of these factors. In light of this, it is clear that MLD changes can both act as a driver of phenology changes
535 | in itself and act as a proxy for other drivers, which complicates the interpretation. The cross correlation analysis therefore
536 | does not point to the validity of a certain bloom timing theory such as Critical Depth Hypothesis or the Disturbance
537 | Recovery Theory (Behrenfeld, 2010) but it does highlight the covariance of the NPP and MLD phenology.

538 |

540 | The biogeochemical modules included in the earth system models are by necessity simplistic, with PISCES simulating two
541 | phytoplankton functional types representing nanophytoplankton and diatoms and HAMOCC only one. However, even with
542 | reduced complexity interpretation is not straightforward. Compared to observations, community structure has been shown to
543 | affect the NPP and models containing a more dynamic phytoplankton community have a more non-linear response to climate
544 | change due to decreases in large cells and an increasing amount of regenerated production (Fu et al., 2016). Thus, more
545 | complex biogeochemical models may generate different results. The simpler biogeochemical model included in NorESM2-
546 | LM may be the reason for the lower variability seen in the NPP results (Fig. 4).

547

549 For this work we have used fully coupled earth system models as opposed to ocean only models, that are often used for
550 similar work (eg. Henson et al., 2018, 2009). The exchange of heat, momentum and freshwater is more accurately treated in
551 coupled models than in ocean only models. This affects, for example, temperature and stratification. It has also been
552 demonstrated that interactive coupling affects the variability of these variables (e.g. Bhatt et al. 1998, Barsugli and Battisti,
553 1998). The biogeochemical response is therefore expected to differ in the coupled vs. the uncoupled case. Because of more
554 realistic physics with respect to uncoupled models, we believe using coupled models might constitute an important step
555 forward in the larger effort of trying to understand what phenology changes might occur in the future.

556

558 5 Summary and conclusions

559 Using daily output for the period 1750-2100 under historical and SSP5-8.5 from two CMIP6 fully coupled ESMs, we have
560 analyzed NPP for an area covering 30-60°N, 67°W-9°E in the North Atlantic, with an emphasis on the phenology and the day
561 of peak NPP for an area covering 25-65°N in the North Atlantic. We have compared the vertically integrated NPP for
562 the two ESMs with the satellite based CAFE model. Both models ESMs show deviations from the CAFE data, partly
563 due to unresolved eddies in the Gulf stream region. Averaged over the domain, the, At least for EC-Earth3-CC, this is
564 especially true in the Gulf Stream region.

565

567 Furthermore, we separated the domain in biogeochemical provinces in accordance with Longhurst et al. (1995) in order to
568 look at spatial averages. The seasonal cycle of the CAFE data displays a longer season growing season in most provinces
569 than the two ESMs, where, NorESM2-LM better captures is typically better at capturing the timing of peak NPP and EC-
570 Earth3-CC is closer in annual average NPP in most provinces. The multi-decadal variability is smaller in NorESM2-
571 LM than in EC-Earth3-CC. The CAFE data seem to show larger multidecadal interannual variability than both ESMs
572 though this is difficult to determine given the relatively short (2003-2021) satellite record.

39
40

575 **The ES**M data show that shifts in the seasonal cycle occur mainly during the 21st century with reduced NPP as well
576 **as a peak NPP occurring earlier in the year.** The largest change in the day of peak NPP occurs in the north-western part of
577 the domain for both ESMs. Using change-point analysis, we have shown that the largest two change points in the area
578 averaged day of peak NPP occurs after the year 2000 in both ESMs. The first of the two change points occurs in 2010 in EC-
579 Earth3-CC and in 2007 in NorESM2-LM. One additional major change point was detected in 2070 in NorESM2-LM and
580 2090 in EC-Earth3-CC. We have also shown that the largest change point in the day of peak NPP occurring after the year
581 2000 is a robust feature even for individual grid points. Comparing the average of the last 30 years (2070-2099) to average
582 over the period 1850-1879, the day of peak NPP is earlier by 1/11 day/s in NorESM2-LM/EC-Earth3-CC but with a regional
583 standard deviation of 31/33 days respectively, highlighting the heterogeneous regional pattern displayed in both ESMs.
584 Furthermore, in similar to the change points in the day of peak NPP, the largest change points in the first day of MLD
585 smaller or equal to 40m occur in the 21st century. Cross correlation shows significant correlation between this variable and
586 the day of peak NPP for most of the biogeochemical provinces. The largest change towards an earlier day of peak NPP
587 occurs in the northern parts for both ESMs. In EC-Earth3-CC the largest change occurs in the biogeochemical province
588 BPLR and in NorESM2-LM in the arctic province ARCT. Moreover, the changes in the day of peak NPP are far outside the
589 range of the natural variability diagnosed from the PI-control run in large parts of the domain. For future work it would be
590 very interesting to see what a similar change point analysis would reveal in low and moderate emission scenarios. For all
591 provinces, the change points occur earlier in EC-Earth3-CC than in NorESM2-LM.

594 Cross correlation analysis showed significant correlation between the day of MLD shallower than 40 m and the day of peak
595 NPP in most regions. The peak correlation occurs at zero lag, but correlations are significant at many both positive and
596 negative lags. The large range of correlated lags we ascribe to forced and unforced low frequency variability affecting both
597 parameters.

600 | **Our results point to a phenological shift shifts occurring in the early 21st century in the vertically integrated NPP in**
601 | **different parts of the North Atlantic (30°-60°N, 67°W-9°E). 25-65°N). Shifts in the phenology may have an impact on**
602 | **fishery yields through the mismatch of fish spawning and available resources. Furthermore, carbon sequestration in**
603 | **this highly productive region may be affected by changes in ecosystem structure in turn affecting the export**
604 | **production; and the general efficiency of the biological pump.**

605 |

606 | **Code availability:** The EC-Earth3 code is available from the EC-Earth development portal for members of the consortium.
607 | All code related to CMIP6 forcing is implemented in the component models. Model codes developed at ECMWF, including
608 | the atmosphere model IFS, are intellectual property of ECMWF and its member states. Permission to access the EC-Earth3
609 | source code can be requested from the EC-Earth community via the EC-Earth website (<http://www.ec-earth.org/>, EC-Earth
610 | consortium, 2019a) and may be granted if a corresponding software license agreement is signed with ECMWF. The
611 | repository tag for the version of EC-Earth that is used in this work is 3.3.1. Currently, only European users can be granted
612 | access due to license limitations of the atmosphere model. The component models NEMO, LPJ-GUESS, TM5, and PISM are
613 | not limited by their licenses.

614 | The NorESM code can be accessed via zenodo: Seland, Ø., Bentsen, M., Olivié, D., Toniazzo, T., Gjermundsen, A., Graff,
615 | L. S., Debernard, J. B., Gupta, A. K., He, Y., Kirkevåg, A., Schwinger, J., Tjiputra, J., Aas, K. S., Bethke, I., Fan, Y., Gao,
