19 **ABSTRACT**

20 Human CO₂ emissions are modifying ocean carbonate chemistry, causing ocean acidification, and
21 likely already impacting marine ecosystems. In particular, there is concern that coastal, benthic
22 calcifying organisms will be negatively affected by ocean acidification, a hypothesis largely
23 supported by laboratory studies. The inter-relationships between carbonate chemistry and marine
24 calcifying communities *in situ* are complex and natural mesocosms such as tidal pools can provide
25 useful community-level insights. In this study, we manipulated the carbonate chemistry of
26 intertidal pools to investigate the influence of future ocean acidification on net community
27 production (NCP) and calcification (NCC) at emersion. Adding CO₂ at the start of the tidal
28 emersion to simulate future acidification (+1500 μatm pCO₂, target pH: 7.5) modified net
29 production and calcification rates in the pools. By day, pools were fertilized by the increased CO₂
30 (+20 % increase in NCP, from 10 to 12 mmol O₂ m⁻² hr⁻¹), while there was no measurable impact
31 on NCC. During the night, pools experienced net community dissolution (NCC < 0), even in
32 present-day conditions, when waters were supersaturated with regards to aragonite. Adding CO₂
33 in the pools increased nocturnal dissolution rates by 40% (from -0.7 to -1.0 mmol CaCO₃ m⁻² hr⁻¹)
34 with no consistent impact on night community respiration. Our results suggest that ocean
35 acidification is likely to alter temperate intertidal community metabolism on sub-daily timescales,
36 enhancing both diurnal community production and nocturnal calcium carbonate dissolution.

37 **SHORT SUMMARY**

38 Human CO₂ emissions are modifying ocean carbonate chemistry, causing ocean acidification, and
39 likely already impacting marine ecosystems. Here, we added CO₂ in intertidal pools at the start of
40 emersion to investigate the influence of future ocean acidification on net community production
41 (NCP) and calcification (NCC). By day, adding CO₂ fertilized the pools (+20 % NCP). By night,
42 pools experienced net community dissolution, a dissolution that was further increased (+40 %) by
43 the CO₂ addition.

46 INTRODUCTION

47 The ongoing increase of anthropogenic carbon dioxide (CO₂) in the atmosphere and the ocean –
48 resulting in ocean acidification - is likely to create adverse living conditions for marine coastal
49 communities (IPCC, 2019). Ocean acidification is projected to further decrease average surface
50 pH by up to 0.4 units by 2100 ([scenario RCP8.5](#), Kwiatkowski et al., 2020), and is identified as a
51 major threat to marine ecosystems (IPCC, 2019). Lower seawater pH has significant effects on
52 marine organisms physiology and fitness: from altered survival and reduced growth (see review
53 by Kroeker et al. 2013), to changes in pH homeostasis (e.g., Kottmeier et al., 2022), metabolic
54 rates, and energy trade-offs (e.g., Dorey et al., 2013; Pan et al., 2015) and reduced feeding
55 efficiency (e.g., Stumpff et al., 2013). Marine calcifiers - the builders of calcified structures
56 (CaCO₃) - have been a focus of ocean acidification research due to the sensitivity of calcification
57 to the carbonate saturation state (Ω), defined as follows:

$$58 \quad \Omega = [\text{Ca}^{2+}] [\text{CO}_3^{2-}] / K'_{\text{sp}}$$

59 where K'_{sp} is the stoichiometric solubility product for the considered carbonate polymorph (i.e.,
60 Ω_a for aragonite or Ω_c for calcite). The saturation state depends on temperature, pH, and pressure
61 (lower Ω when pH or temperature decreases and pressure increases). When $\Omega < 1$, inert carbonate
62 minerals tend to dissolve. The polymorphs composing the calcified structure like calcite and to a
63 greater extent aragonite and high-magnesium calcite, are prone to dissolution when pH decreases.
64 For instance, in Atlantic surface waters (at 20°C), saturation state equilibrium ($\Omega = 1$) is reached
65 at pH 7.3 ($p\text{CO}_2 = 2650 \mu\text{atm}$) for calcite but at pH 7.6 (1250 μatm) for aragonite. For high-
66 magnesium calcite, experiments from (Yamamoto et al., 2012) demonstrate that inert (dead) high-
67 magnesium calcite from coralline algae passively dissolves at Ω_a values between 3.0 and 3.2 (also
68 see Ries et al. 2016). Organisms with calcified structures are thus likely to experience reduced net
69 calcification due to ocean acidification, both through enhanced dissolution, and reduced gross
70 calcification rates.

71 Aside from acidifying the ocean (increased H⁺), increased ocean CO₂ uptake could affect
72 the productivity of algae and marine plants. As CO₂ dissolves in the ocean, the dissolved inorganic
73 carbon (DIC: CO₂, HCO₃⁻ and CO₃²⁻) concentration increases. DIC is the substrate for marine
74 photosynthesis (mainly CO₂ and HCO₃⁻), and as such, it can limit photosynthetic rates when scarce.

75 In algae and marine plants that are carbon limited (permanently or periodically), elevated DIC
76 could also directly increase photosynthetic rates and Mackey et al., (2015) propose that these rates
77 could be further increased by the higher concentration gradient between water and the
78 photosynthetic cells. However, the authors point out that while positive effects are theoretically
79 expected, they may be small, specific to species' biology and the environment they live in, and
80 difficult to predict (see also Hurd et al., 2019). In terrestrial ecosystems, the Intergovernmental
81 Panel on Climate Change defines CO₂ fertilization as 'the enhancement of plant growth as a result
82 of increased atmospheric CO₂ concentration' (Jia et al., 2019) and reports that CO₂ fertilization
83 has likely already happened, although the magnitude of this effect depends on the plants, or
84 assemblages/ecosystems considered (and on other factors constraining growth).

85 The response of single species to changes such as ocean acidification and increased DIC
86 concentrations are often insufficient to predict community-level impacts. Ecological interactions
87 such as competition or predation can affect the outcome of perturbation experiments (Kroeker et
88 al., 2012). For instance, Paiva et al. (2021) showed that the laboratory growth of an isopod species
89 was an order of magnitude slower than when raised in the presence of other species from its
90 community. In another study, Legrand et al. (2019) showed that the presence of grazers increased
91 coralline algal calcification (+50% in winter and +100% in summer), but when grazers were
92 combined with ocean acidification, algal calcification decreased more than with acidification
93 alone. Not taking into account such interactions can therefore result in poorly characterizing the
94 effects of ocean acidification. Furthermore, while critical for a mechanistic understanding of the
95 processes affecting marine biota, laboratory studies are seldom realistic. Typically performed in
96 controlled, simplified, and stable conditions (e.g., with respect to temperature and food), laboratory
97 studies can better assess the effect of pH alone (Widdicombe et al., 2010). However exposure to a
98 stable pH (e.g., 7.6 vs. 8.0), fails to reflect the daily and seasonal variability observed in natural
99 ecosystems, in particular coastal ones (Torres et al., 2021). Natural mesocosm perturbation
100 experiments are thus essential tools to investigate future changes in variable and complex
101 ecosystems, difficult to capture in the lab (Andersson et al., 2015; Barry et al., 2010).

102 Most *in situ* mesocosm experiments investigating the effect of ocean acidification have
103 been conducted on planktonic communities, kept in large "bags" equilibrated to the desired pH
104 (Riebesell et al., 2013). These studies demonstrate that adding CO₂ can significantly change the

105 organization of the plankton community (Spisla et al., 2021), and increase autotrophic biomass in
106 high-nutrient conditions (Schulz et al., 2013). Due to the technical challenges, however, benthic
107 calcifying communities are seldom manipulated this way *in situ* (Widdicombe et al., 2010). Two
108 such manipulation experiments are the studies by Albright et al. (2016, 2018), where the authors
109 used NaOH and CO₂ to reproduce pre-industrial and future pH conditions on a coral reef and found
110 evidence that reef growth had been reduced by 7% over the industrial era and was likely to decline
111 further. Other studies have investigated such community-level effects by either simulating
112 “artificial”, simpler, assemblages in laboratory setups (e.g., Cox et al., 2015; Pansch et al., 2016)
113 or using phenomena such as natural CO₂ vents. For instance, in the vents of Ischia, as pH decreases,
114 the presence of calcifying species declines (see review by Foo et al., 2018). Alternatively,
115 Kwiatkowski et al. (2016) used locally-induced acidification due to respiration (no CO₂ addition)
116 in tidal pools, a naturally closed system, and demonstrated that nighttime dissolution of these
117 communities was positively correlated with Ω . Here, we used tidal pools of the English Channel as
118 ephemeral mesocosms, where we modified carbonate chemistry conditions at the start of emersion
119 through CO₂ addition.

120 Temperate rocky tidal pools - or rockpools - are highly dynamic systems that have been long
121 studied by naturalists since they are easy to reach and their ecosystem structure generally resemble
122 subtidal benthic communities (Ganning, 1971). Tidal pool organisms from the upper shore, well-
123 adapted to pool conditions, form typical benthic communities: often low in diversity, they consist
124 of a few characteristic macroalgal (e.g., *Ulva sp.*) and animal species (e.g., limpets). In winter, red
125 macroalgae – including calcifying algae – often dominate the pools and while they do not disappear
126 in summer, a bloom of soft green macroalgae is generally observed during the warm season.
127 Temperature, salinity, oxygen, and pH in the pools are extremely variable, often far outside the
128 seasonal range of nearby free-flowing seawater (Legrand et al., 2018; Morris & Taylor, 1983).
129 Tidal pools generally emerge from the ocean twice a day in regions of semidiurnal tides with the
130 duration dependent on shore location and the tidal coefficient. On short timescales tidal pools act
131 as closed systems, with carbonate chemistry easily manipulated and temporal changes reflecting
132 *in situ* community metabolism (no water mass transport and negligible air-sea gas exchange).

133 In the present study, we used tidal pools as natural mesocosms to investigate the effect of ocean
134 acidification on communities dominated by calcifying red algae. We measured diurnal and

135 nocturnal net community calcification and production (or respiration) following CO₂ addition
136 across three seasons (winter, spring, and summer), to assess how tidal pool community metabolism
137 may respond to end of the 21st century high ocean acidification (pH 7.5).

138

139 **MATERIAL AND METHODS**

140 **Field site**

141 The experiments were performed on a rocky intertidal shore characterized by granitic substrate on
142 the North coast of Brittany, France, between 2019 and 2021. The beach of Bloscon (48°43'30.0"N
143 3°58'10.5"W) is situated in Roscoff at the entrance of the Bay of Morlaix and has a hydrology
144 principally affected by the waters of the English Channel and to a lesser extent the Penzé and
145 Morlaix rivers (**Fig. 1**). This area is characterized by strong, oscillating, semidiurnal tides of up to
146 9 m. Temperatures are generally low in the deeper flowing water (from 9-10 °C in winter to 16-17
147 °C in summer), and salinity is close to that of the adjacent Atlantic (~35; see **Supp. Mat. Fig. S1**
148 for detailed temperature and salinity data from the two nearby SOMLIT monitoring stations
149 Estacade and Astan, a network described in Cocquempot et al., 2019).

150 **Tidal pool characterization**

151 For this study, we chose five tidal pools with high coverage in calcifying algae ($\geq 30\%$ of the pool
152 surface area). Both crustose (CCA) and articulated (branching) coralline algae (ACA) were
153 present. The field site has an eastern exposure, resulting in full morning sun and relatively early
154 shade in the evening. Foreshore locations of the pools resulted in daily emersion year-round
155 including during neap tides (mid-tide, approx. 5-6 m above chart datum). Pools emerged for 6-7 h
156 during low-tide periods. During that time, pools were completely separated from the adjacent open
157 water and their depths were effectively constant in winter (low-evaporation season), an indication
158 that there was no seawater leakage.

159 The volume of each of the five pools (from 16 to 39 L; **Fig. 2**) was estimated in April 2021
160 at the end of the emersion period just before high-tide flooding, by measuring salinity changes
161 when a known volume of freshwater was added and well mixed. To estimate the pools' initial
162 volumes, we also took into consideration the measured salinity changes throughout the emersion

163 period to estimate evaporative losses and combined this with the volume directly lost through
164 water sampling (see below). The pool projected area and the relative area covered by each type of
165 algae were estimated from aerial photographs, with a scale and analyzed using ImageJ (U. S.
166 National Institutes of Health, Bethesda, Maryland, USA, <https://imagej.nih.gov/ij>). Pool area
167 ranged from 0.3 to 0.67 m² (Fig. 2). The pools had slightly different community composition with
168 dominant calcifying red algae represented by *Lithophyllum incrustans* (CCA: 30 to 74.77 % of the
169 benthic cover) and *Ellisolandia elongata* (ACA: 0 to 6 % of the benthic cover). The remaining
170 pool area was either free of algal cover with only bare granitic rock visible or covered by soft
171 macroalgae. In summer (September 2020 and 2021), the pools also hosted the green algae *Ulva*
172 *sp.* and *Enteromorpha sp.* (2 to 44 % of the benthic cover: see **Supp. Mat. Pools: Fig. SP1-2**, for
173 results detailed by season) and, in Pool E, small single branches of the brown algae *Sargassum*
174 *muticum*, covering less than 0.5 % of the pool. One limit of this method of aerial photography is
175 that it only takes into account what is visible from above (2D). These estimates may thus be biased
176 against algae that were hidden under the green algae canopy in summer or that were in
177 crevices/under rocks. We also noted the presence of diverse heterotrophs such as anemones, sea
178 sponges, small gobies, and shrimps. Calcifying invertebrates were represented by four gastropod
179 species: *Phorcus lineatus*, *Patella ulysiponensis*, *Patella vulgata* and *Gibbula pennanti*.

180 Study design and seawater manipulation

181 Fieldwork was conducted during the low-tide emersion periods, day and night. We refer to the
182 period from the beginning to the end of the pool emersion as a “low-tide emersion period” and to
183 each seasonal sampling period as a “field session” (Table 1). We sampled during three seasons:
184 winter (February 2020 and 2021), spring (April 2021), and summer (September 2020 and 2021).
185 During each field session, all the pools experienced both “future” (approximately year 2100 under
186 high emissions) and present-day (“present”, non-manipulated control) initial carbonate chemistry
187 conditions. During each low-tide emersion period (n = 23), we randomly selected two or three
188 pools in which we decreased pH to 7.5 at the start of the emersion. The following low-tide
189 emersion period, this was reversed and pools that had been subject to present-day conditions in the
190 previous low-tide emersion period were subject to future conditions and *vice versa*. However, due
191 to diverse constraints, in two of the 23 emersion periods all the pools were left under present-day
192 conditions.

193 **Table 1: Sampling schedule:** The dates of each field session are presented. Pools were monitored
194 throughout multiple low-tide emersion periods (diurnal and nocturnal).

Season	Dates	Low-tide emersion periods (N)	
		Diurnal	Nocturnal
Winter	14-17 February 2020	2	0
	9-19 February 2021	8	2
Spring	28-29 April 2021	2	0
Summer	2-11 September 2020	5	1
	6-9 September 2021	0	3

195

196 In this experiment, we compared "present" and "future" seawater carbonate chemistry
197 conditions. To simulate "future" carbonate chemistry conditions, we added small volumes of CO₂-
198 enriched seawater (total of ~100-200 mL) at the start of the emersion period in 50 mL increments
199 until the well-mixed pool water reached the desired pH levels (pH = 7.65, reached in less than 10
200 min.). CO₂-enriched seawater was prepared by super-saturating adjacent seawater in CO₂ using a
201 high-pressure CO₂ cylinder.

202 **Sampling and measurement of seawater parameters**

203 **Temperature, salinity, pH, oxygen, and ammonium:** From the start of the emersion period, we
204 measured five parameters periodically using HACH-Lange (Loveland, USA) probes: temperature,
205 pH_T (IntelliCAL PHC101, accuracy: ± 0.02 pH units), salinity (conductivity probe IntelliCAL
206 CDC401, ± 0.1 units), oxygen concentration (optical sensor IntelliCAL LDO101, accuracy: ± 0.1
207 mg L⁻¹ for 0 to 8 mg L⁻¹, ± 0.2 mg L⁻¹ for greater than 8 mg L⁻¹, maximum 22 mg L⁻¹) and NH₄⁺
208 concentration (ion selective electrode IntelliCAL ISENH4181, range: 0.018 - 9000 mg L⁻¹ NH₄⁺-
209 N). Pools were well-mixed before any measurement to assure no influence of gradients forming in
210 the pools. The measurement frequency during the emersion periods was every 15-20 min during
211 the day (n = 1392) and reduced to once an hour at night (n = 159), when temperature, pH and light
212 variations were limited or absent. pH was calibrated on the total scale (pH_T) using TRIS (2-amino-
213 2-hydroxy-1,3-propanediol) and AMP (2-aminopyridine) buffer solution with a salinity of 35.0,
214 following the recommendations from (Dickson et al., 2007).

215 **Total alkalinity:** Discrete samples for total alkalinity (TA) analysis were collected hourly. The
216 average time between two samples was 1.0 ± 0.2 hours ($n = 492$, median = 1.0) during daytime
217 and 1.4 ± 0.9 hours ($n = 135$, median = 1.0) during nighttime. Seawater (150 mL) was filtered with
218 $0.7 \mu\text{m}$ GF/F borosilicates filters directly after sampling. These samples were stored in a dark cool
219 box until the end of the tide (max. 7 h). Upon return to the lab, they were stored at 4°C in the dark
220 until they were either analyzed within the week or poisoned with $50 \mu\text{L}$ of saturated HgCl_2 (see
221 "sample processing"). TA was assessed potentiometrically using $50.0 \pm 0.5 \text{ g}$ of seawater and a
222 semi-automated titration system (0.1 M HCl, Titrino 848 plus by Metrohm, Switzerland; electrode
223 calibrated on the National Bureau of Standards scale). TA was determined using Gran titration
224 (Gran, 1952) according to the method of Haraldsson et al. (1997) and verified against reference
225 standards provided by A. Dickson (Scripps Institute of Oceanography, University of South
226 California, San Diego, United States). TA samples were analyzed with single ($n = 312$) or duplicate
227 ($n = 320$) measurements (the median of the standard deviation between duplicates was $1.05 \mu\text{mol}$
228 kg^{-1}). TA was salinity-normalized before further calculations, to take into account possible dilution
229 from rain or concentration from evaporation.

230 To take into account the influence of the changes in nutrients (NO_3^- , NO_2^- , PO_4^{3-} and NH_4^+)
231 on the changes in TA (Gazeau et al., 2015), we sampled seawater for nutrients in winter (February
232 2020) and summer (September 2020). Samples were taken during the day at the start and end of
233 the emersion periods in the five pools. Around 60 mL of seawater was immediately filtered on 0.2
234 μm cellulose filters, stored in 125 mL polyethylene bottles in a cool dark box (max. 7h), and then
235 frozen at -20°C until analysis. Nutrient concentrations were obtained using an AA3 auto-analyzer
236 (Seal Analytical) using the method from Aminot & K erouel (2007). Changes in nutrient
237 concentrations were near-negligible contributions to TA changes throughout a low-tide emersion
238 period ($< 6 \mu\text{mol kg}^{-1}$ i.e., $< 2\%$ of the observed change in TA, see full details in **Supp. Mat.**
239 **Nutrients**) and thus are ignored here.

240 **Light measurements:** Surface irradiance (photosynthetically active radiation, PAR) was
241 continuously recorded (every minute) during experiments at the field station, using a Li-Cor flat
242 quantum light sensor (LI-190R) and logger (LI-1500, LI-COR, Germany).

243 **Adjacent waters:** Temperature, salinity, pH and TA ($n = 5$) were similarly sampled and measured
244 at the sampling site during ebb tide, for the three seasons.

245 **Carbonate chemistry calculations**

246 The carbonate system parameters (e.g., $p\text{CO}_2$, DIC concentration, CO_3^{2-} concentration, and Ω_a , the
247 aragonite saturation state) were calculated from the measurements of pH_T , TA, temperature and
248 salinity using the R package *seacarb* (Gattuso et al., 2021) with the default dissociation constants
249 recommended by Dickson et al. (2007), except for the low temperatures encountered in February
250 2021 where the refined constants of Sulpis et al. (2020) were used. When salinity decreased by
251 more than 1.5 units per hour, data were excluded to avoid rain effects in the present study. When
252 calculated DIC and Ω_a were negative, likely due to inaccuracies in the measurement and
253 computation of the carbonate system, values were approximated to be 0 (7/627 values). [The air-](#)
254 [sea gas fluxes due to net diffusive transport were considered to be negligible in the pools \(see](#)
255 [detailed explanation the interactive discussion\).](#)

256 **Biological activity calculations**

257 The rates of Net Community Calcification (NCC; $\text{mmol CaCO}_3 \text{ m}^{-2} \text{ h}^{-1}$) and Net
258 Community Production (NCP) or Community Respiration (CR; $\text{mmol O}_2 \text{ m}^{-2} \text{ h}^{-1}$ or mmol C m^{-2}
259 h^{-1}) were calculated between two consecutive sampling times. These rates respectively represent
260 the measured changes of net CaCO_3 precipitation and net organic carbon production (or oxygen
261 consumption) by the community. Positive NCC represents net CaCO_3 precipitation (gross
262 precipitation > dissolution) and negative rates represent net dissolution (dissolution >
263 precipitation). NCP is positive when the community primary production exceeds respiration and
264 negative when community primary production is less than respiration. We use CR-(~~not NCP~~) for
265 nights, when there is no primary production (oxygen consumption and carbon release only).

266 NCC was calculated using the alkalinity anomaly method (Smith & Key, 1975). Briefly,
267 for each mol of CaCO_3 precipitated, two moles of HCO_3^- combine with Ca^{2+} , and TA decreases
268 by two moles (Eq. 1). Two independent estimates of NCP (or CR) were calculated, one derived
269 from changes in ΔO_2 (NCP_{O_2} or CR_{O_2}) and one derived from ΔDIC and NCC (NCP_{DIC} or CR_{DIC}).

270 NCC and NCP (or CR) were thus calculated as follows:

271
$$\text{NCC} = \frac{\Delta\text{TA}}{2\Delta t} \times \frac{V}{S} \quad (1)$$

272
$$NCP \text{ (or } CR)_{O_2} = \frac{\Delta O_2}{\Delta t} \times \frac{V}{S} \quad (2)$$

273
$$NCP \text{ (or } CR)_{DIC} = \frac{-\Delta DIC}{\Delta t} \times \frac{V}{S} - NCC \quad (3)$$

274 with ΔTA (mmol L⁻¹), ΔDIC (mmol L⁻¹) and ΔO_2 (mmol L⁻¹) the change in concentration of TA,
 275 DIC and O₂, between consecutive samples and Δt the duration between consecutive samples (h),
 276 V pool volume (L), S the pool surface area (m²).

277 Up to seven NCC and NCP (or CR) rates were calculated for each pool during each
 278 emersion period (one per hour). These rates were used to investigate the direct correlation between
 279 biological activity and environmental factors such as light intensity or Ω_a .

280 Rates calculated this way are however not independent from each other (i.e., the rate
 281 measured at t+2 is dependent on the rate at t+1), limiting further statistical analyses on the effect
 282 of the treatment. This is why, to investigate the effect of pH treatment (“present” vs. “future”) on
 283 community biological activity, we also calculated NCC and NCP or CR using linear regressions
 284 (NCC_{lm} and NCP_{lm} or CR_{lm}) between TA, [DIC] and [O₂] and time after the start of the emersion
 285 period (for detailed results of the regressions, e.g., goodness-of-fit, see **Supp. Mat. LM1-3**). The
 286 few data from diurnal tides that were taken after sunset were excluded from these regressions. For
 287 oxygen, data ~~was~~ were limited to the first three hours of emersion as high O₂ concentrations (>22
 288 mg L⁻¹) and supersaturation (>200 %) led to inaccurate measurements and/or possible oxygen
 289 degassing afterwards (see **Supp. Mat. LM2**). This regression approach provides a single estimate
 290 of the rate of NCC, NCP_{DIC} (or CR_{DIC}) and NCP_{O₂} (or CR_{O₂}) for each pool during each emersion
 291 period (n = 17 diurnal and 6 nocturnal low-tide emersion periods x 5 pools = 115). These rates
 292 were then used in generalized linear mixed models (GLMM) to assess the effect of pH treatment
 293 on diurnal and nocturnal biological activity (see “*statistical analyses*” below).

294 We calculated community calcification and production budgets (respectively CCB and
 295 CPB) at emersion as an indication of the night/day balance in calcification and production: when
 296 CCB/CPB is positive the pool community calcifies/produces more by day than they
 297 dissolve/respire at night. Both were calculated for winter (February 2020 and 2021) and summer
 298 (September 2020 and 2021) for each pool as follows:

299
$$CCB = NCC_D + NCC_N \quad (4)$$

300
$$CPB = NCP_D + CR_N \quad (5)$$

301 with NCC_D and NCP_D (> 0) the average diurnal NCC and NCP for a given pool for a treatment
302 and a season and NCC_N and CR_N (< 0) the average nocturnal NCC and dark respiration for the
303 same conditions. Three approaches were used for estimating CPB, given the uncertainties of each
304 NCP estimate (see discussion): (1) O_2 -derived estimates of NCP (CPB_{O_2}), (2) DIC- derived
305 estimates (CPB_{DIC}) and (3) a “mixed” approach that combined nocturnal CR_{O_2} and diurnal NCP_{DIC}
306 (CPB_m), under the assumption that one mol of carbon is produced/consumed when one mol of O_2
307 is produced/consumed. Although CPB resemble gross community production in the way the rates
308 are calculated (difference between light and dark net production/respiration rates), if one wanted
309 to reuse these rates for gross community production, they should be do so with care due to
310 differences in night and day temperature (see extended discussion on this subject in Bracken et al.,
311 2022). The treatment effect was assessed on CCB and CPB by comparing the change due to the
312 “future” treatment in each pool.

313

314 **Statistical analyses**

315 All data are presented as mean \pm standard deviation (SD). The analyses were made using the
316 software R (R Core Team, 2017). The level of significance used was 5%. Because data were
317 measured on the same five pools but on different days for different treatments, we used GLMM to
318 test for the effect of treatment on NCC_{lm} and on O_2 and DIC-derived NCP_{lm} (or CR_{lm}), assigning
319 sampling days (i.e., low-tide emersion periods) as the random factor and pools (five levels), mean
320 temperature of the pool during low-tide emersion period (a continuous proxy for season) and
321 treatment (*Treat*: “future” vs. “present”) as fixed factors. This was performed using the R package
322 *nlme* (Pinheiro et al., 2018). Models with and without standardized residuals were compared using
323 ANOVAs and, when different, Akaike Information Criteria (AIC) was used to choose the best
324 fitted-model of the two. For GLMM, mean daily PAR was not used as it has strong collinearity
325 with mean daily temperature/season. We used ANOVAs to test the effect of temperature, pool and
326 treatment on initial (averaged over the first hour of emersion) and final (averaged for > 5 hours
327 after emersion) carbonate chemistry conditions. The normality of the data was tested using
328 Shapiro–Wilk tests and qq-plots, while variance homogeneity was tested with Bartlett tests.

329

330 RESULTS

331 1/ Environmental conditions

332 **Adjacent waters:** Temperatures (and salinity) measured in the seawater adjacent to the pools were
333 6-7°C in winter (February; salinity $S=35.0$), 11-12°C in spring (April; $S=35.5$) and 17-18°C in
334 summer (September; $S=36.0$). This seawater was characterized by average pH_T of 8.01 ± 0.06
335 units, total alkalinity of $2319 \pm 6 \mu\text{mol kg}^{-1}$, $p\text{CO}_2$ of $445 \pm 69 \mu\text{atm}$, $\Omega_a = 2.2 \pm 0.3$ and $[\text{O}_2] =$
336 $100 \pm 1 \%$ of air saturation (or $10.1 \pm 1.5 \text{ mg L}^{-1}$; $n=5$).

337 **Light duration and intensity:** In Roscoff, day:night (i.e., no light) periods are typically 10h:14h
338 in February, 14h:10h in April and September. Photosynthetically active radiation (PAR) was two
339 to three times higher in spring/summer (Fig. 3A: April/September $\sim 1500 \mu\text{mol m}^{-2} \text{ s}^{-1}$) than in
340 winter (February $\sim 500 \mu\text{mol m}^{-2} \text{ s}^{-1}$).

341 **Carbonate chemistry conditions at the start of the emersion period (< 1h post emersion):**
342 Both for diurnal and nocturnal tides, the initial pH was significantly lower in pools with added
343 CO_2 than in the present-day pools (Day: $pH_T = 8.2 \pm 0.1$ vs. 7.5 ± 0.2 units; Night: 8.0 ± 0.1 vs.
344 7.4 ± 0.1 units for “present” and “future” pools respectively; *Treat* $p < 0.001$; detailed results in
345 Fig. S2-3, Table S1-2). This corresponds to $p\text{CO}_2$ of 260 ± 100 vs. $1900 \pm 835 \mu\text{atm}$ (day) and
346 510 ± 90 vs. $2310 \pm 410 \mu\text{atm}$ (night) for pools in “present” and “future” conditions respectively.
347 Adding CO_2 in the pools increased the mean DIC concentration by $320 \mu\text{mol kg}^{-1}$ during the day
348 and $240 \mu\text{mol kg}^{-1}$ during the night. In “present-day” conditions, the pools started at supersaturated
349 levels with regards to aragonite (day: $\Omega_a = 3.3 \pm 1.3$, night: 2.2 ± 0.3). Adding CO_2 significantly
350 decreased Ω_a (*Treat*: $p < 0.001$, Table S1) leading to initial “future” conditions often
351 undersaturated with regards to aragonite ($\Omega_a = 0.8 \pm 0.5$) by day and always undersaturated
352 conditions by night ($\Omega_a = 0.6 \pm 0.1$). Furthermore, in “future” diurnal conditions, pools were
353 always undersaturated with respect to aragonite from the start of the emersion period in February
354 ($\Omega_a = 0.5 \pm 0.2$) but not in April ($\Omega_a = 1.1 \pm 0.7$) and September ($\Omega_a = 1.2 \pm 0.5$; Table S1). At the
355 start of emersion, total alkalinity was $2303 \pm 34 \mu\text{mol kg}^{-1}$ (similar to adjacent seawater), and
356 uncorrelated with treatment ($p > 0.05$) and temperature ($p > 0.6$).

357 As data was averaged on the first hour post-emersion, the mean initial oxygen
358 concentration calculated was already affected by NCP by day ($14.0 \pm 2 \text{ mg O}_2 \text{ L}^{-1}$) and CR by
359 night ($9.5 \pm 1.5 \text{ mg O}_2 \text{ L}^{-1}$; vs. $10.1 \pm 1.5 \text{ mg O}_2 \text{ L}^{-1}$ for adjacent seawater). This was also visible
360 in CO_2 partial pressure, with lower $p\text{CO}_2$ than expected during the first hour post-emersion by day
361 ($262 \pm 102 \text{ } \mu\text{atm}$ vs. $445 \pm 69 \text{ } \mu\text{atm}$ for adjacent seawater) and higher $p\text{CO}_2$ at night (508 ± 88
362 μatm) in the “present-day” conditions.

363 2/ Diurnal tides

364 **Diurnal pool chemistry:** Starting from the aforementioned values at emersion, the pools followed
365 a clear temporal evolution due to solar irradiance and community metabolism (**Fig. 3**). Firstly, we
366 observed increases in salinity (+1.5 units on average, **Fig. 3A**) and temperature (+4°C in
367 September, +6°C in April on average) in summer and spring. In winter, temperatures tended to
368 decrease (-1.7°C on average) with air temperatures colder than that of the seawater; salinity was
369 stable (35.5 ± 0.8).

370 Secondly, we observed positive NCP corroborated by a doubling in oxygen concentration
371 (**Fig. 3A**) a few hours after the start of emersion. In parallel, the seawater DIC concentration
372 decreased by half from the initial concentration (from 2130 ± 195 to $1140 \pm 560 \text{ } \mu\text{mol kg}^{-1}$; **Fig.**
373 **3B**), the range of which largely depended on the season (**Fig. S2**). For instance, in February, DIC
374 consumption in pool seawater averaged $\sim 700 \text{ } \mu\text{mol kg}^{-1}$ over a low-tide period, while it averaged
375 $\sim 1500 \text{ } \mu\text{mol kg}^{-1}$ in September. Particularly extreme conditions, with DIC concentrations
376 effectively reaching $0 \text{ } \mu\text{mol kg}^{-1}$, were observed in two of the pools, at three tides in September
377 2020 (see further details below in “5/ *The particular case of September 2020 tides*”). At the end
378 of diurnal emersions, average $p\text{CO}_2$ was always below $100 \text{ } \mu\text{atm}$, reaching as low as $1 \pm 2 \text{ } \mu\text{atm}$
379 in September (**Fig. 3B, Table S1**). As a result, diurnal pH_T increased to 9.1 ± 0.6 by the end of
380 emersion, with maximum values up to 10.3 in summer (**Fig. 3B**). At the end of a diurnal emersion
381 period, the pools’ pH was stable, reaching either a plateau or decreasing after sunset (see PAR in
382 **Fig. 3A**). Similarly, at the end of diurnal emersion periods, Ω_a was high (5.6 ± 3.0 on average;
383 max 10.4). Lastly, we observed a diurnal decrease in TA by $415 \text{ } \mu\text{mol kg}^{-1}$ on average, indicative
384 of net calcification.

385 It is noteworthy that the carbonate chemistry conditions experienced at the end of diurnal
386 emersion converged whatever the initial treatment (**Fig. S2, Table S1**). For instance, while Ω_a was
387 significantly different between treatments at the start of the emersion period, both treatments
388 reached similar Ω_a at the end of emersion (> 5 h) of around 5.3 ± 2.2 (ANOVA: Treat: $p = 0.1$,
389 Temp: $p = 0.002$, Pool: $p = 0.01$). There was less convergence for pH_T where, even five hours after
390 emersion, there were still statistically significant, albeit small, differences between treatments (p
391 < 0.001 for pH_T with 9.2 ± 0.6 for “present” and 9.0 ± 0.6 for “future” pools).

392 **Diurnal biological activity:** Net community production was positive during daytime, except at
393 sunset (**Fig. 3C**). NCP was significantly correlated to light intensity (PAR) and further results for
394 hourly NCP and their correlation to hourly averaged PAR, Ω_a and temperature can be found in the
395 **Supp. Mat. (Fig. S5S6 and S6S7)**.

396 As expected, seasons/temperature affected net oxygen production (O_2 -derived NCP_{lm}),
397 increasing from 7 ± 3 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ in February to 18 ± 11 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ in September
398 (**Fig. 4A and Table 2A**: GLMM, $p < 0.001$). CO_2 addition increased O_2 -derived NCP_{lm} by 20%
399 % on average over all seasons, from 10 ± 7 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ in “present” conditions to 12 ± 9
400 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ ($p = 0.0015$). Net oxygen production differed across pools ($p < 0.003$), with
401 significantly more productivity in pool C (17.6 ± 12.7 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$) and D (10.6 ± 5.6 mmol
402 $\text{O}_2 \text{ m}^{-2} \text{ hr}^{-1}$), compared to the pools A, B and E (8.1 ± 4.1 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$).

403 Results are similar for DIC-derived NCP_{lm} (**Fig. 4A and Table 2B**), with primary
404 production ranging from 6 ± 2 $\text{mmol C m}^{-2} \text{ hr}^{-1}$ in February up to 12 ± 5 $\text{mmol C m}^{-2} \text{ hr}^{-1}$ in
405 September ($p < 0.001$). As for O_2 -derived NCP_{lm} CO_2 addition increased DIC-derived NCP_{lm} by
406 20 % on average over all seasons ($p < 0.001$, **Fig. 4A**). This increase was particularly apparent in
407 the summer, where NCP_{lm} increased from 11 ± 4 $\text{mmol m}^{-2} \text{ hr}^{-1}$ in the “present” treatment to $15 \pm$
408 5 $\text{mmol C m}^{-2} \text{ hr}^{-1}$ in the “future” treatment (+ 35 %). ~~Compared to pool A,~~
409 ~~productivity~~Productivity (NCP_{lm}) was significantly lower in pools B and E than in pool A, and
410 significantly higher in pools C and D ($p < 0.003$).

411 By day, with the exception of sunset, net community calcification was positive (NCC and
412 $\text{NCC}_{\text{lm}} > 0$: **Fig. 3C and 4B**) and occurred in an environment that was supersaturated with regards
413 to aragonite (**Fig. 3B**). This was with the exception of a few emersion periods in September 2020

414 where dissolution was observed despite high saturation state conditions (further details below).
415 Similar to NCP_{lm} , diurnal net calcification rates (NCC_{lm}) were strongly influenced by
416 temperature/season (**Fig. 4B** and **Table 2C**: GLMM, $p < 0.001$) ranging from 1.2 ± 0.5 mmol
417 $CaCO_3$ m^{-2} hr^{-1} in February to 3.3 ± 1.3 mmol $CaCO_3$ m^{-2} hr^{-1} in September. NCC hourly rates
418 positively correlated with averaged Ω_a ($p < 0.0001$; $NCC = 0.15 \times \Omega_a + 0.85$; linear regression
419 presented in **Fig. S6S7**), significantly but not strongly ($R^2 = 10\%$). CO_2 addition did not influence
420 NCC_{lm} rates during the day ($p = 0.47$). However, NCC_{lm} did differ across pools ($p < 0.003$): rates
421 were relatively low in pool E – lowest CCA cover (30%) – (1.4 ± 1.4 mmol $CaCO_3$ m^{-2} hr^{-1}), and
422 high in pool D – highest CCA cover (70%) – (2.2 ± 0.8 mmol $CaCO_3$ m^{-2} hr^{-1}) compared to the
423 three other pools (2.0 ± 1.25 mmol $CaCO_3$ m^{-2} hr^{-1}).

424 **Table 2: Results of the generalized linear mixed-effect models for A) O_2 -derived NCP_{lm}**
425 **(mmol O_2 m^{-2} hr^{-1}), B) DIC-derived NCP_{lm} (mmol C m^{-2} hr^{-1}) and C) NCC_{lm} (mmol $CaCO_3$ m^{-2}**
426 **hr^{-1}) during the day and night.** The models include three fixed factors: *Temp* (mean temperature:
427 a continuous factor), *Treat* (for CO_2 “future” treatment vs. “present”, two levels) and *pools* (vs. A,
428 five levels), and one random effect (*low-tide emersion period* or the calendar day at which the pool
429 was measured). Significant p -values are highlighted in bold.

434

435 **3/ Nocturnal tides**

436 **Nocturnal pool chemistry:** Seawater temperatures during the nights were stable (**Fig. 3A**)
437 throughout the emersion period in summer (from $17.3 \pm 0.4^\circ\text{C}$ < 1 h post-emersion to $17.2 \pm 0.2^\circ\text{C}$
438 > 5 h post-emersion) and winter (from $8.4 \pm 1.4^\circ\text{C}$ to $7.8 \pm 2.7^\circ\text{C}$ in February; no April nights).
439 We highlight the wide range of winter seawater temperatures with an exceptionally cold tidal cycle
440 (5°C on the 13th of February 2021) due to air temperatures of $3\text{-}4^\circ\text{C}$ (observations from the Île de
441 Batz meteorological station). There was a decline in salinity at night in some winter emersion
442 periods (**Fig. 3A**), due to high air humidity and/or rain. Data where salinity dropped by more than
443 1.5 units in less than an hour were removed from further analyses on net community calcification
444 and respiration.

445 After five hours of emersion, O_2 concentration had decreased by half (from $\approx 10.1 \pm 1.5$ mg
446 $\text{O}_2 \text{ L}^{-1}$ to 4.9 ± 3.3 mg $\text{O}_2 \text{ L}^{-1}$) (**Fig. 3A**) due to community respiration. Simultaneously, pH_T
447 decreased to 7.6 ± 0.2 (“present”) or stayed at 7.4 ± 0.2 (“future”; **Fig. 3B and S2, Table S1**), with
448 significant effects of pools, treatment and temperature ($p < 0.001$ for all three). DIC concentration
449 increased by $+256 \mu\text{mol kg}^{-1}$ on average over an emersion period. The range of this increase
450 depended on the temperature and the pool: in winter ($5\text{-}10^\circ\text{C}$), present-day pool seawater gained
451 $+130 \mu\text{mol kg}^{-1}$ ($+60$ for “future” pools) of DIC over an emersion period, when in summer they
452 gained $+370 \mu\text{mol kg}^{-1}$ for “present” (“future”: $+310 \mu\text{mol kg}^{-1}$) pools. (**Fig. S3**). Saturation state
453 converged towards similar undersaturated levels at night (**Fig. 3B and S2, Table S1**): Ω_a stayed
454 stable in the “future” treatment (0.7 ± 0.2 units on average) and decreased in the “present-day”
455 treatment (-1.2 units from initial Ω_a). At the end of nocturnal emersion Ω_a were still statistically
456 different due to the initial treatment ($p < 0.001$ for *Treat*, *Temp* and *Pools*).

457 **Nocturnal biological activity:** At night, oxygen was consumed, i.e., we observed dark respiration
458 (CR; **Fig. 3C**). Community respiration (O_2 -derived CR_m) varied according to season (**Fig. 4A** and
459 **Table 2A**: $p < 0.001$): temperature linearly increased nocturnal respiration rates from -1.0 ± 1.2
460 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ in February to -4.7 ± 1.3 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$ in September. The CO_2 treatment did
461 not influence night respiration ($p = 0.39$). Respiration rates were significantly influenced by pools
462 ($p = 0.03$), probably linked to the relative biomass of heterotrophs and autotrophs; respiration was
463 significantly higher in pool C (-4.6 ± 2.8 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$) and significantly lower in pool E (-2.4
464 ± 1.4 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$) than in pools A, B and D (-3.4 ± 2.1 $\text{mmol O}_2 \text{ m}^{-2} \text{ hr}^{-1}$).

465 Night respiration estimated using DIC and NCC was near zero ($CR_{lm} = -0.2 \pm 0.7 \text{ mmol m}^{-2}$
466 hr^{-1}). At these low rates, uncertainties associated with much higher rates of net dissolution
467 (negative NCC) sometimes led to spuriously positive DIC-derived CR estimates, hindering
468 interpretation. Nevertheless, DIC-derived community respiration was ten times lower in February
469 than in September (-0.2 ± 0.7 and $-2.3 \pm 1.1 \text{ mmol C m}^{-2} \text{ hr}^{-1}$ respectively), although it was not
470 linearly driven by temperature ($p = 0.053$; **Fig. 4B** and **Table 2B**). Adding CO_2 to the pools
471 influenced DIC-derived community respiration in a way that was inverse to that seen with O_2 , but
472 as stated above, this was likely an artifact of subtracting NCC from small DIC changes. As for O_2 ,
473 DIC-derived CR_{lm} significantly changed depending on the pools.

474 At night, the pools experienced significant net community dissolution ($NCC < 0$; **Fig. 3C**)
475 even when waters were supersaturated with regards to aragonite in the “present” treatment (**Fig.**
476 **3B**: $\Omega_a > 1$). Nocturnal net dissolution rates (NCC_{lm}) were not significantly affected by temperature
477 in the range investigated ($5\text{-}18^\circ\text{C}$; **Fig. 4C** and **Table 2C**: $p = 0.57$). However, adding CO_2 in the
478 pools increased net dissolution rates ($p = 0.0017$) from $-0.7 \pm 0.3 \text{ mmol CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$ to $-1.0 \pm$
479 $0.4 \text{ mmol CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$ (+40 %). Similarly, looking instead at hourly rates (NCC), dissolution
480 correlated significantly ($p < 0.0001$) with Ω_a ($NCC = 0.34 \times \Omega_a - 1.22$; $R^2 = 11 \%$; **Fig. S6S7**).
481 The strength of this correlation depended on seasons and pools (**Fig. S7S8**). Net dissolution rates
482 (NCC_{lm}) significantly differed by pool ($p < 0.0017$): the lowest rates were observed in pool E ($-$
483 $0.4 \pm 0.2 \text{ mmol CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$) – the pool with the lowest CCA cover –, and the highest dissolution
484 in pool D – the pool with the highest CCA cover (-1.0 ± 0.4 vs. $-0.9 \pm 0.3 \text{ mmol CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$
485 for A, B and C).

486

487 **4/ Influence of the treatment on CPB and CCB**

488 Pools fixed more carbon during the day than they respired at night, i.e., the community production
489 budget (CPB: balance between night and day) was positive in all the pools, both in winter and
490 summer and whatever the treatment (**Fig. 5**). CPB_{DIC} and CPB_m estimates were typically lower
491 than CPB_{O_2} (in 14/20 cases and 18/20 cases respectively). The production budget was significantly
492 lower in winter than in summer (FEB: $CPB_{O_2} = 3 \pm 1 \text{ mmol O}_2 \text{ m}^{-2} \text{ h}^{-1}$, SEP: $7 \pm 5 \text{ mmol O}_2 \text{ m}^{-2}$
493 h^{-1} ; t-test: $t = -2.4$, $df = 9.8$, $p = 0.03$). Adding CO_2 increased CPB in all the pools in summer by +
494 $3.0 \pm 2.1 \text{ mmol O}_2 \text{ m}^{-2} \text{ h}^{-1}$, an increase in production by 50 to 80 % (ΔCPB ; **Fig. 5**). In winter, there

495 was no evidence of such a “fertilization effect” across the most accurate CPB estimates for this
496 season (CPB_{O2}, CPB_m): we only observed a significant increase in production due to CO₂ addition
497 in two of the pools (+60 % to +120 % for A and B). For the three other pools, CPB either induced
498 minimal changes (< 20 % for C and E) or a decrease in production (D: down to -34 %). DIC-
499 derived ΔCPB in winter (all positive) should be interpreted with caution since some nocturnal
500 CR_{lm} were spuriously positive in the “future” treatment (see “nocturnal biological activity” above).

501 The pools calcified more during the day than they dissolved at night (CCB > 0), both in
502 summer and winter (**Fig. 5**). CCB was significantly lower in winter than in summer (FEB: CCB =
503 0.2 ± 0.2 mmol CaCO₃ m⁻² h⁻¹, SEP: 1.2 ± 0.6 mmol CaCO₃ m⁻² h⁻¹; t-test: $t = -5.2$, $df = 11.7$, $p =$
504 0.0002). In winter, adding CO₂ decreased CCB by more than 80 % in pools C, D, and E (**Fig. 5**).
505 The CO₂ addition even resulted in a transition from a positive community calcification balance to
506 dissolution in pool C (133 % change, from +0.5 to -0.2 mmol CaCO₃ m⁻² h⁻¹). For the two other
507 pools (A and B), winter CO₂ addition increased their relatively small calcification balance (A: +87
508 %, from 0.1 to 0.2 mmol CaCO₃ m⁻² h⁻¹ and B: +71 %, from 0.2 to 0.3 mmol CaCO₃ m⁻² h⁻¹). In
509 summer, changes in CCB due to treatment appeared minimal in pools A, B and E (< 15 % change)
510 and either increased (C: +67%) or decreased (D: -57%) in the two other pools. ~~In analyses not
511 presented here, when this budget takes into account winter night:day duration (14:10), all the
512 pools' budgets switch to net dissolution in future conditions.~~

513

514 **5/ The particular case of September 2020 tides**

515 During diurnal tides of September 2020 (high PAR and high temperature summer conditions), we
516 observed an unexpected phenomenon: dissolution occurred at extremely high pH_T values (9-10)
517 in pools C and E (**Fig. 6**). Under these conditions effectively all the seawater DIC in these pools
518 was consumed by photosynthesis and calcification (DIC ≈ 0 mmol kg⁻¹) four hours after emersion.
519 As such, the CO₃²⁻ concentration was also effectively zero and the pools reached very low
520 saturations states ($\Omega_a \approx 0$) despite high pH (**Fig. 6**). These conditions were quickly followed by
521 indicators of CaCO₃ dissolution (increasing TA and DIC) instead of the expected diurnal
522 precipitation. It is therefore noteworthy that dissolution may happen at high pH, and that pH and

523 Ω can decorrelate (Fig. 7) in situations with high photosynthesis and limited mixing of water
524 masses.

525

526 **DISCUSSION**

527 Temperate tidal pools are environments of extreme variability. In our pools, we observed seawater
528 temperatures that could increase by up to 10°C in a few hours compared to the adjacent ocean.
529 During diurnal emersion periods, oxygen concentrations doubled and pH could increase to pH 10
530 in present-day summer conditions. At night, pH routinely reached levels usually used as the
531 “treatment” for ocean acidification perturbation experiments (~7.6). Organisms present in the tidal
532 pools may therefore already be adapted or acclimatized to extreme variability in pH and saturation
533 state, which could affect their responses to ocean acidification (Andersson et al., 2015). For
534 example, CCA from a site with naturally high $p\text{CO}_2$ variability calcified ~50 % more than
535 individuals from a nearby site of low variability when submitted to oscillating high $p\text{CO}_2$
536 treatments (Johnson et al., 2014). Here we show that, even in intertidal communities likely already
537 acclimated or adapted to variable conditions, with potentially large phenotypic plasticity,
538 acidification can still modify net community production and calcification rates.

539 **Diurnal fertilization under CO₂ addition**

540 Adding CO₂ to simulate future seawater acidification in the pools led to a diurnal fertilization
541 effect. ~~This increase in the~~The community’s net primary production increased by 20% on average
542 across all seasons, which was particularly visible in summer (+ 35%), ~~at higher~~when
543 temperatures/metabolic rates were high. Adding CO₂, we also added substrate for photosynthesis
544 in the form of DIC (Fig. 3B) that the algae of the pools can assimilate, potentially supporting
545 higher DIC use and algal primary production. This effect was apparent from the start of the
546 emersion, suggesting a direct effect of increasing DIC concentration in the pools. It seems that
547 photosynthesis in the pools was carbon-limited and that carbon addition therefore enhanced
548 primary production, in winter and to an even greater extent in summer. During photosynthesis, the
549 uptake of inorganic carbon leads to a significant decrease in DIC - even in present-day conditions.
550 Intertidal algae are typically adapted to this with coralline algae in particular containing CCMs
551 (CO₂ concentrating mechanisms) that allow them to achieve primary production in low DIC

552 concentrations (Raven, 2011). Increasing seawater DIC may however promote an increase in
553 active and/or passive CO₂ and HCO₃⁻ fluxes towards photosynthetic compartments. Borowitzka
554 (1981) found that the photosynthetic rate of an intertidal CCA was highest at pH 6.5 to 7.5
555 (increased from pH 8.1), a change in pH that was achieved using HCl, suggesting that increased
556 photosynthetic activity could also be linked to proton gradients/pumps and/or decreased energy
557 expenditure needed to operate CCMs rather than directly related to CO₂ gradients or higher
558 substrate availability.

559 In winter and summer, pools in present-day and future conditions were autotrophic at
560 emersion (NCP_D > CR_N, **Fig. 5**). If we consider the CPB as integrated diurnal NCP and nocturnal
561 CR over 24 hours (assuming equal day:night duration), this means that the pools always fixed
562 more carbon during the day than they respired at night at emersion (NCP >> CR), regardless of
563 treatment. One methodological uncertainty we highlight regarding net production is that diurnal
564 DIC-derived NCP estimations were 50 % higher than O₂-derived NCP estimates (**Fig. 3C and Fig.**
565 **4**, NCP_{DIC} = 1.6 ± 0.05 NCP_{O₂} by day; R² = 75 %). This discrepancy was far less apparent during
566 nights, when methods agreed on respiration rates (CR_{DIC} = 1.0 ± 0.09 CR_{O₂}; R² = 56 %). While
567 O₂-derived NCP appears accurate during the night, O₂ production during the day is likely to have
568 been underestimated due to degassing (e.g., visible formation of oxygen bubbles at the surface of
569 algae, >150 % air saturation by day vs. < 100 % at night). Thus, estimating diurnal net production
570 using oxygen measurements may not be appropriate in algae-dominated environments such as
571 these tidal pools. Nevertheless, despite the difference in absolute NCP estimates, both approaches
572 indicate a diurnal fertilization effect.

573

574 **Nocturnal dissolution under CO₂ addition**

575 In the present study, natural mesocosms - temperate coralline-dominated tidal pools - were used
576 to investigate the effect of ocean acidification on net calcification at the community level. As we
577 observed a fertilization effect of CO₂ addition by day, we could have expected that it would also
578 enhance diurnal calcification – as photosynthesis and calcification are tightly linked (Martin et al.,
579 2013; Martin et al., 2013; Williamson et al., 2017) -, but this was not observed. Treatment had no
580 significant effect on the daytime net calcification rates, and diurnal variability in calcification
581 appears to be predominately driven by PAR, temperature, and metabolic activity (NCP). Increasing
582 metabolic rates - in turn increasing calcification rates - may have however counterbalanced any

583 calcification suppression or increased dissolution due to acidification, making its effect invisible.
584 Noisette et al. (2013) similarly found no effect of $p\text{CO}_2$ treatment on light calcification for *E.*
585 *elongata*. However, the authors reported a significant decrease in light calcification in *L.*
586 *incrustans*, net calcification even switched to net dissolution in 750 and 1000 $\mu\text{atm } p\text{CO}_2$
587 treatments. While our “future” treatments started at $p\text{CO}_2$ levels higher than 1000 μatm , the fact
588 that CO_2 addition did not influence diurnal calcification could also be due to favorable saturation
589 state conditions in the micro-environment in which calcification occurs. The diffusive boundary
590 layer (DBL) can enhance CaCO_3 precipitation micro-environment conditions due to the uptake of
591 CO_2/DIC for photosynthesis. For instance, in light conditions, CCA surface pH has been shown to
592 reach as high as 8.6 (Houlihan et al., 2020) in surrounding seawater at pH 7.7 (+1.1 pH units),
593 which would be highly favorable to calcification. [Although there are conflicting results indicating](#)
594 [that saturation state of the ambient seawater is a key driver of coralline algal calcification, the](#)
595 [biomineralization process in coralline algae has also been shown to present a certain degree of](#)
596 [biological control \(de Carvalho et al., 2017; Nash et al., 2019\). Recent work using boron isotopes](#)
597 [\(\$\delta^{11}\text{B}\$ \) as a proxy for pH showed that coralline algae have ability to elevate pH at their site of](#)
598 [calcification \(Cornwall et al., 2017\).](#) But more complex interactions may also be at work, e.g.,
599 CCA may use increases in HCO_3^- (due to CO_2 dissolution) to calcify, making them more resistant
600 to ocean acidification, as suggested by Comeau et al. (2013).

601 There was net CaCO_3 dissolution in the pools at night ($-0.7 \text{ mmol CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$), even
602 when waters were still supersaturated with regards to aragonite under present-day conditions.
603 Night dissolution may be a sign that the DBL of the calcifiers inhabiting the pools is
604 undersaturated, possibly as a result of respiration. Indeed, Houlihan et al. (2020) observed that
605 nocturnal algal respiration by CCA, increased CO_2 in the DBL, decreasing pH of the DBL by 0.1
606 units. Such a small pH decrease is ~~however~~ unlikely to explain alone an undersaturation of the
607 calcifying environment as aragonite saturation state was still above 1.2 in most of the “present-
608 day” conditions. However, given the solubility of high-Mg calcite - the mineral composing *L.*
609 *incrustans* and *E. elongata* in particular (Ries, 2011) - can be twice that of aragonite (Sulpis et al.,
610 2021; Yamamoto et al., 2012), it is possible that undersaturation already occurs at night for this
611 mineral even for $\Omega_a > 1$. [Another reason for night dissolution might be linked to the patellid limpet,](#)
612 [an opportunistic \(Schaal & Grall, 2015\) and dominant grazer in rockpools, that can be particularly](#)
613 [active at night\(Lorenzen, 2007\). Encrusting coralline algae can be an important food source for](#)

614 [these herbivores and the large percentage of grazed coralline algal CaCO₃ in their gut \(Maneveldt](#)
615 [et al., 2006\) could dissolve easily at night.](#)

616 Adding CO₂ (from 445 to 1500-2000 μatm) at the start of emersion significantly increased
617 net dissolution (NCC_{lm}), by 40 % in summer and 70 % in winter. In a previous single-species
618 experiment, Noisette et al. (2013) demonstrated that - for *L. incrustans* from an area close to our
619 site – dark dissolution doubled with increasing *p*CO₂ (1000 μatm vs. 380 μatm), unlike *E. elongata*,
620 for which there was no effect of *p*CO₂: the ACA even calcified in the dark up to 750 μatm (see
621 also similar results from Egilisdottir et al., 2013). Since *L. incrustans* is the major calcifying species
622 of the tidal pools we studied, it is likely this species drives the results we observed at the pool
623 community scale. Regardless of the treatment, nocturnal net dissolution rates (NCC) were also
624 significantly correlated with Ω_a, results similar to those found by Kwiatkowski et al. (2016) in
625 temperate tidal pools of California, without CO₂ addition.

626 In summer, pools in present-day and future conditions were precipitative (CCB > 0),
627 meaning that diurnal net calcification exceeded nocturnal net dissolution, regardless of treatment.
628 Adding CO₂ in summer did not consistently change CCB, with most pools showing little change
629 in CCB due to treatment. By contrast, in the colder winter, the calcification budget was at least 50
630 % lower than in summer (“present”), with some pools that had comparable net calcification during
631 the day to net dissolution at night. During this season, adding CO₂ had variable impacts on CCB,
632 decreasing it in three of the pools by more than 80 % and increasing relatively small CCB in two.
633 These variable effects may be due to differences in community composition and highlight the
634 difficulty in generalizing the results of natural mesocosm manipulations in which the initial
635 community composition is not controlled. Nevertheless, we expected CO₂ addition to have a
636 greater negative effect in winter (more dissolution) than in summer, with saturation states being
637 lower due to colder temperatures, making it more of a “crucial”/ “bottleneck” season. This
638 emphasizes the need to study the effect of ocean acidification across seasons and temperature
639 ranges, especially given the associated changes in algal community composition and metabolic
640 activity.

641 [A limit of the CCB in the current study is that we only considered the tidal pools as closed \(emersed\)](#)
642 [systems. However, in an acidifying ocean, tidal pool communities are submersed for nearly 12 hours per](#)
643 [day, resulting in long exposure to low pH. More accurate and realistic budgets would need to integrate these](#)

644 [immersion periods, which might have additive negative effects on calcification \(see e.g., Legrand et al.,](#)
645 [2018 for tidal assemblage experiments on net production/respiration\).](#)

647 **Instances of aragonite undersaturation at high pH**

648 An unexpected phenomenon happened in the pools C and E in summer: although we measured
649 very high pH values, we observed that total alkalinity suddenly increased, a sign of fast net
650 dissolution. When we then computed the carbonate chemistry, the saturation states were
651 surprisingly low ($\Omega_a = 0$ for $\text{pH}_T = 10$), which was due to near-zero DIC concentrations – and thus
652 near-zero CO_3^{2-} concentrations. In these particular conditions, which occurred towards the end of
653 the tidal emersion period, any CaCO_3 precipitation was less than dissolution; precipitation may
654 even have been impossible due to a lack of DIC substrate. In intertidal pools with a high density
655 of *Zostera marina*, Miller & Kelley (2021) observed a similar decoupling between pH and Ω_a with
656 increases in pH not leading to an increase in saturation state at high pH values due to a lack of
657 DIC/ CO_3^{2-} . In our study, we observed even more drastic decoupling between expected changes in
658 pH, Ω_a and NCC, with some of the fastest net dissolution rates observed at very high pH and very
659 low Ω_a values that were a consequence of near complete consumption of DIC by community
660 production (**Fig. 7**). Macroalgae cultivation has been proposed as a method of bioremediation to
661 local acidification, in particular to improve aquaculture environments (e.g., Bergstrom et al., 2019;
662 Gao & Beardall, 2022): increase in algal or marine plant cover would reverse or buffer the negative
663 effects of acidification on heterotroph calcifiers. Our results and those of Miller & Kelley (2021)
664 suggest that phytoremediation should not consider pH as the sole indicator for “acidification
665 remediation”, and that periodical decreases in saturation state in macroalgae- or seaweed-
666 dominated environments in summer (and during marine heatwaves), may need to be considered
667 for these proposed types of remediations.

669 **Conclusion**

670 Relative to its area, human societies are disproportionately reliant on the coastal ocean for the
671 provision of natural resources and climate regulation. Yet our understanding of how anthropogenic
672 carbon emissions and associated ocean acidification will influence natural coastal ecosystems and
673 community metabolism remains limited. In the present study, we manipulated the carbonate
674 chemistry of natural temperate intertidal pools to explore the potential impact of future ocean

675 acidification on community-level calcification and production. We find evidence of large seasonal,
676 diel and community-specific differences in the sensitivity of intertidal community metabolism to
677 acidification. Diurnally, acidification was found to enhance net community production, with this
678 “fertilization effect” indicating algal photosynthesis is naturally carbon limited in such
679 environments at emersion. Diurnal net community calcification was unaffected by acidification.
680 In contrast, nocturnal acidification resulted in greater net community dissolution in the intertidal
681 pools yet had no consistent effect on community respiration. Integrated over day/night emersion
682 periods, the intertidal mesocosms maintained positive net community calcification and production
683 under both present-day and future conditions. Albeit considerable differences between individual
684 pools and strong seasonal dependencies, our results indicate that the net calcification and
685 production of temperate intertidal communities - likely acclimated/adapted to variable conditions
686 - could be affected by future acidification.

687

688 **ACKNOWLEDGEMENTS**

689 We thank Elsa Perruchini, Léonard Dupont, Corentin Clerc, Priscilla Le Mezo, Alban Planchat,
690 Maud Chevalier, Anne Cornillon, Annabel Antheaume, Maïlys Roux and Clarisse Dufaux for their
691 kind assistance with fieldwork. This project is fully funded by the CHANEL research chair:

Formatted: Bibliography, Left

1 Figures with legends -

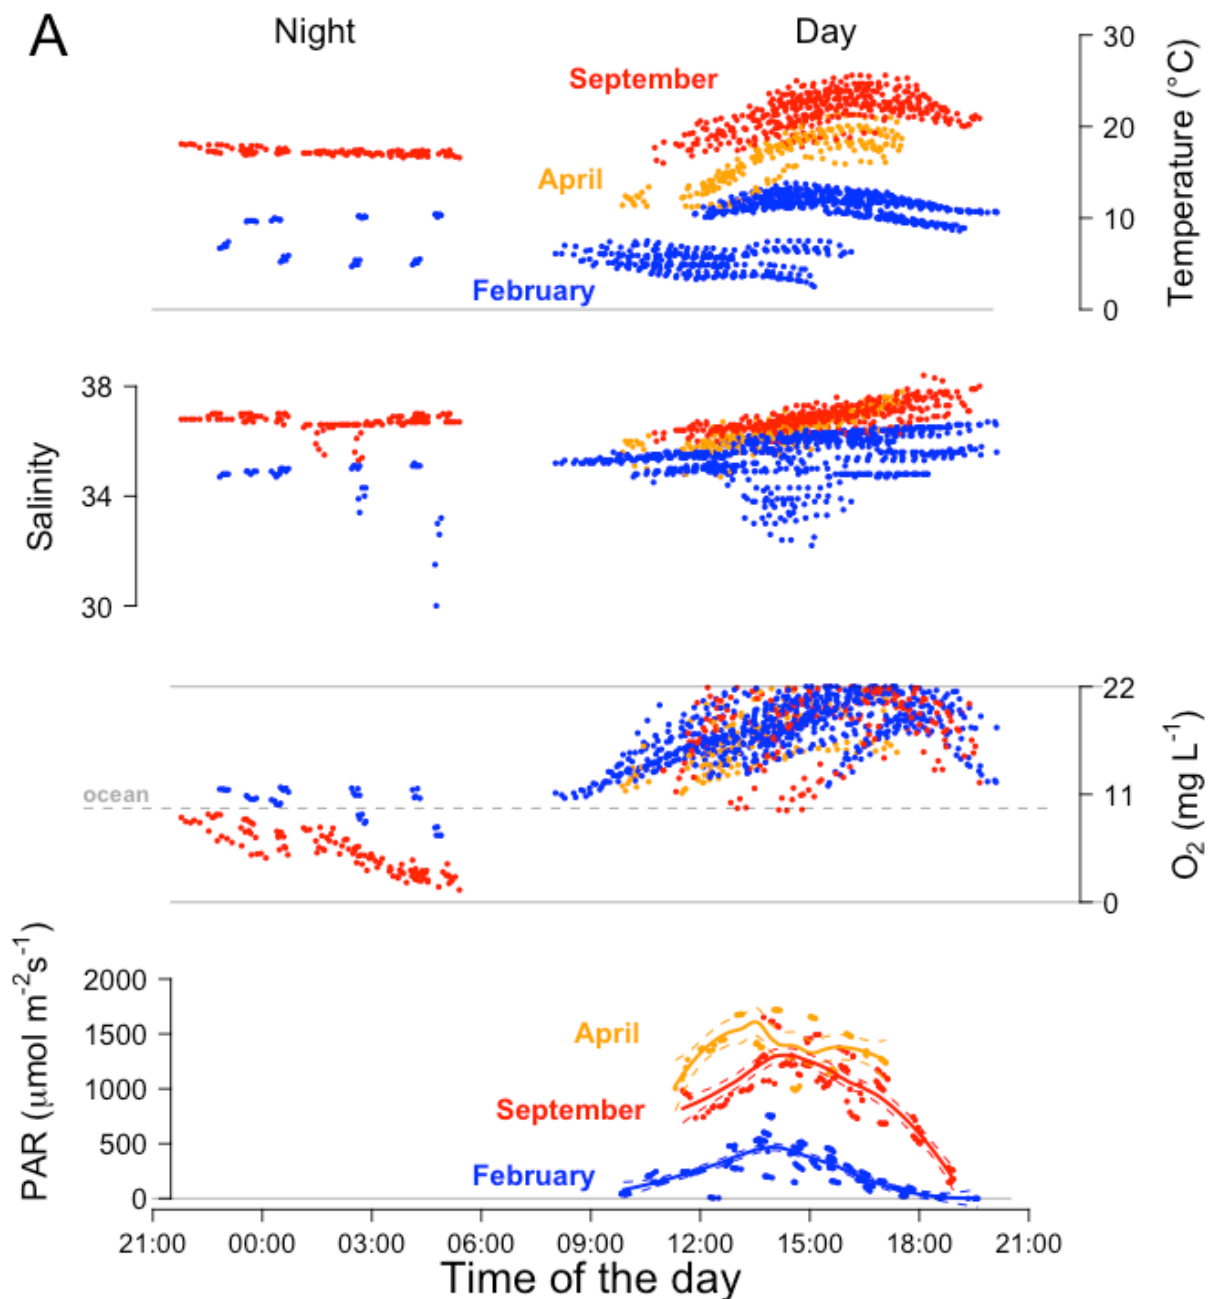

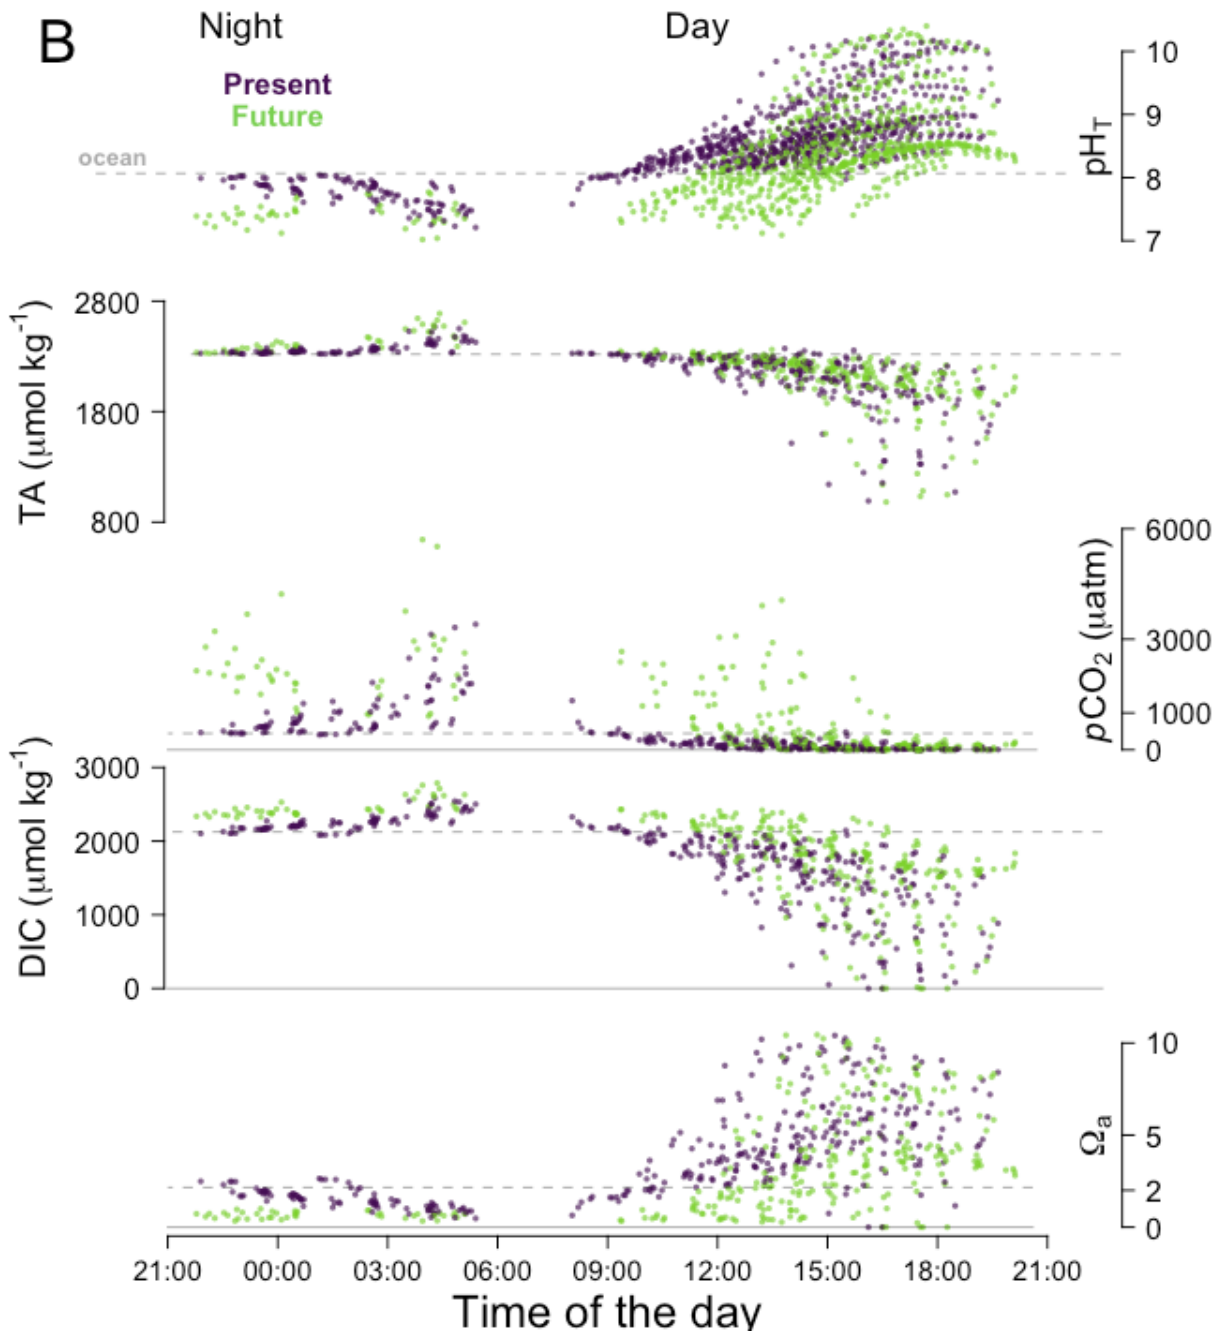

2 **Figure 1 - Field site location** on a map of Europe (left). The study site (Bloscon) is located in Roscoff,
3 Brittany, France (right, top: river mapping data from *HydroSHEDS*, 1. Penzé river and 2. Morlaix
4 river; bottom: satellite image from *Google Earth*: earth.google.com/web/, acquired in June 2022). The
5 SOMLIT stations Astan and Estacade are indicated with triangles (www.somlit.fr).

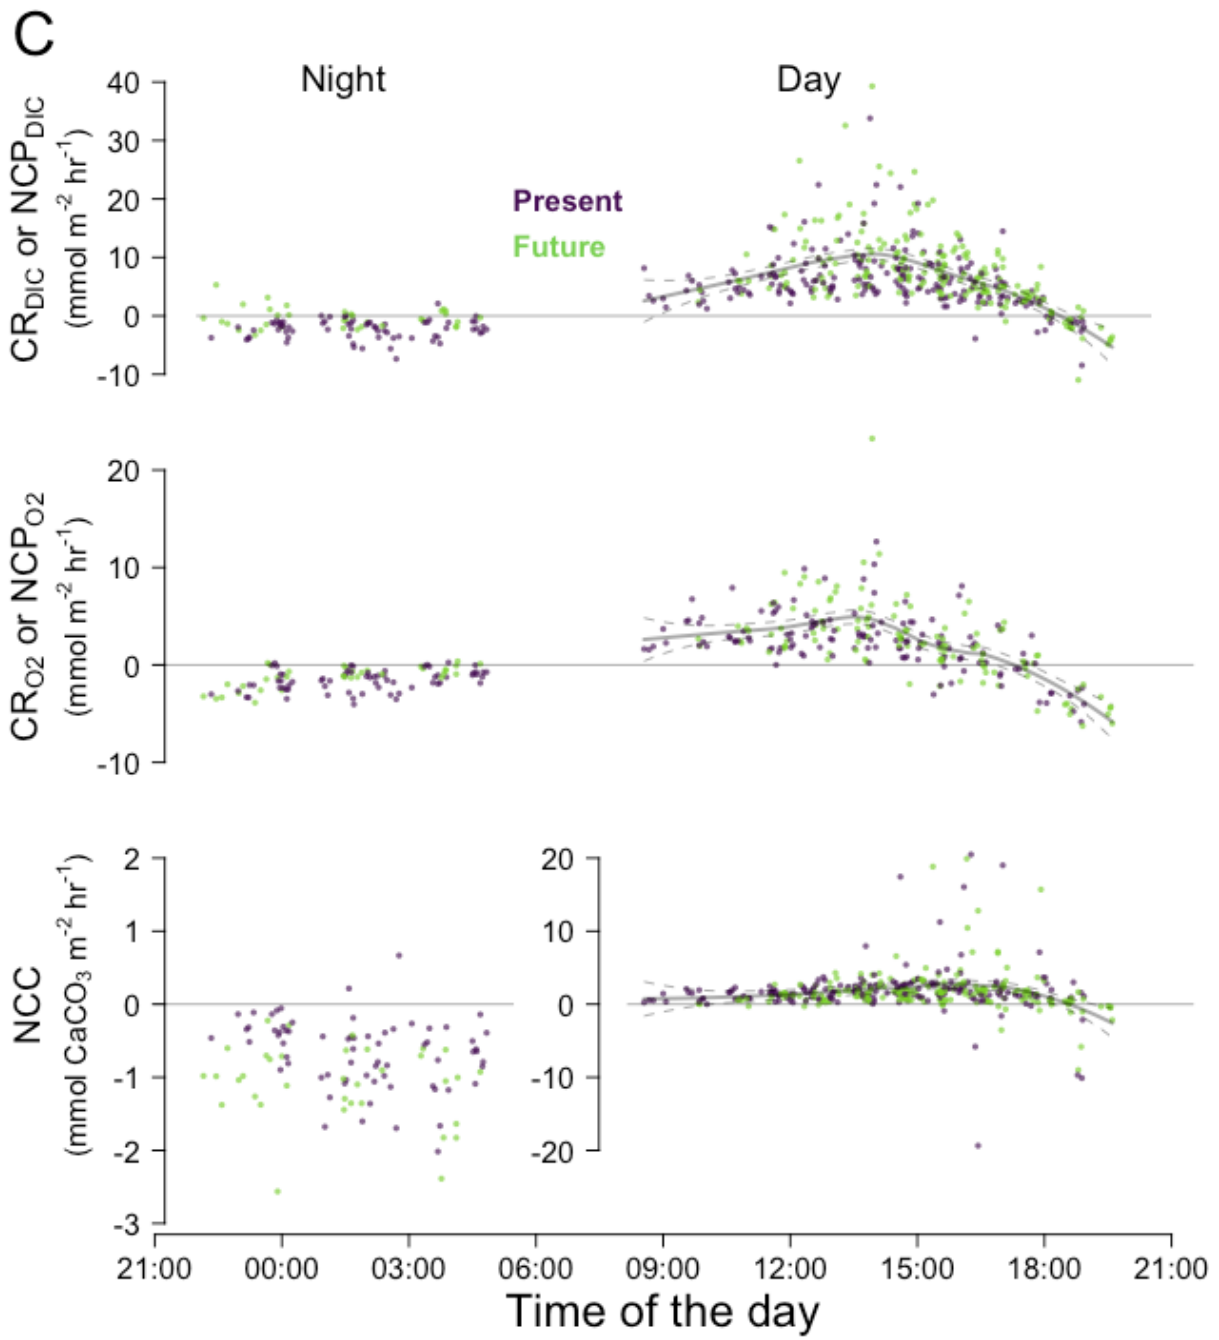

7 **Figure 2 - Pool area, volume and coverage** - Surface of the five pools (A-E, September 2020) covered
 8 by crustose coralline algae (CCA, pink), articulated coralline algae (ACA, purple) and green algae
 9 (green) or free of algae (“bare rock”, grey). The length of the bars represents total pool surface area
 10 (m²) and the volume of each pool (L) is indicated above. The relative coverage (%) of calcifying algae
 11 (ACA + CCA) in each pool is given. Details for the other seasons are available in **Supp. Mat. Pools**
 12 **Fig. SP1 and SP2.**

13 **Figure 3** - Composite daily pool conditions and biological activity for all pools. A) temperature
 14 ($^{\circ}\text{C}$), salinity and oxygen concentration (mg L^{-1}) and Photosynthetically Active Radiation (PAR,
 15 $\mu\text{mol m}^{-2} \text{s}^{-1}$), B) pH_T , Total Alkalinity (TA, $\mu\text{mol kg}^{-1}$), pCO_2 (μatm), dissolved inorganic carbon
 16 (DIC, $\mu\text{mol kg}^{-1}$) and aragonite saturation state (Ω_a), and C) DIC and O_2 -derived NCP or CR
 17 ($\text{mmol C or O m}^{-2} \text{hr}^{-1}$) and NCC ($\text{mmol CaCO}_3 \text{m}^{-2} \text{hr}^{-1}$). Colors represent seasons (A: blue for
 18 February, orange for April, red for September) and treatment (B and C: purple for “present” and green
 19 for “future”). Horizontal dotted grey lines represent the mean values of the adjacent ocean. Curves
 20 were fitted by season for PAR and for diurnal NCP and NCC using a local polynomial regression
 21 (*loess*) with 95% confidence interval. Number of observations: $n = 1551$ for temperature, salinity and
 22 pH_T , $n = 1169$ for oxygen concentration (data recorded $< 22 \text{ mg L}^{-1}$) and $n = 632$ (hourly data) for the
 23 carbonate chemistry parameters, NCC and NCP or CR (B). All pools are shown.

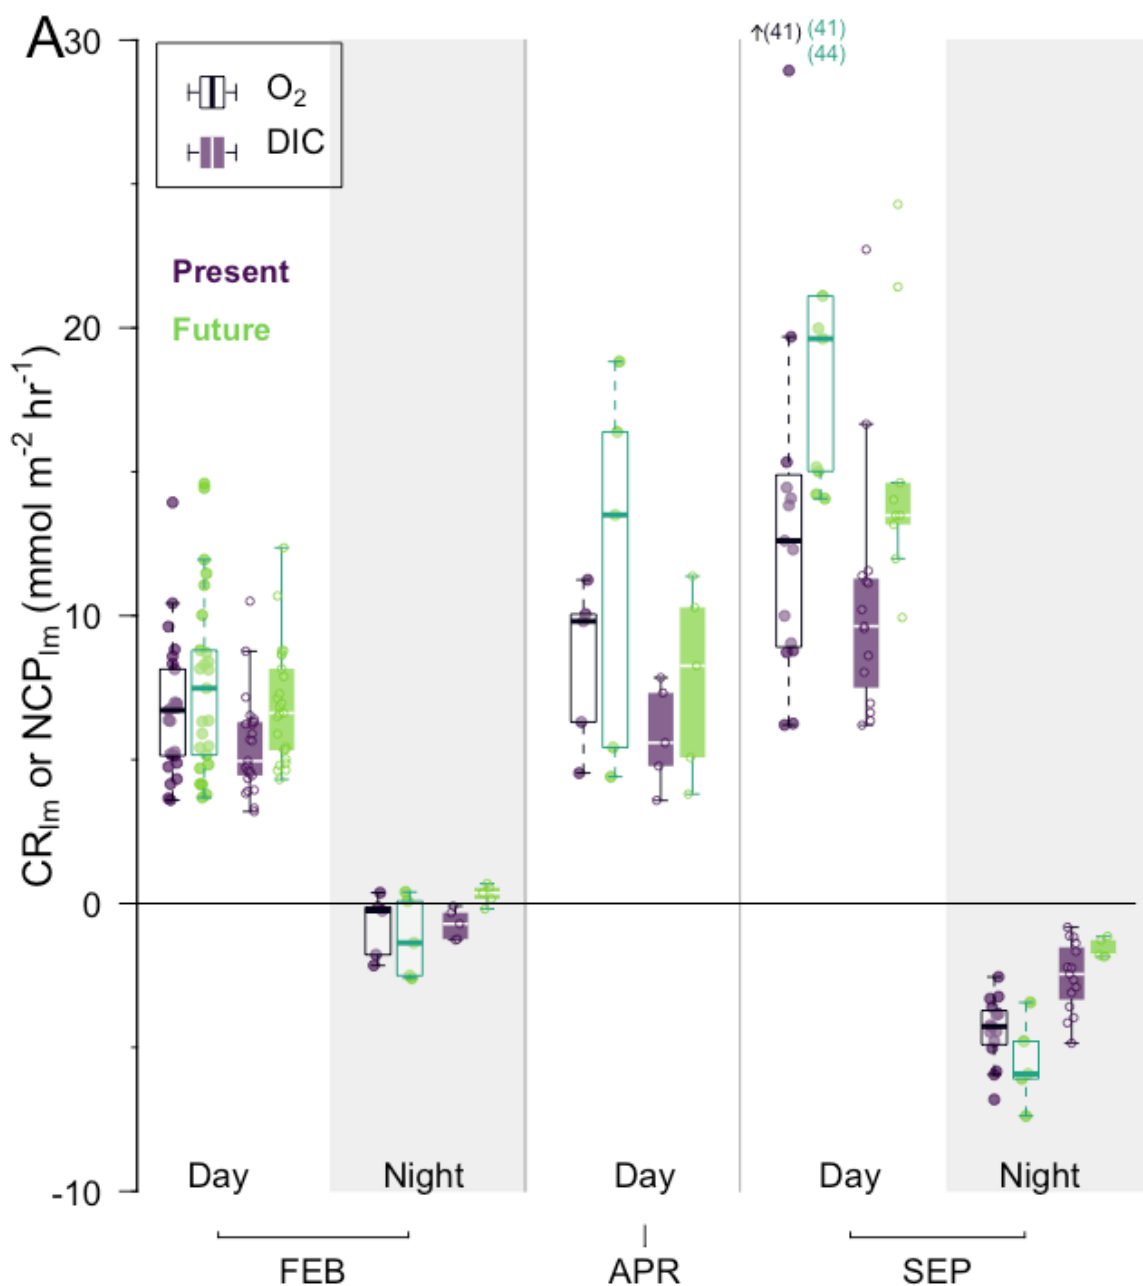

26

27

28 **Figure 4 – A) O₂-derived (white boxes) and DIC-derived (colored boxes) NCP_{lm} (mmol m⁻² hr⁻¹),**
 29 **and B) NCC_{lm} (mmol CaCO₃ m⁻² hr⁻¹) during the day and night (shaded areas), by season and**
 30 **by treatment** (purple for “present” and green for “future”) – Rates are presented as boxplots showing
 31 median, 1st and 3rd quartile and 1.5 inter-quartile range (bars), with overlaid individual observations
 32 (round symbols). Individual rates were calculated for each pool, each tide and each treatment: n = 50
 33 (FEB-day), n = 10 (FEB-night), n = 10 (APR-Day), n = 25 (SEP-Day), n = 20 (SEP-Night). Seasons:
 34 FEB for winter (pooled February 2020 and 2021), APR for spring (April 2021) and SEP for summer
 35 (pooled September 2020 and 2021). *Note that for NCC_{lm}, nights (<0) and days (>0) have different y-*
 36 *axis scales for better visualization of night differences. Statistical details of the linear regressions can*
 37 *be found in the corresponding **Supplementary Materials**. For O₂-derived NCP_{lm}, in September, three*
 38 *rates were out of the range plotted and their values are indicated next to the small arrow.*

39

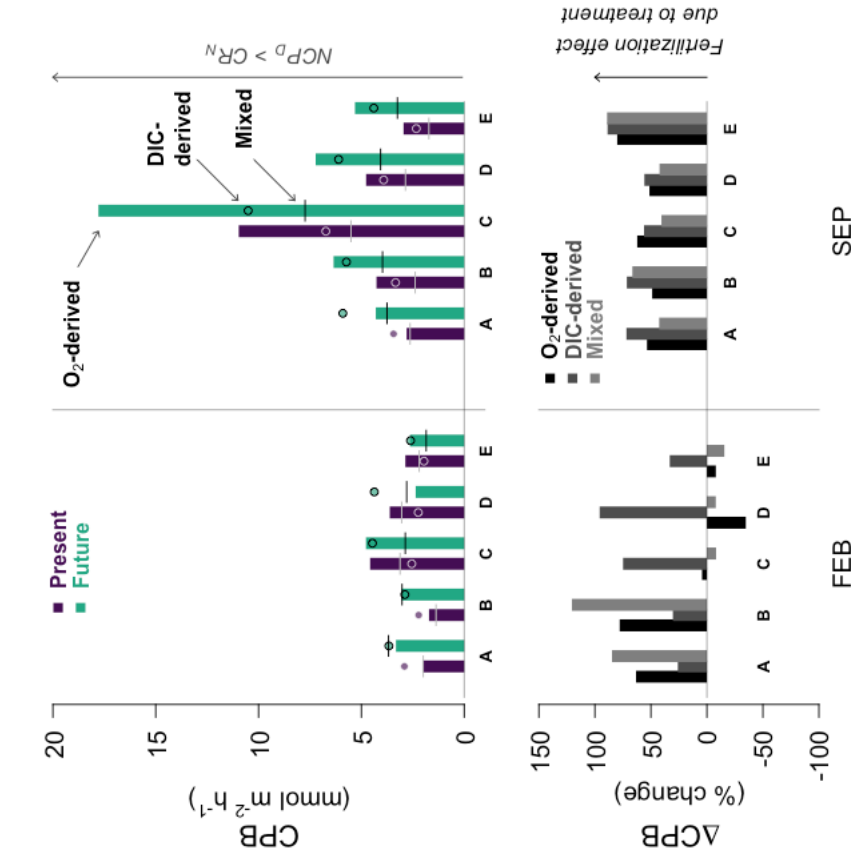

40

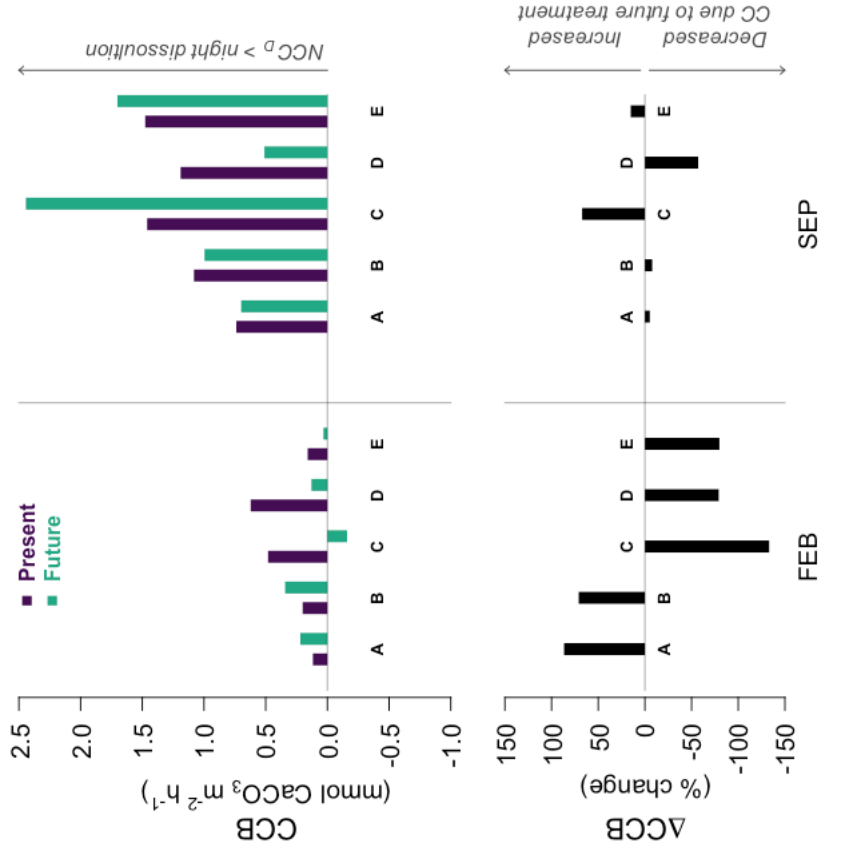

41

42

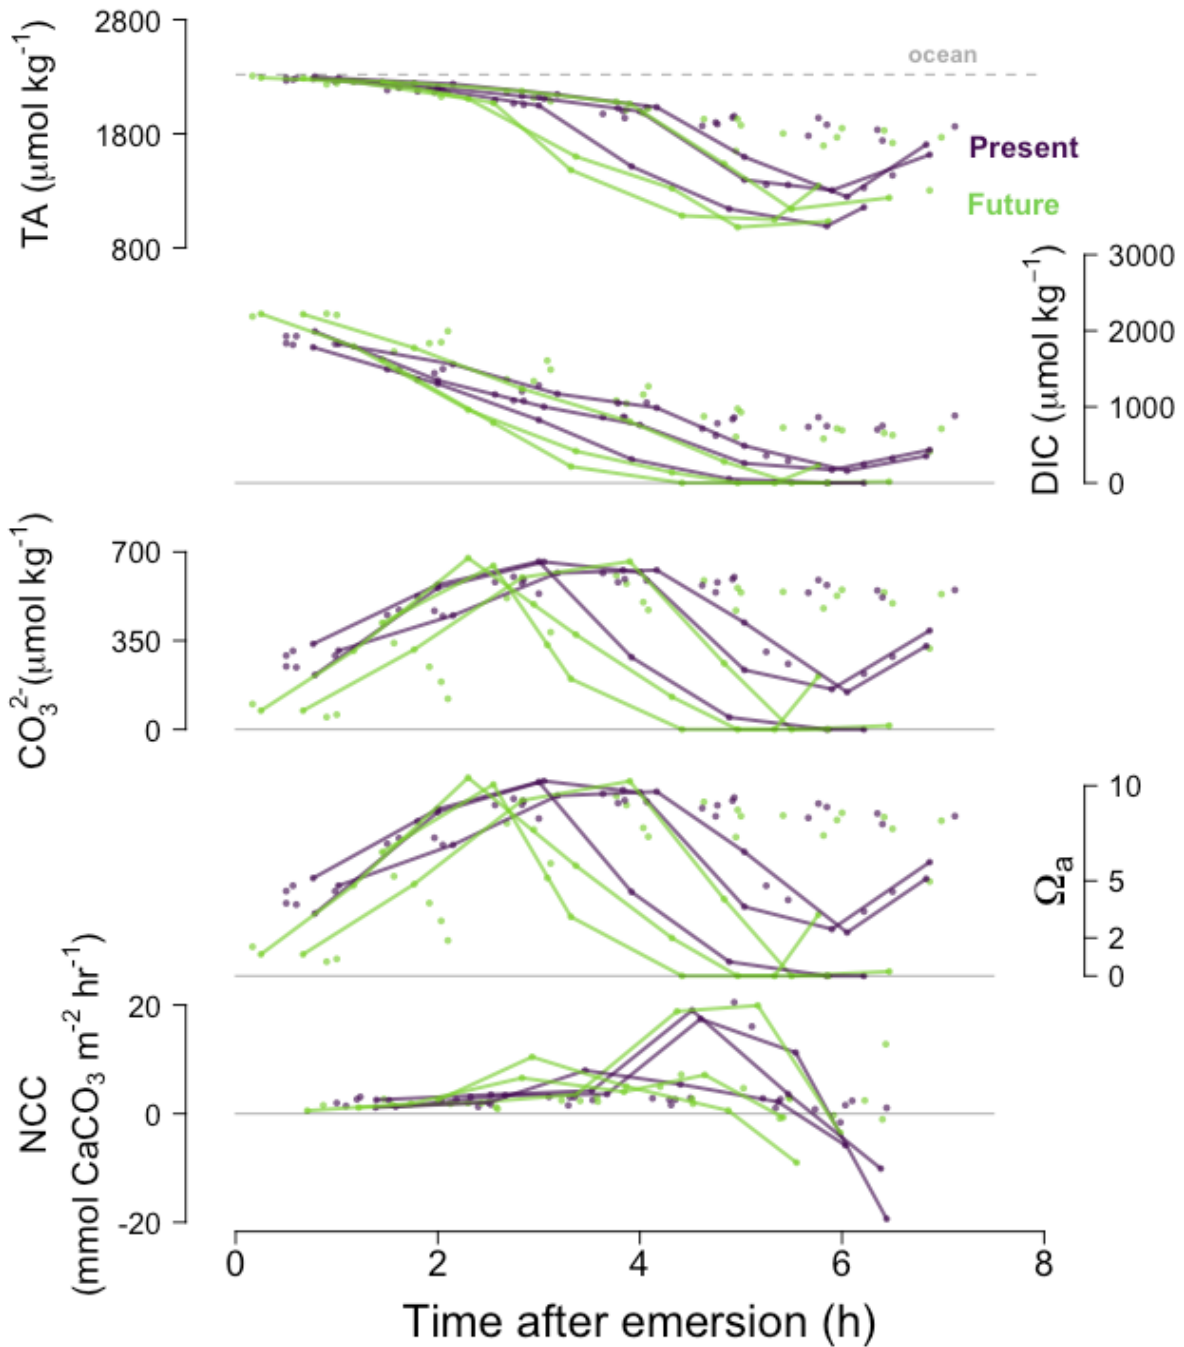

Community production budget

Community calcification budget

43 **Figure 5 – Community production budget: CPB¹⁾, and calcification budget: CCB (upper right panel, mmol CaCO₃ m⁻² hr⁻¹) by treatment**
 44 (purple for “present” and green for “future”) for each pool and season (same legend as Fig. 4). CPB >0 if diurnal NCP > nocturnal respiration and
 45 CCB > 0 if diurnal NCC > nocturnal dissolution. CPB was estimated three different ways: from O₂-derived NCP (bars), from DIC-derived NCP
 46 (round symbols) and from nocturnal O₂-derived CR combined with diurnal DIC-derived NCP (“mixed”, vertical segments). **The bottom panels**
 47 **present the change (%) of diel production (ΔCPB: left) and diel calcification (ΔCCB: right) due to CO₂ addition.** Positive ΔCCB indicates
 48 a fertilization effect due to the CO₂ addition; negative ΔCCB is expected if the CO₂ addition decreases net calcification/increases net dissolution.
 49 All three methods to estimate CPB indicate a fertilization effect in summer.

50

51 **Figure 6 - Time series for September 2020 diurnal data only: A) Total Alkalinity (TA, $\mu\text{mol kg}^{-1}$),**
 52 **dissolved inorganic carbon, CO_3^{2-} concentration ($\mu\text{mol kg}^{-1}$), aragonite saturation state (Ω_a)**
 53 **and NCC ($\text{mmol m}^{-2} \text{hr}^{-1}$) with time after emersion, by treatment (purple for “present” and green**
 54 **for “future”). The lines in bold represent individual pools C and E that switched from calcification to**
 55 **dissolution when pH_T was still above 9. A similar figure in **Supp. Mat. (Fig. S4)** shows that**
 56 **sunset/irradiance are not correlated with the sudden change towards dissolution.**

57

58 **Figure 7 – At very high pH there was both fast net calcification (red) and rapid net dissolution**
 59 **(blue):** In some extreme cases, pH_T was not a good indicator of seawater saturation state (Ω_a). Selected
 60 dataset of diurnal low-tide emersion periods from September 2020. Colors represent NCC (in mmol
 61 $\text{CaCO}_3 \text{ m}^{-2} \text{ hr}^{-1}$, as presented in **Fig. 3C**). Dashed horizontal lines represent saturation state for
 62 aragonite ($\Omega_a = 1$) and for high-Mg calcite ($\Omega_a = 2$).
