16 **Abstract**

17 Thermokarst processes likely result in new habitats harboring novel bacterial communities
18 in degraded permafrost soil (PB), thermokarst lake sediments (SB), and lake water (WB).
19 Our study aimed to investigate the paired PB, SB, and WB across the Qinghai-Tibet Plateau
20 (QTP) by assessing the spatial pattern of diversity as well as assembly mechanisms of these
21 bacterial communities. Each habitat had distinct bacterial assemblages, with lower alpha
22 diversity and higher beta diversity in WB than in SB and PB. However, up to 41% of the
23 OTUs were shared by PB, SB, and WB, suggesting that many taxa originate from the same
24 sources via dispersal. SB and WB had reciprocal dispersal effects and both were correlated
25 with PB. Dispersal limitation was the most dominant assembly process shaping PB and SB
26 while homogeneous selection was the most dominant for WB. Bacterial communities of
27 the three habitats correlated differently with environmental variables, but latitude, mean
28 annual precipitation, and pH were the common factors associated with their beta diversity,
29 while total phosphorus was the common factor associated with their assembly processes.
30 Our results imply that thermokarst processes result in diverse habitats that have distinct
31 bacterial communities that differ in diversity, assembly mechanisms, and environmental
32 drivers.

33 **Keywords:** thermokarst; permafrost; bacteria, community assembly, Qinghai-Tibet
34 Plateau

35 **1 Introduction**

36 Permafrost is an important landscape in high latitude and altitude regions, covering 15%
37 of the land area of the Northern Hemisphere (Obu, 2021) and 40% of the Qinghai-Tibet
38 Plateau (QTP) (Zou et al., 2017; Gao et al., 2021), and containing twice as much carbon as

39 is currently present in the atmosphere (Schuur et al., 2009; Hugelius et al., 2014; Mishra et
40 al., 2021). Permafrost is highly sensitive to climate warming (Wu et al., 2007; Jorgenson
41 et al., 2010; Biskaborn et al., 2019), which is expected to reduce 50-90% of permafrost
42 cover by 2100 (Lawrence et al., 2012; Chadburn et al., 2017). As a result of ice-rich
43 permafrost thaw, thermokarst lakes and ponds are formed (Kokelj and Jorgenson, 2013;
44 Farquharson et al., 2016) and extensively distributed across the Arctic and sub-Arctic
45 regions (de Jong et al., 2018) as well as the QTP (Niu et al., 2011; Luo et al., 2020). The
46 initial sediment and water in thermokarst lakes originate from the melting of permafrost,
47 and they are continuously replenished through the collapse of permafrost and precipitation
48 (West and Plug, 2008; de Jong et al., 2018). Thus, thermokarst lake sediments and water,
49 as well as the surrounding degraded permafrost soil, represent three distinct habitats
50 derived from the original permafrost during the process of thermokarst formation (Figure
51 1). It is well known that thermokarst processes substantially influence regional
52 hydrological, ecological, and biogeochemical processes (Chin et al., 2016; In'T Zandt et
53 al., 2020; Manasypov et al., 2021) and initiate a strong positive climate feedback to global
54 warming (Walter et al., 2006; Schuur et al., 2008; Schaefer et al., 2011; Anthony et al.,
55 2018). However, the microbial differences and relationships among these distinct habitats
56 in thermokarst landscapes are largely unknown.

57 Understanding microbes in thermokarst landscapes, and elsewhere, is important because
58 microbial communities play pivotal roles in driving biogeochemical and ecological
59 processes. To understand thermokarst microbial communities, we need to understand the
60 assembly mechanisms structuring them, a central research topic in microbial ecology
61 (Stegen et al., 2012; Nemergut et al., 2013; Zhou et al., 2014; Zhou and Ning, 2017). In

62 the assembly of microbial communities, both deterministic and stochastic processes occur
63 simultaneously but with contributions that can vary (Chase, 2010; Zhou et al., 2013;
64 Vellend et al., 2014; Makoto et al., 2019). Typically, deterministic processes place a strong
65 emphasis on niche-based mechanisms, including ecological selection, environmental
66 filtering, and biotic interactions (Zhou and Ning, 2017). Conversely, stochastic processes
67 involve neutral mechanisms like random birth and death, unforeseen disturbance,
68 probability-based dispersal, and ecological drift (Chave, 2004; Chase, 2010; Zhou et al.,
69 2014). In various ecosystems or habitats, the significance of deterministic and stochastic
70 processes can differ greatly and be shaped by a multitude of environmental factors (Tripathi
71 et al., 2018; Aguilar and Sommaruga, 2020; Jiao and Lu, 2020; She et al., 2021). During
72 thermokarst formation, vast areas of permafrost have been transformed to thermokarst
73 lakes, leading to major changes in physicochemical environments as well as in biological
74 communities of these regions. Thus, it is also expected that the microbial communities
75 experience major changes in occupying degraded permafrost soil, thermokarst lake
76 sediments, and lake water, and in doing so, display different assembly mechanisms (Figure
77 1).

78 Better understanding community assembly in these systems is important because thawing
79 permafrost and thermokarst lakes are greenhouse gas emission hotspots (In'T Zandt et al.,
80 2020; Mu et al., 2020; Elder et al., 2021). Close relationships between biogeochemical
81 processes and microbial community assembly have been generally demonstrated (Bier et
82 al., 2015; Graham et al., 2016; Le Moigne et al., 2020; Ren et al., 2022a). Assembly
83 processes inevitably influence biogeochemical functions by shaping community diversity
84 and composition (Graham et al., 2016; Leibold et al., 2017; Mori et al., 2018). For example,

85 dispersal (a stochastic process) can suppress biogeochemical functioning by increasing the
86 proportion of maladapted taxa (Strickland et al., 2009; Nemergut et al., 2013; Graham and
87 Stegen, 2017), while selection (a deterministic process) may have positive influence on
88 biogeochemical function by facilitating locally adapted taxa (Graham et al., 2016). In
89 particular, stochastic dispersal has been suggested to suppress the mineralization of organic
90 carbon in soil and water (Le Moigne et al., 2020; Luan et al., 2020). Therefore, it is
91 hypothesized that the relative influence of deterministic and stochastic processes on
92 community assembly could impact the biogeochemical functions of microbial
93 communities (Strickland et al., 2009; Nemergut et al., 2013; Pholchan et al., 2013; Graham
94 and Stegen, 2017). Given the importance to understand how microbial community
95 variations affect the biogeochemical cycles in permafrost and thermokarst landscapes, it is
96 necessary to have a deeper understanding of the assembly mechanisms in shaping
97 microbial communities that form following permafrost degradation.

98 In this paper we evaluated these ideas on the Qinghai-Tibet Plateau (QTP), which is known
99 as the “Third Pole” of the Earth and is therefore uniquely positioned as an indicator of
100 global change (Yao et al., 2012). Pronounced environmental changes in response to climate
101 warming on the QTP have been observed and documented, especially in the past half
102 century (Piao et al., 2012; Zhang et al., 2018; Ren et al., 2019a). Major changes are
103 predicted to continue on the QTP and permafrost thawing is among the most prominent but
104 little is known about the microbial communities in these rapidly emerging ecosystems. To
105 fill this gap, we investigated water and sediment in thermokarst lakes across the QTP as
106 well as permafrost soil around the lakes (Figure 1). Our aims were to (1) assess the spatial
107 pattern of alpha and beta diversity of bacterial communities, and (2) evaluate the

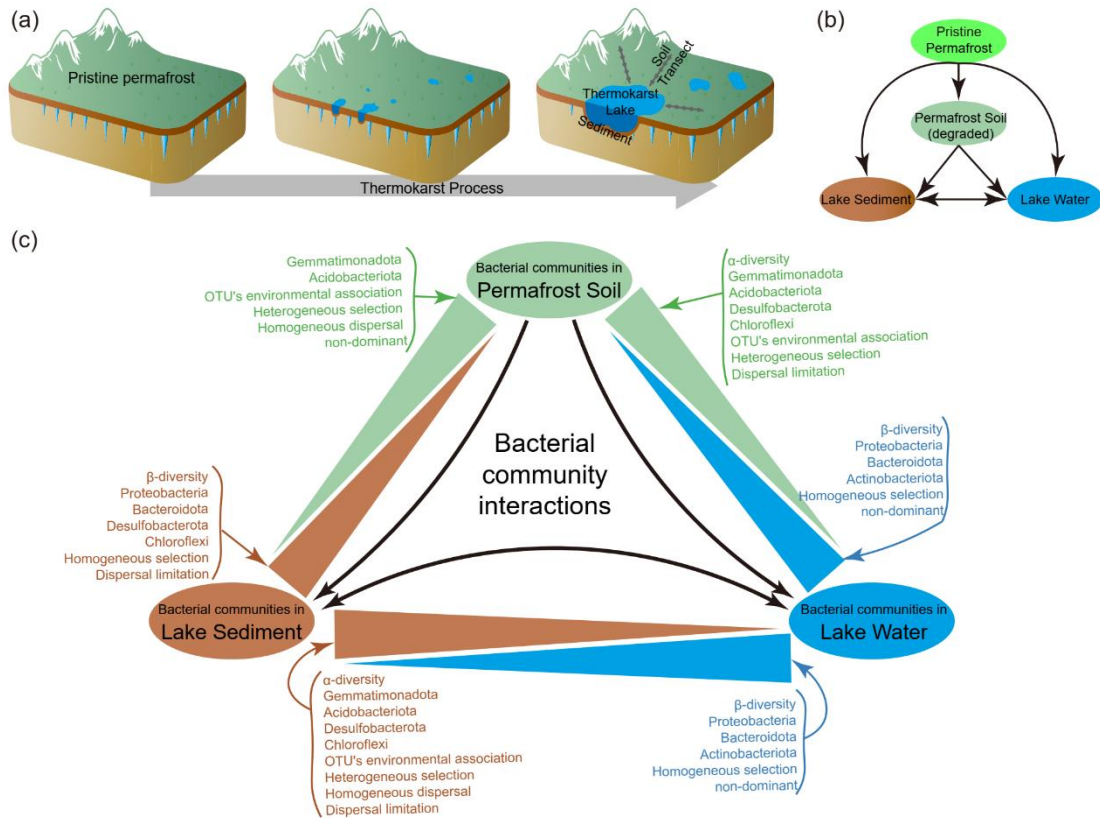

108 community assembly mechanisms and environmental responses of the bacterial
109 communities in degraded permafrost soil, as well as in the sediment and water of
110 thermokarst lakes.

111 **2 Methods**

112 *2.1 Study area, field sampling, and chemical analysis*

113 This work was conducted across the QTP in July 2021 (Figure S1). In total, 44 sites were
114 investigated by collecting paired samples of lake water, lake sediment, and surrounding
115 permafrost soil (Figure 1a) (Ren et al., 2022a). The sampling strategy and chemical
116 analysis methods were described in detail in our previous publications (Ren et al., 2022a,
117 b). For water sampling of each lake, surface water samples were collected at a depth of 0.3
118 to 0.5 m with three replicates. For microbial analysis, 200 mL of water was filtered using
119 a 0.2- μ m polycarbonate membrane filter (Whatman, UK) for DNA extraction. The
120 remaining water samples were transported to the lab for other physicochemical
121 measurements. For sediment sampling, the top 15 cm of sediment was collected from 3
122 points. Sediment samples for microbial analysis were collected in a 45-mL sterile
123 centrifuge tube, and the remaining samples were air-dried for analyzing physicochemical
124 properties. For permafrost sampling, five topsoil cores were collected along three 25-m
125 transects with increasing distances to the lake shore, respectively. The soils from one
126 transects were homogenized. Soil samples for microbial analysis were stored in 45-mL
127 sterile centrifuge tubes and the remaining soils were used for analyzing physicochemical
128 properties. For each sampling site, pH, conductivity (Cond), organic carbon (DOC in water
129 and SOC in sediment and soil), total nitrogen (TN), and total phosphorus (TP) were
130 measured according to our previous publications (Ren et al., 2022a, b). Moreover, the QTP

131 climate dataset (Zhou, 2018) was obtained from the National Tibetan Plateau Data Center
 132 (<https://data.tpdc.ac.cn/en/>), and was utilized to extract the mean annual temperature (MAT)
 133 and mean annual precipitation (MAP) for each of the study sites.

134
 135 Figure 1 (a) The process of thermokarst lake formation in ice-rich permafrost (modified
 136 from Ren et al, 2022a). (b) A schematic view of the relationships between permafrost soil,
 137 lake sediment, and lake water. (c) Summary of the differences between distinct habitats of
 138 the bacterial communities in permafrost soil, lake sediment, and lake water.

139 **2.2 DNA extraction, PCR, and sequencing**

140 The Magen Hipure Soil DNA Kit (Magen, China) was used to extract DNA from soil (0.5
 141 g frozen soil), sediment (0.5 g frozen sediment), and water (membrane filter) samples
 142 according to the manufacturer's protocols. Extraction blanks were routinely performed in

143 parallel. The prokaryotic 16S rRNA gene's V3-V4 hypervariable regions were amplified
144 using universal primers 343F-TACGGRAGGCAGCAG and 798R-
145 AGGGTATCTAATCCT (Nossa et al., 2010). PCRs were conducted in 25 µl reaction
146 mixture containing 2.5 µl of TransStart buffer, 2 µl of dNTPs, 1 µl of each primer, 0.5 µl
147 of TransStart Taq DNA polymerase, and 20 ng template DNA. The PCR reactions were
148 conducted on a thermal cycler (ABI GeneAmp® 9700, USA) using the followed procedure:
149 initial denaturation at 94 °C for 5 min, 24 cycles of denaturation at 94 °C for 30 s followed
150 by annealing at 56 °C for 30 s and extension at 72 °C for 20 s, and a final extension at
151 72 °C for 5 min. To reduce amplification bias, three individual PCR amplifications were
152 performed for each sample and the triplicate PCR products were combined and purified.
153 DNA libraries were verified on 2% agarose gels and quantified using a Qubit 4 Fluorometer
154 (Thermo Fisher Scientific, Waltham, USA). Next generation sequencing of the amplicon
155 products was conducted on an Illumina Miseq Platform (Illumina, San Diego, CA, USA).
156 Automated cluster generation and 250/300 paired-end sequencing with dual reads were
157 performed following the manufacturer's instructions. The forward and reverse reads were
158 joined and assigned to samples based on barcode and truncated by cutting off the barcode
159 and primer sequence. Raw sequences were trimmed of ambiguous bases and low-quality
160 sequences (quality score lower than 20). After trimming, the paired-end reads were joined
161 and de-noised using QIIME1.9.1 (Caporaso et al., 2010). The sequences were subjected to
162 the following denoising criteria: sequences with ambiguous or homologous regions, as well
163 as those below 200 bp in length, were excluded; sequences with at least 75% of bases
164 having a quality score above Q20 were retained; and chimeric sequences were identified
165 and eliminated. All sequences from extraction blanks were removed. The effective

166 sequences were grouped into Operational Taxonomic Units (OTUs) using a 97% sequence
167 similarity threshold and annotated the taxonomic classifications against the SILVA 138
168 database (released on 02-Nov-2020) (Quast et al., 2013). The singletons were removed,
169 and the sequences were rarefied to the lowest number of sequences per sample (24,251
170 sequences) to eliminate the bias from the sampling effort.

171 **2.3 Analyses**

172 Three α -diversity indices, including observed number of OTUs (OTU richness), Shannon
173 diversity, and phylogenetic diversity (PD), were calculated using QIIME 1.9.1 (Caporaso
174 et al., 2010). The “ses.mntd” function in the picante 1.8.2 package was used to calculate
175 the standardized effect size measure of the mean nearest taxon distance (SES.MNTD) for
176 assessing the phylogenetic clustering of bacterial communities (Kembel et al., 2010). The
177 β -diversity was calculated as the Bray-Curtis distance based on the relative abundance of
178 OTUs. In order to determine the habitat niche occupied by each taxon, we utilized the
179 “spaa” package (Zhang, 2016) in R to calculate the Levin's niche width (Levins, 1968). The
180 formula of niche breadth is $B_i = 1 / \sum_1^n p_i^2$, where B_i represents the niche breadth of OTU_i
181 across the communities, n is the total number of communities, and p_i is the proportion of
182 OTU_i in each community. Differences in α -diversity and β -diversity among bacterial
183 communities in different habitats, including permafrost soil bacterial communities (PB),
184 lake sediment bacterial communities (SB), and lake water bacterial communities (WB),
185 were assessed using Wilcoxon rank-sum test. The relationships between taxonomic and
186 environmental variables were assessed using Spearman correlation, and the P-values were
187 corrected using the FDR method (Benjamini and Hochberg, 1995). Mantel tests were
188 performed to examine the correlation between environmental variables and β -diversity. A

189 Non-metric Multidimensional Scaling (NMDS) analysis was conducted to examine the
190 distribution of PB, SB, and WB using the “metaMDS” function in the vegan 2.5-7 package
191 based on the Bray-Curtis distance using the relative abundance of OTUs. (Oksanen et al.,
192 2020). The distinctiveness of these communities was confirmed through a non-parametric
193 statistical test (ANOSIM) using the “anosim” function in the vegan package. The habitat
194 niche occupied by each species was estimated by calculating Levin’s niche breadth (Levins,
195 1968) with the use of the spa 0.2.2 package (Zhang, 2016). Species with a broader niche
196 breadth were distributed more evenly across a wider range of habitats, compared to those
197 with a narrower niche breadth.

198 Structural equation modeling (SEM) was conducted to assess the relationships among
199 location (including latitude, longitude, and elevation), climate (including mean annual
200 temperature and mean annual precipitation), and physicochemical variables (including pH,
201 conductivity, nutrients concentrations and stoichiometric ratios) of each habitat
202 (permafrost soil, lake sediment, and lake water), as well as their bacterial communities (PB,
203 SB, and WB). In model building, the SEM incorporated prior knowledges: (a) location and
204 climate factors potentially influence all the studied bacterial communities, (b)
205 physicochemical factor of each habitat potentially influences the corresponding bacterial
206 communities, and (c) permafrost soil potentially influences thermokarst lake sediment and
207 water, while lake sediment and water interact with each other. In the SEM, location, climate,
208 and physicochemical environments were reduced in dimensions by principal component
209 analysis (PCA), respectively, using the “prcomp” function of the vegan package, and the
210 first axis (PCA1) was used in SEM. For community structure, the first axis of NMDS was
211 used. SEM was constructed using the lavaan package (Rosseel, 2012). The fit of SEM was

212 assessed using standard indices, including chi-square (χ^2), goodness-of-fit index (GFI),
213 comparative fit index (CFI), root mean square residual (RMR), and root mean squared error
214 of approximation (RMSEA) (Hu and Bentler, 1999; Barrett, 2007).

215 Phylogenetic trees of bacteria were constructed in the R package ggtree 3.2.1 (Yu et al.,
216 2017) using the top 1000 abundant OTUs in PB, SB, and WB, respectively. For each
217 phylogenetic tree, a heatmap was built in the inner ring represents Spearman's correlation
218 between OTUs and environmental variables. The middle ring was built to represent the
219 frequency of the OTUs in our studied sites. The outer ring was built to represent the relative
220 abundance of the OTUs.

221 A null model analysis was performed to investigate the processes shaping the assembly of
222 bacterial communities in permafrost soil, lake sediment, and lake water using the R
223 package picante 1.8.2 (Kembel et al., 2010). This analysis based on the calculation of the
224 beta nearest taxon index (β NTI) to measure the extent of deterministic processes in shaping
225 the phylogenetic composition of the communities, as well as a Bray–Curtis-based Raup-
226 Crick matrix (RC_{Bray}) to assess the relative influences of stochastic processes (Stegen et al.,
227 2013; Zhou and Ning, 2017). Because homogeneous selection results in communities that
228 share greater phylogenetic similarity, the proportion of homogeneous selection was
229 calculated as the fraction of pairwise comparisons with β NTI < -2. On the other hand,
230 heterogeneous selection, leading to communities with lesser phylogenetic similarity, was
231 measured as the fraction of pairwise comparisons with β NTI > +2. Because homogeneous
232 dispersal results in communities exhibiting greater taxonomic resemblance, the extent of
233 its impact was measured as the proportion of pairwise comparisons with $-2 < \beta$ NTI < 2
234 and $RC_{\text{Bray}} < -0.95$. Conversely, communities constrained by dispersal limitation display

235 lesser taxonomic similarity, and the measure of dispersal limitation was derived from the
236 fraction of pairwise comparisons with $-2 < \beta\text{NTI} < 2$ and $\text{RC}_{\text{Bray}} > 0.95$. Finally, the
237 fraction of the pairwise comparisons with $-2 < \beta\text{NTI} < 2$ and $-0.95 < \text{RC}_{\text{Bray}} < 0.95$ was
238 identified as “undominated”. Mantel tests were conducted to test the relationships between
239 environmental variables and βNTI .

240 All the statistical analyses were carried out in R 4.1.2 ([R Core Team, 2020](#)).

241 **3 Results**

242 *3.1 General distribution patterns of α -diversity*

243 After quality filtering, 3,201,132 high quality sequences were obtained and clustered into
244 9,361 OTUs, of which, 3870 OTUs were core OTUs shared by bacterial communities in
245 permafrost soil, lake sediment, and lake water (Figure S2). Moreover, a large number of
246 OTUs were shared by PB and SB ($n=7053$), of which, 16.4% were enriched in lake
247 sediment and 19.3% were enriched in permafrost soil (Figure S2). However, a relatively
248 small number of OTUs were shared by PB and WB ($n=4007$) and by SB and WB ($n=4431$),
249 and only a very small proportion of OTUs were enriched in lake water (Figure S2).
250 Bacterial communities had a significantly lower α -diversity in lake water than in lake
251 sediment and permafrost soil (Figure 2a). α -diversity was not significantly different
252 between PB and SB (Figure 2a). Correlation analyses showed that phylogenetic diversity
253 of PB was positively correlated with SOC, TN, and C:N:P ratios (Figure 2b). For SB, α -
254 diversity indices were positively correlated with MAT, MAP, SOC, TN, C:P and N:P,
255 while negatively correlated with latitude and pH (Figure 2b). For WB, α -diversity indices
256 were negatively correlated with pH, and Shannon diversity was negatively correlated with
257 DOC, TN, and C:P (Figure 2b).

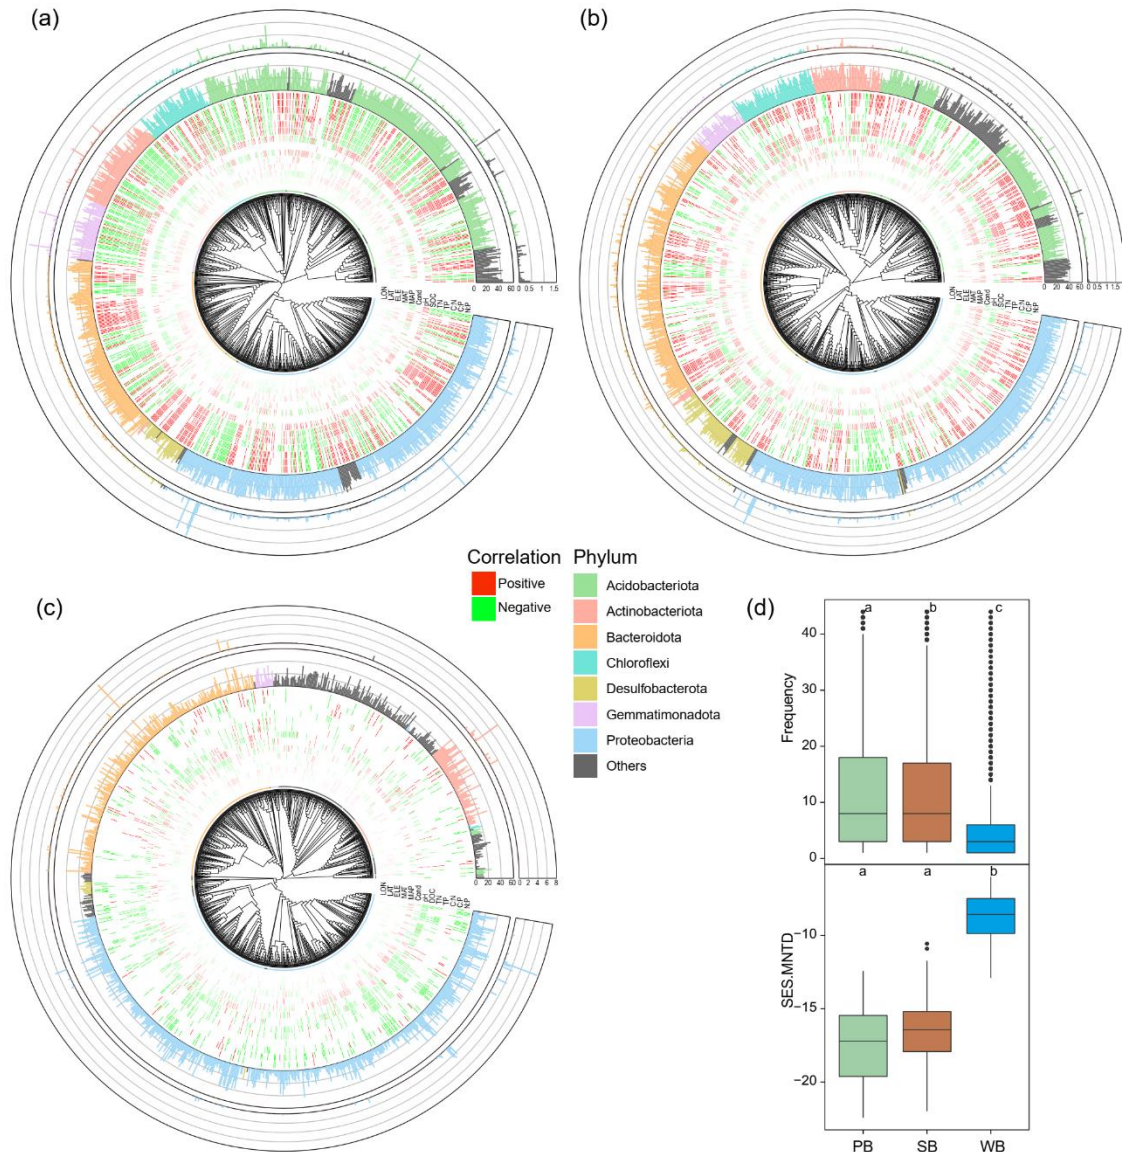

258 PB and SB had a significantly greater phylogenetic diversity than WB (Figure 2a and
 259 Figure 3). The OTUs in PB had significantly higher frequency than that of SB and WB
 260 (Figure 3). The top 1000 abundant OTUs in PB were highly correlated with environmental
 261 variables, particularly with latitude, MAP, SOC, TN, TP, and C:N:P ratios (Figure 3a). The
 262 top 1000 abundant OTUs in SB were more commonly positively correlated with MAP,
 263 SOC, TN, and C:N:P ratios, but more commonly negatively correlated with latitude and
 264 pH (Figure 3b). The top 1000 abundant OTUs in WB had relatively fewer significant
 265 relationships with environmental variables in general, but were negatively correlated with
 266 latitude, conductivity, pH, DOC, TN, and C:N:P ratios, while more positively correlated
 267 with MAP (Figure 3c). In addition, WB had significantly higher SES.MNTD than PB and
 268 SB (Figure 3d), suggesting higher phylogenetic clustering of bacterial taxa in WB.

269

270 Figure 2 (a) Alpha diversity of bacterial communities in permafrost soil (PB), lake
 271 sediment (SB), and lake water (WB). The different low-case letters represent significant
 272 differences assessed using Wilcoxon rank-sum test. (b) Spearman correlations show the
 273 relationships between alpha diversity and environmental factors. The color represents the

274 correlation coefficient, which is shown in number when the result is statistically significant
 275 ($p < 0.05$).

276

277 Figure 3 Phylogenetic tree of the top 1000 OTUs in bacterial communities in (a) permafrost
 278 soil, (b) lake sediment, and (c) lake water. Tree tips are colored by major phylum. The
 279 inner ring of the heatmap represents spearman's correlation between OTUs and
 280 environmental variables. Only significant ($p < 0.05$) results are shown. The middle ring

281 represents the frequency of the OTUs in our studied sites. The outer ring represents the
282 relative abundance of the OTUs. (d) Boxplots showing differences of OTU's frequency and
283 SES.MNTD values among bacterial communities in permafrost soil (PB), lake sediment
284 (SB), and lake water (WB). The different lower-case letters represent significant
285 differences assessed using Wilcoxon rank-sum test.

286 ***3.2 Community composition and β -diversity patterns***

287 PB were dominated by Proteobacteria (30.4%), Acidobacteriota (25.3%), Bacteroidota
288 (11.4%), Actinobacteriota (6.8%), Chloroflexi (5.2%), and Gemmatimonadota (5.2%)
289 (Figure 4a). SB were dominated by Proteobacteria (35.2%), Bacteroidota (20.0%),
290 Acidobacteriota (11.3%), Desulfobacterota (6.4%), Chloroflexi (6.3%), and
291 Actinobacteriota (5.8%) (Figure 4a). WB were dominated by Proteobacteria (46.9%),
292 Bacteroidota (29.2%), and Actinobacteriota (17.4%) (Figure 4a). While Proteobacteria
293 were predominant in all three habitat types, these dominant phyla had significantly
294 different relative abundances among these habitats. Proteobacteria and Bacteroidota had a
295 significantly higher relative abundance in WB than in SB and PB (Figure 4a). The relative
296 abundance of Actinobacteriota was the highest in WB but was not significantly different
297 between PB and SB (Figure 4a). Gemmatimonadota and Acidobacteriota were
298 significantly enriched in PB than in SB and WB. Desulfobacterota and Chloroflexi were
299 significantly enriched in SB than in PB and WB (Figure 4a).

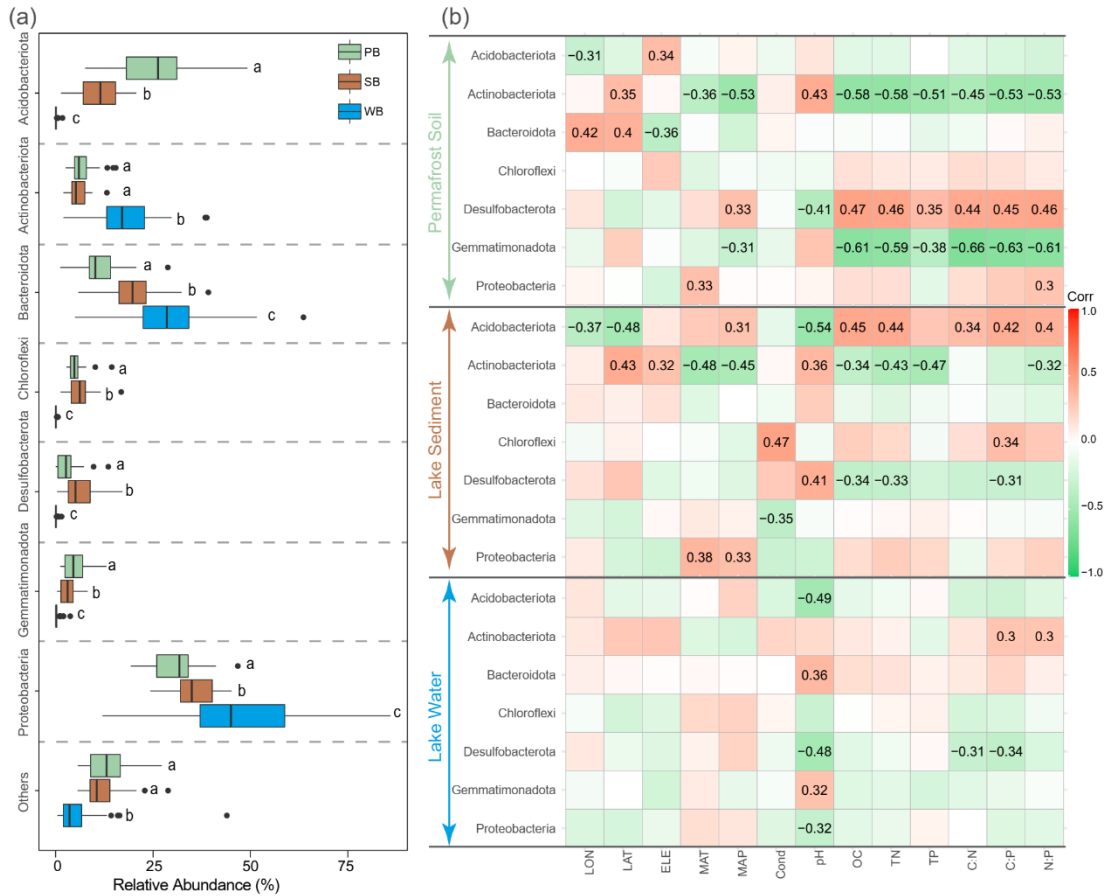

300 These phyla responded differently to environmental variables (Figure 4b). For example,
301 Actinobacteriota and Gemmatimonadota in PB and Actinobacteriota and Desulfobacterota
302 in SB were negatively correlated with nutrient concentrations and ratios, while
303 Desulfobacterota in PB and Acidobacteriota in SB were positively correlated with nutrient

304 concentrations and ratios (Figure 4b). pH frequently correlated with taxa in various
305 taxonomic groups across all three habitats (Figure 4b)

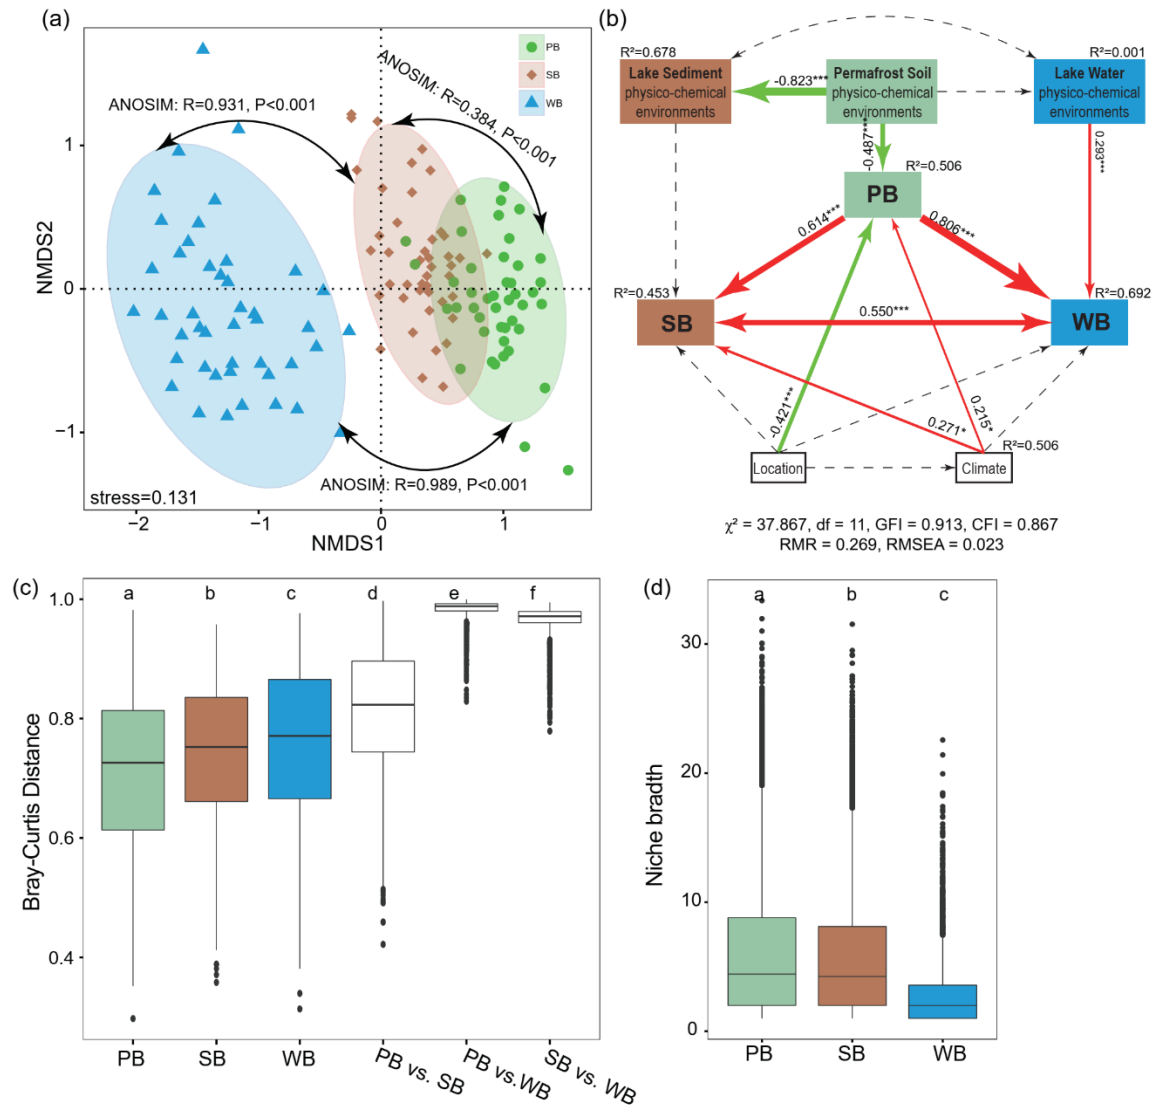

306 Nonmetric multidimensional scaling (NMDS) analysis along with non-parametric
307 statistical tests showed that bacteria in different habitats formed distinct communities
308 (Figure 5a). The extent of difference was larger for WB vs PB ($\beta=0.98$; $R_{ANOSIM} = 0.989$,
309 $P<0.001$) than the differences for WB vs SB ($\beta=0.96$; $R_{ANOSIM} = 0.967$, $P<0.001$). There
310 was the least dissimilarity between PB and SB ($\beta=0.81$; $R_{ANOSIM} = 0.384$, $P<0.001$). The
311 fitted SEM model showed that PB had direct effects on SB and WB, and the latter two had
312 reciprocal effects on each other (Figure 5b). In addition, location, climate, and permafrost
313 soil physicochemical environments had direct effects on PB. Climate had direct effects on
314 SB while lake water physicochemical environments had direct effects on WB (Figure 5b).

315 WB had a higher β -diversity than SB and PB, suggesting that bacterial communities were
316 more spatially heterogeneous in lake water than in lake sediment and permafrost soil
317 (Figure 5c). Taxa in PB had higher habitat niche breadths than taxa in SB and WB (Figure
318 5d). We estimated the distance decay relationship of bacterial community similarity.
319 Significant distance-decay relationships were observed for all communities but the fitness
320 values were relatively low (Figure S3), indicating weak decay of community similarity
321 with geographic distance in thermokarst landscape. We also explored the main
322 environmental variables that influence the variations of the bacterial communities (Figure
323 6). β -diversities of PB, SB, and WB were all significantly correlated with latitude, MAP,
324 and pH (Figure 6). In addition, β -diversity of PB was also significantly correlated with all
325 the other environmental variables except MAT and conductivity. β -diversity of SB was
326 also significantly correlated with conductivity and C:N (Figure 6). β -diversity of WB was

327 also significantly correlated with elevation, MAT, conductivity, DOC, TN, and TP (Figure
 328 6). The results suggested that the compositional variation among PB, SB, and WB was
 329 differentially structured by spatial, climatic, and physicochemical variables.

330
 331 Figure 4 (a) Relative abundances of major phyla in bacterial communities in permafrost
 332 soil (PB), lake sediment (SB), and lake water (WB). The different low-case letters represent
 333 significant differences assessed using Wilcoxon rank-sum test. (b) Spearman correlations
 334 show the relationships between the relative abundance of major phyla and environmental
 335 factors. The color represents the correlation coefficient, which shown in number when the
 336 result is significant ($p < 0.05$).

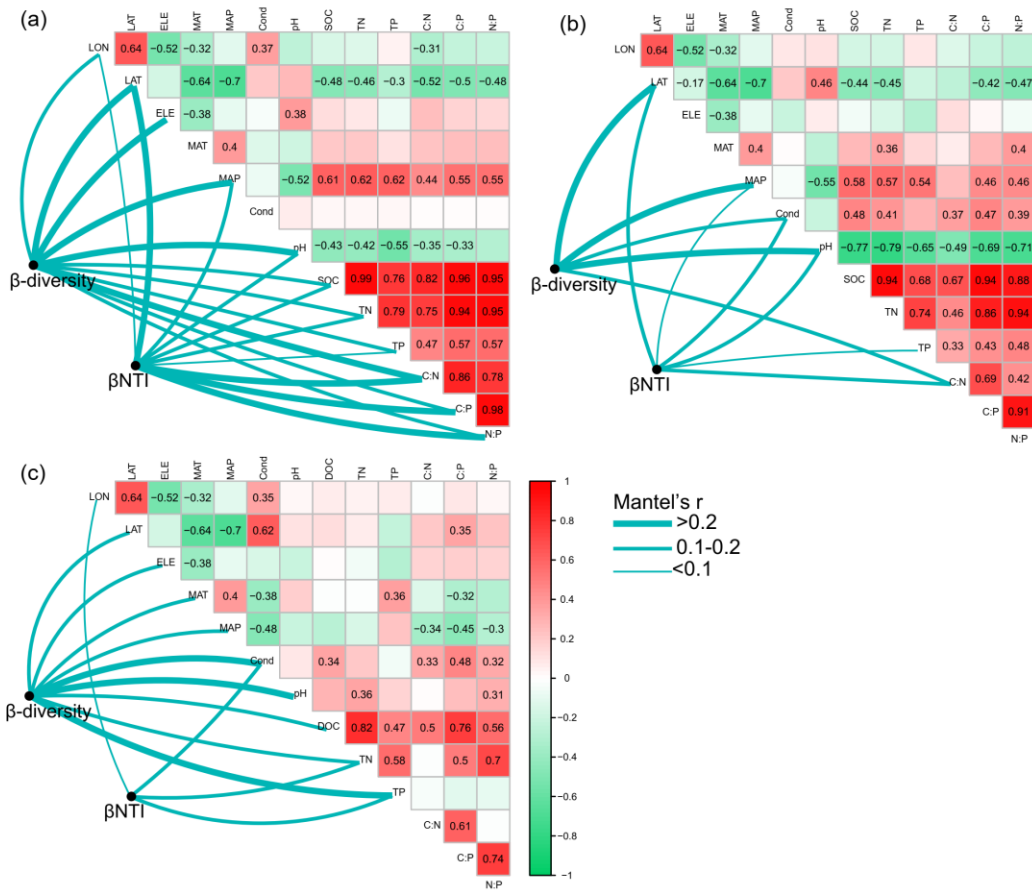

338

339 Figure 5 (a) Non-metric multidimensional scaling (NMDS) ordination showing the
 340 distribution of bacterial communities in permafrost soil (PB), lake sediment (SB), and lake
 341 water (WB). The differences between these communities are confirmed by the non-
 342 parametric statistical test (ANOSIM). (b) Structural equation modeling analysis depicting
 343 the relationships between location (including latitude, longitude, and elevation), climate
 344 (including mean annual temperature and mean annual precipitation), physicochemical

345 environments (pH, conductivity, nutrients concentrations and stoichiometric ratios) of each
 346 habitat. Solid and dashed arrows represent the significant and nonsignificant relationships,
 347 respectively. Red and green arrows represent positive and negative relationships,
 348 respectively. Significant path coefficients are shown adjacent to the path with *, **, and
 349 *** denoting the significant level of $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively. (c) β -
 350 diversities within and between PB, SB, and WB. (d) Habitat niche breadth of the bacterial
 351 communities.

352

353

354

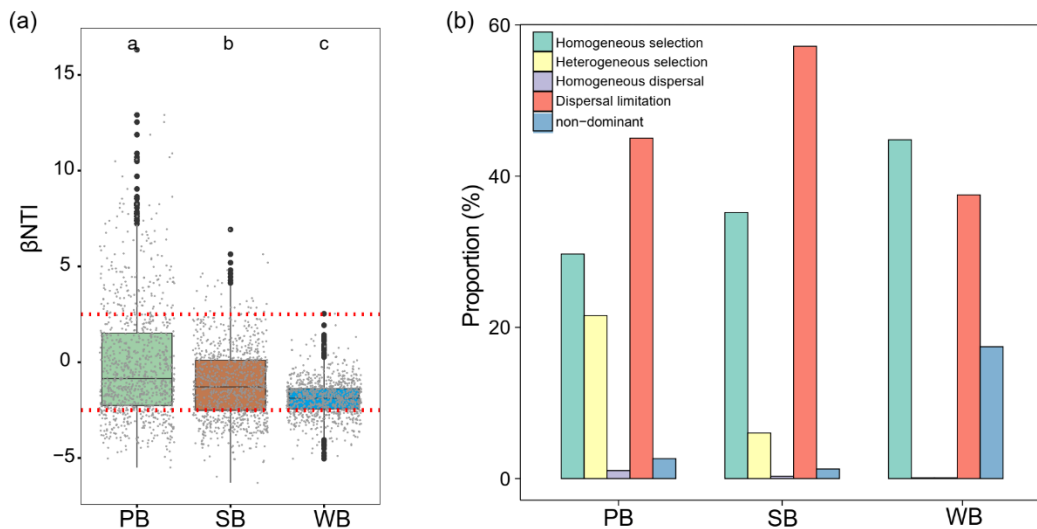

355 Figure 6 Pairwise correlations between environmental variables as well as the Mantel tests
356 between environmental variables and β -diversity and beta nearest taxon index (β NTI) for
357 (a) bacterial communities in permafrost soil, (b) bacterial communities in lake sediment,
358 and (c) bacterial communities in lake water. β -diversity was calculated as Bray-Curtis
359 distance. The lines denote significant relationships while the line width represents the
360 Mantel's r statistic. Pairwise correlations between environmental variables are shown in
361 color gradient matrix. The color represents Pearson's correlation coefficient, which shown
362 in number when the result is significant ($p < 0.05$). The abbreviations of the environmental
363 variables are explained in the Methods section.

364 ***3.3 Assembly processes***

365 To explore the mechanisms underlining the observed distribution patterns, a null-model-
366 based framework was employed to quantify the deviation of phylogenetic turnover. PB had
367 significantly higher β NTI than SB and WB (Figure 7a). Deterministic processes
368 contributed 51.3%, 41.2%, and 44.9% to community variations for the bacterial
369 communities in permafrost soil, lake sediment, and lake water, respectively (Figure 7b). In
370 particular, the results showed that homogeneous selection contributed a larger fraction to
371 the assembly of the WB (44.8%), followed by SB (35.2%) and PB (29.7%) (Figure 7b).
372 Heterogeneous selection influenced PB (21.6%) more than SB (6.0%) and WB (0.1%).
373 Dispersal limitation contributed a larger fraction to SB (57.2%) than to PB (45%) and WB
374 (37.5%).

375 The relationships between β NTI and major environmental variables were used to estimate
376 changes in the relative influences of deterministic and stochastic assembly processes.
377 Mantel tests showed that the assembly processes of bacterial communities in permafrost

378 soil, lake sediment, and lake water had similarities and differences in the responses to
 379 environmental variables (Figure 6). Particularly, differences of TP were significantly
 380 associated with β NTI of PB, SB, and WB, implying that an increasing divergence of TP
 381 could contribute to a shift from homogeneous selection to heterogeneous selection in the
 382 assembly of bacterial communities in the QTP thermokarst landscape. Moreover, β NTI of
 383 PB was also significantly associated with other environmental variables, except elevation,
 384 MAT, and conductivity. β NTI of SB was also significantly associated with latitude, MAP,
 385 conductivity, pH, and C:N, while β NTI of WB was significantly associated with longitude,
 386 conductivity, and TN.

387
 388 Figure 7 (a) The values of β NTI with horizontal dashed red lines indicate upper and lower
 389 significance thresholds at β NTI = +2 and -2, respectively in the three habitat types. (b) The
 390 contribution of deterministic (homogeneous and heterogeneous selection) and stochastic
 391 (dispersal limitations and homogenizing dispersal) processes to turnover in the assembly
 392 of bacterial communities in permafrost soil (PB), lake sediment (SB), and lake water (WB).
 393 “Non-dominant” indicates that the fraction was not dominated by any single process.

394 **4 Discussion**

395

396 *4.1 Alpha diversity and community composition*

397

398 Thermokarst lakes are known to have sediments that derive from the permafrost soil and
399 are constantly replenished by the collapse of nearby permafrost (Payette et al., 2004; West
400 and Plug, 2008; Veremeeva et al., 2021). This suggests that permafrost soil and lake
401 sediments are likely to have high levels of similarity in bacterial diversity and community
402 composition. Thus, there is no doubt that permafrost soil, lake sediments, and lake water
403 should share a certain number of bacteria. Indeed, our study showed that 41% OTUs were
404 shared among PB, SB, and WB, while 75% OTUs were shared between PB and SB.
405 Additionally, our prior research has shown that there are close correlations between the
406 abiotic features of the two environments (Ren et al., 2022b). However, despite these
407 similarities and connections, we found substantial differences in the bacterial communities
408 of permafrost soil and lake sediments. As proposed by the Baas-Becking hypothesis (Baas-
409 Becking, 1934), environmental selection is partially responsible for variation in microbial
410 communities, which are also shaped by other ecological processes, such as diversification
411 and dispersal limitation. In our study, alpha diversity and the dominant phyla found in PB
412 and SB responded differently to various environmental variables. In addition, there were
413 significant differences in composition and structure among PB, SB, and WB, while the
414 dissimilarities between PB and SB were the lowest.

415 Bacterial communities in lake water had significantly lower alpha diversity as well as
416 distinct community composition and structure in comparison to bacterial communities in
417 permafrost soil and lake sediment. However, PB and SB had direct influence on WB. For
418 thermokarst lakes, the water first originates from the thawing of the ice-rich permafrost
419 and the lake is then fed by precipitation-derived and permafrost-derived water (Yang et al.,
420 2016a; Narancic et al., 2017; Wan et al., 2019). Microorganisms present in lake water have
421 a diverse range of sources, including terrestrial inputs and other sources such as bacteria
422 distributed with the atmosphere, associated with plants and animals, and carried by
423 migratory birds and animals (Ruiz-Gonzalez et al., 2015). Thus, there was a relatively small
424 proportion of OTUs shared between permafrost soil and lake water, as well as between
425 lake sediment and water, and only a few shared OTUs were enriched in lake water. It is a
426 well-established fact that different habitats often support distinct microbial communities
427 (Fierer et al., 2012; Hugerth et al., 2015; Louca et al., 2016). The contrast in bacterial
428 community composition between lake sediments and water has been extensively
429 documented (Briee et al., 2007; Gough and Stahl, 2011; Yang et al., 2016b; Ren et al.,
430 2017). In addition, sediment generally harbor a higher species-level diversity of bacteria
431 compared to lake water (Lozupone and Knight, 2007; Ren et al., 2019b). For example, in
432 a permafrost thaw pond of Andes, it was also found that water samples had lower alpha
433 diversity than lake sediment and permafrost samples (Aszalós et al., 2020). Permafrost soil
434 and lake sediment may provide more habitat heterogeneity for bacterial taxa than the water
435 column, supported by our observation that the bacterial taxa had higher niche breadth in
436 permafrost soil and lake sediment than in lake water. Moreover, in hydrologically
437 connected terrestrial-aquatic ecosystems, bacterial communities can present distinct but

438 directional spatial structure driven by terrestrial recruited taxa (Ruiz-Gonzalez et al., 2015).
439 Thus, these community similarities between distinct bacterial habitats might be the result
440 of common bacterial source (original permafrost) and the differences are likely caused by
441 subsequent environmental selection, colonization from multiple other bacterial sources,
442 and distinct assembly mechanisms.

443 Despite connections driven by dispersal, distinct thermokarst habitats had different
444 bacterial community composition, as seen in previous work (Ottoni et al., 2022). All the
445 dominant phyla were significantly different in relative abundance among PB, SB, and WB.
446 In this study, Proteobacteria, Bacteroidota, Actinobacteriota, Gemmatimonadota,
447 Acidobacteriota, Desulfobacterota, and Chloroflexi dominated bacterial communities in
448 permafrost soil and/or thermokarst lakes despite high variabilities. Similar dominance of
449 these taxa has also been found in permafrost and thermokarst landscapes in other areas
450 (Aszalós et al., 2020; Belov et al., 2020; Wu et al., 2022). The most commonly reported
451 bacterial groups in permafrost environments include members of Proteobacteria,
452 Acidobacteria, Actinobacteria, Bacteroidetes, Firmicutes, and Chloroflexi (Steven et al.,
453 2009; Altshuler et al., 2017; Ottoni et al., 2022), as observed in our samples.

454 ***4.2 Beta diversity and assembly processes***

455 In our studied regions across the QTP, PB, SB, and WB all had a high beta diversity
456 (average values > 0.7), with WB showing the highest, suggesting that bacterial
457 communities shifted substantially across the large spatial scale of our sampling. Moreover,
458 beta diversities of PB, SB, and WB were significantly correlated with each other, further
459 suggesting that the bacteria in different habitats had a considerable proportion of members
460 from the same source, the original pristine permafrost soil. The significantly lower mean

461 SES.MNTD for PB indicate that bacterial communities in permafrost soil were more
462 closely phylogenetically clustered and suffered stronger environmental filtering than those
463 in lake sediment and water (Langenheder et al., 2017), consistent with the observation that
464 PB had lower beta diversity than SB and WB. SES.MNTD is sensitive to changes in lineage
465 close to the phylogenetic tips (Kembel et al., 2010). The higher SES.MNTD observed for
466 SB and WB suggest the possibility that the bacteria in lake sediment and water exhibit a
467 substantial divergence in the co-occurring species, and thermokarst lakes have experienced
468 colonization by bacterial species originating from distinct clades or lineages from external
469 sources following permafrost thaw (Webb et al., 2002; Stegen et al., 2013).

470 The structure of bacterial communities can vary across spatiotemporal scales and different
471 habitats (Ren et al., 2017; Aguilar and Sommaruga, 2020; Pearman et al., 2020). A key
472 objective in the field of microbial ecology is to determine the relative influence of
473 stochastic and deterministic processes in shaping the assembly of communities (Stegen et
474 al., 2013; Zhou and Ning, 2017). In this study, bacterial communities in lake water
475 displayed a higher influence of homogeneous selection but lower influence of
476 heterogeneous selection compared to those in lake sediments and permafrost soil. Long-
477 term changes in thermokarst lakes result in homogenized habitats and consequently strong
478 homogenous selection on bacterial communities (Ning et al., 2019). In contrast, permafrost
479 soil is a highly heterogeneous environment across spatial scales (Etzelmüller, 2013;
480 Nitzbon et al., 2021), creating a wide range of habitats which can impose strong
481 heterogeneous selection pressures on bacterial communities. Furthermore, permafrost soil
482 is characterized by limited nutrient availability due to the frozen state of organic matters
483 (Beermann et al., 2017; Zhang et al., 2023), while lake water offers a more diverse and

484 abundant array of dissolved organic compounds and nutrients. As a result, bacterial
485 communities in permafrost soil might be more sensitive to variations in resource
486 availability, rendering them more strongly influenced by heterogeneous selection. In
487 addition, dispersal limitation contributed a larger fraction to SB (57.2%) than to PB (45%)
488 and WB (37.5%). The dispersal of microorganisms is often considered as a passive process
489 that results in community variation and turnover coupled with the function of
490 environmental filtering (Cline and Zak, 2014; Stegen et al., 2015; Custer et al., 2022). The
491 high dispersal limitation of microbial communities in thermokarst lakes may be attributed
492 to several factors. These include the isolated nature of thermokarst lakes, which are
493 endorheic and therefore have limited connectivity, as well as the strong restriction on
494 microbial dispersal and the presence of strong environmental filtering processes.
495 Additionally, the prolonged frozen phase of thermokarst lakes and permafrost soil restrict
496 the movement of microorganisms (Vargas Medrano, 2019; Vigneron et al., 2019).
497 Furthermore, geographical barriers, exemplified by prominent mountain ranges like the
498 Tanggula Mountains, Kunlun Mountains, Nyenchen Tanglha Mountains, and Bayan Har
499 Mountains, serve as impediments to the dispersal of both macro- and microorganisms (Wan
500 et al., 2016; Yu et al., 2019; Ren et al., 2022c). Particularly in lake sediment, where
501 bacterial communities are more isolated over distances and will not disperse as far as those
502 in lake water and permafrost soil, resulting in stronger influence of dispersal limitation
503 (Martiny et al., 2006; Xiong et al., 2012). Although the “everything is everywhere”
504 hypothesis suggests that many microorganisms have a cosmopolitan distribution, their
505 slow mobility allows for the development of regional phylogenetic differences and the
506 emergence of specialized, endemic taxa in isolated habitats, resulting in a low likelihood

507 of microorganisms dispersing to suitable distant sites (Telford et al., 2006). Therefore,
508 dispersal processes in this thermokarst landscape may be restricted by the lack of
509 hydrological connection, limited movement of water, short duration since thawing, and
510 strong environmental filtering, contributing to the observed high dispersal limitation in the
511 studied permafrost soil and thermokarst lakes. This inference is supported by many
512 previous studies showing that dispersal limitation plays a major role in structuring
513 microbial communities in lakes (Telford et al., 2006). Strong dispersal limitation for
514 bacterial communities in permafrost has also been documented across an Alaskan boreal
515 forest landscape (Bottos et al., 2018).

516 ***4.3 Environmental influences***

517 Understanding how environmental factors shape bacterial communities is a crucial aspect
518 in the field of microbial ecology (Fierer and Jackson, 2006; Pla-Rabes et al., 2011). In our
519 study, bacterial communities were differentially correlated with various measured
520 environmental variables. In our data, pH was consistently identified as a strong correlate
521 of microbial community structure and diversity, as is often observed in terrestrial and
522 aquatic ecosystems worldwide (Fierer and Jackson, 2006; Xiong et al., 2012). While such
523 correlations between pH and bacterial communities have been widely found, the regulation
524 mechanisms still remain unknown (Malard and Pearce, 2018). Moreover, the influences of
525 pH are often species- and location-specific (Malard and Pearce, 2018; Egelberg et al.,
526 2021). In this study, pH had significantly negative relationships with alpha diversity of
527 bacterial communities in lake sediment and water, and had negative or positive correlations
528 with some phyla. Moreover, differences in pH might drive community variation observed
529 between PB, SB, and WB, and shift community assembly processes for PB and SB.

530 Moreover, with permafrost degrading and thermokarst developing, nutrient status will be
531 strongly altered in permafrost areas. Organic carbon and nutrient stocks in permafrost are
532 decreasing ([Turetsky et al., 2020](#); [Wu et al., 2021](#)) and thermokarst lakes are developing,
533 leading to dynamic environmental change ([Luo et al., 2015](#); [Vucic et al., 2020](#)). These
534 environmental disruptions likely impose strong influences on bacterial communities in
535 thermokarst landscapes. Our study showed that nutrient (C, N, and P) concentrations and
536 stoichiometric ratios were strongly related to alpha diversity (particularly for SB) and
537 community variation and assembly (particularly for PB). High organic matter content, for
538 instance, has been shown to support diverse and complex microbial communities ([Garrido-](#)
539 [Benavent et al., 2020](#); [Ren and Gao, 2022](#)). The role of nutrient availability in shaping
540 bacterial communities has also been well established ([Torsvik et al., 2002](#); [Lee et al., 2017](#);
541 [Zhou et al., 2020](#)). For example, Actinobacteria and Gemmatimonadota have a negative,
542 while Gemmatimonadota has a positive relationship with organic carbon and nutrients in
543 permafrost ([Romanowicz and Kling, 2022](#); [Fu et al., 2023](#)), in line with our results. The
544 fact that different bacterial phyla exhibited varied responses to changes in organic carbon
545 and nutrient further emphasizes the intricate interplay between microorganisms and their
546 environment. Due to their ecological strategies, metabolic features, and environmental
547 preferences, bacteria in permafrost respond differentially to nutrient status and other
548 stressors, driving adaptive changes in community composition and function ([Mackelprang](#)
549 [et al., 2017](#)). In addition, compared to permafrost soil and lake water, lake sediment can
550 exhibit more stable physicochemical conditions. However, permafrost soil and lake water
551 experience more dynamic and extreme environmental changes, which drive the bacterial
552 communities. The results of SEM also in line with bacterial community assembly that

553 deterministic processes had stronger influences on PB and WB than on SB. In addition,
554 thermokarst lakes have sediment directly formed from permafrost soil, and thus, permafrost
555 soil environments and bacterial communities had strong associations with that of lake
556 sediment.

557 In addition to physicochemical environments, location and climate were also suggested to
558 influence bacterial communities in distinct habitats. On the QTP in particular, air
559 temperature and precipitation are increasing in most regions (Xu et al., 2008; Lu et al.,
560 2018). Warming and altered precipitation regimes under climate change have been
561 demonstrated to affect alpha diversity and composition of stream microbial communities
562 at continental scales (Picazo et al., 2020). Our study indicates that location (particularly
563 latitude) and climate (particularly MAP) factors are important in shifting bacterial
564 communities in thermokarst landscapes. Particularly for bacterial communities in
565 permafrost soil, location and climate have been evidenced as strong factors in shaping
566 microbial communities (Taş et al., 2018; Barbato et al., 2022). Understanding large-scale
567 pattern of bacterial communities is increasingly important to offer insights into the impacts
568 of climate change (Picazo et al., 2020; Ren et al., 2021). As global climate changes, QTP
569 is getting warmer and more humid (Xu et al., 2008; Lu et al., 2018). Therefore, significant
570 alterations to the physical, chemical, and biological properties of thermokarst lakes on the
571 QTP can be expected in the coming decades. Based on “space-for-time” substitution, our
572 study serves as a foundation for predicting the potential impact of climate change on
573 bacterial communities in thermokarst landscapes.

574 **5 Conclusion**

575 In this study, we investigated bacterial communities in paired water and sediment samples
576 in thermokarst lakes as well as permafrost soil around the lakes across the QTP. esults
577 showed that each habitat had distinct bacterial assemblages, with lower alpha diversity in
578 lake water and higher beta diversity in lake sediment and permafrost soil. There was
579 considerable overlap in OTUs across habitats. Bacterial communities in permafrost soil
580 and lake sediment were influenced by dispersal limitation, while those in lake water were
581 driven by homogeneous selection. Environmental variables, including latitude, mean
582 annual precipitation, and pH, affected bacterial community variations in all habitats. The
583 study highlights the unique bacterial communities and ecological impacts of permafrost
584 degradation in diverse habitats created by thermokarst processes.
