18 Abstract

19 Upscaling chamber measurements of soil greenhouse gas (GHG) fluxes from points to landscape scales
20 remain challenging due to high variability of fluxes in space and time. This study measured GHG fluxes and soil
21 parameters at selected point locations (n=268), thereby implementing a stratified sampling approach on a mixed
22 land-use landscape (~5.8 km²). Based on these field-based measurements and remotely-sensed data on landscape and
23 vegetation properties, we used Random Forest models to predict GHG fluxes at a landscape scale (1 m resolution) in
24 summer and autumn. The results showed improved GHG flux prediction performance when combining field-
25 measured soil parameters with remotely-sensed data. Available satellite data products from Sentinel-2 on vegetation
26 cover and water content played a more significant role than attributes derived from a digital elevation model,
27 possibly due to their ability to capture both spatial and seasonal changes of ecosystem parameters within the
28 landscape. Similar seasonal patterns of higher soil/ecosystem respiration (SR/ER-CO₂) and nitrous oxide (N₂O)
29 fluxes in summer and higher methane (CH₄) uptake in autumn were observed in both the measured and predicted
30 landscape fluxes. Based on the upscaled fluxes, we also assessed the contribution of hot spots to total landscape
31 fluxes. The identified emission hot spots occupied a small landscape area (7 to 16%) but accounted for up to 42% of
32 the landscape GHG fluxes. Our study showed that combining remotely-sensed data with chamber measurements and
33 soil properties is a promising approach for identifying spatial patterns and hot spots of GHG fluxes across
34 heterogeneous landscapes. Such information may be used to inform targeted mitigation strategies at landscape-scale.

35 1. Introduction

36 Atmospheric concentrations of greenhouse gases (GHGs) such as carbon dioxide (CO₂), methane (CH₄), and
37 nitrous oxide (N₂O) have increased since the 1750s, substantially driving global climate change (IPCC, 2019). Soils
38 are key contributors to these GHG fluxes, with recent global emissions of approximately 350 Pg CO₂ equivalents per
39 year (Oertel et al., 2016). Soil GHG emissions have accelerated due to human activities such as land use change for
40 agricultural land expansion (Dhakal et al., 2022). Globally, agricultural soils are significant sources accounting for
41 about 37% of the GHG emissions within the agricultural sector (Tubiello et al., 2013). However, the estimates of soil
42 GHG fluxes are highly uncertain since soil properties, land use, and land management, which are key indirect drivers
43 of the emissions, largely differ across landscapes and regions. For instance, global annual estimates range widely
44 from 67 to 101 Pg C (Jian et al., 2018) for soil respiration, 2.5 – 6.5 Tg N₂O-N for annual soil N₂O emissions (Tian
45 et al., 2020), and 12 – 60 Tg for soil CH₄ uptake rates (Dutaur & Verchot, 2007). These uncertainties make it
46 difficult to accurately quantify the GHG source or sink strengths of soils and to develop targeted mitigation options
47 across scales.

48 Current upscaling approaches from localized measurements of soil GHG fluxes to landscape or regional
49 scales using chamber or site-specific micro-meteorological methods such as eddy-covariance (e.g., Sundqvist et al.,
50 2015; Vainio et al., 2021; Warner et al., 2018; Han et al., 2022), fail to capture the spatio-temporal variation of hot-
51 or cold-spots, resulting in uncertainties in regional and global GHG estimates (Hagedorn & Bellamy, 2011; Levy et
52 al., 2022). Contrary to the eddy-covariance method, chamber-based approaches can be used to capture fine-scale
53 spatial variabilities of soil GHG fluxes within landscapes, e.g., when measurements are conducted at sampling sites
54 representative of the spatial heterogeneities related to land use, land management, and topography (e.g., Warner et
55 al., 2018; Vainio et al., 2021; Wangari et al., 2022). However, the ability of chambers to accurately quantify
56 landscape fluxes over relatively larger areas is limited and closely related to the number of chamber measurement
57 locations per unit area (Wangari et al., 2022). Previous studies have shown that the uncertainties in landscape-scale
58 fluxes from chamber measurements using area-weighted averages increase exponentially with a decrease in the
59 number of chamber measurement locations (e.g., Arias-Navarro et al., 2017; Wangari et al., 2022). Nevertheless, the
60 practicability of increasing the number of chamber measurement locations to quantify landscape fluxes is constrained
61 by extensive human and technical resource requirements, hence there is a need for alternative ways of estimating
62 GHG landscape fluxes.

63 The limitation of extensive chamber measurements required to quantify landscape fluxes can be overcome
64 through modeling approaches that offer cost-effective and more practical alternatives. Machine learning (ML)
65 algorithms are increasingly used to gap-fill spatio-temporal datasets on soil GHG fluxes as they require lesser
66 computational time and expertise than complex biophysical models (Dorich et al., 2020; Zhang et al., 2020; Saha et
67 al., 2021; Adjuik & Davis, 2022; Joshi et al., 2022). Amongst the available ML algorithms, the random forest (RF)
68 algorithm has been evaluated as one of the best for predicting soil GHG fluxes (Hamrani et al., 2020; Adjuik &

69 Davis, 2021; Han et al., 2022). The RF algorithm has been widely applied to gap-fill and upscale soil GHG fluxes in
70 temperate ecosystems from point measurements to larger scales, with relatively better prediction accuracies (e.g.,
71 Philibert et al., 2013; Räsänen et al., 2021; Vainio et al., 2021).

72 Several studies have explored the use of high-resolution remote-sensing (RS) datasets such as digital
73 elevation models (DEMs) and indices from spectral characteristics derived from satellite images in combination with
74 on-site chamber measurements to predict landscape GHG fluxes (e.g., Sundqvist et al., 2015; Warner et al., 2018;
75 Vainio et al., 2021; Räsänen et al., 2021). These studies used RS datasets on landscape and vegetation parameters as
76 proxies for soil physical and chemical characteristics such as soil moisture, soil vegetation cover, and nutrient
77 availability, i.e., key biogeochemical drivers of soil GHG fluxes. However, the above studies have either been
78 conducted over relatively small areas or have focused on individual land uses and GHG fluxes. For instance, only
79 one study has applied a RF approach to predict CH₄ fluxes for a larger (12.4 km²) peatland-forested landscape based
80 on RS data and 279 on-site measurements of soil temperature, moisture, and vegetation (Räsänen et al., 2021). In
81 addition, spatial CO₂ and CH₄ fluxes have been predicted for relatively small (~0.1 km²) forested landscapes using
82 DEM-derived terrain attributes and a few site-measured (temperature and moisture) soil variables (Warner et al.,
83 2018; Vainio et al., 2021). Applying RF models using various RS datasets and soil parameters for soil GHG flux
84 predictions on larger and heterogeneous landscapes in relation to land use, topography, and soil conditions remains
85 unexplored. It is still uncertain whether such landscape flux predictions would improve if supplemented by multiple
86 actual field measurements of soil properties (e.g., texture) and variables (e.g., inorganic N content), which may better
87 describe the geochemical and physical conditions compared to RS-derived indices.

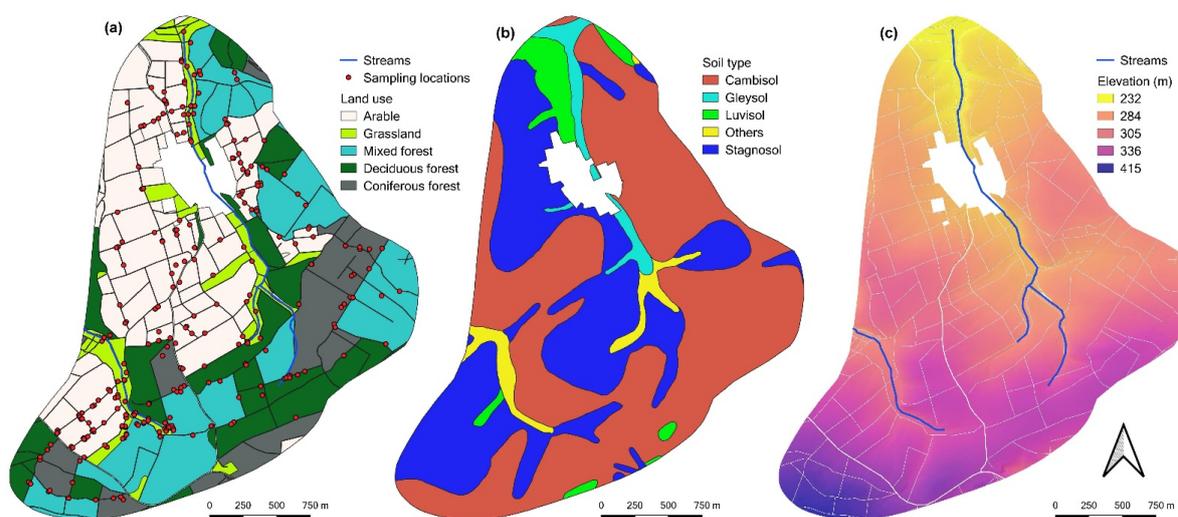

88 In this study, we aimed to determine the potential of applying the RF algorithm to predict the spatial and
89 seasonal variability of soil CO₂, CH₄, and N₂O fluxes using a high number of stratified sampling locations (n = 268)
90 spread across a relatively large (~5.8 km²) landscape with heterogeneous land uses (forest, grassland, and arable
91 land). Specifically, we aimed to: (a) evaluate the effectiveness of high-resolution RS data and relatively low-
92 resolution data on soil physico-chemical parameters in predicting soil GHG fluxes across different land uses; (b)
93 predict high-resolution soil GHG fluxes at a landscape scale and detect GHG hot spots and cold spots; and (c)
94 compare landscape GHG fluxes upscaled from RF-predicted high-resolution maps with aggregated landscape flux
95 estimates from averaged (point) fluxes multiplied by landscape area. We hypothesized improved prediction
96 accuracies using a combination of RS datasets that act as proxies of key drivers of soil GHG fluxes (e.g., vegetation
97 cover and water content) and the site-measured soil parameters representing the actual field conditions. We expected
98 fine-scale hot spots (within a few meters) to occur in cultivated areas and cold spots in forested areas. We also
99 hypothesized that the high-resolution upscaled fluxes from the RF approach, which better captures hot and cold spot
100 regions across the landscape, would avoid possible under- or overestimations of landscape fluxes derived from land
101 use specific area-weighted averages calculated from few point chamber measurement locations.

102 2. Materials and methods

103 2.1 Study area

104 The study area is located within the Schwingbach catchment in Hesse, central Germany (50°30'4.23. N,
105 8°33'2.82. E). The landscape covers an area of approximately 5.8 km² excluding the human settlement areas and
106 road networks. Land uses within the landscape are mainly forests (57%) and arable lands (34%). Grasslands cover
107 about 8% and are primarily located in riparian zones (Figure 1). The dominant soil types are cambisol (69%, forest
108 and arable), stagnosol (23%, mainly arable), and gleysol (5%) which are found along grassland riparian zones
109 (Wangari et al., 2022). The topsoils (0 – 5 cm) in the arable and grasslands have a silt loam texture, while the
110 topsoils in the forest land mostly have a sandy loam texture (Sahraei et al., 2020). The landscape has an average
111 slope of 5% with an elevation range of 233 – 415 m a.s.l. The region has a temperate oceanic climate (Cfb, Köppen
112 climate classification) with annual average precipitation and temperature of 623 mm and 9.6°C based on long-term
113 data (1969 – 2019) (Sahraei et al., 2021).

114

115 **Figure 1:** Map showing (a) the land uses and the location of the stratified sampling sites (selected based on combined classes of
116 land use, slope, and soil type) across the study area; (b) the soil types; and (c) the digital elevation model (DEM; 1 m resolution) of
117 the landscape (source of DEM: Hessische Verwaltung für Bodenmanagement und Geoinformation, <https://hvbg.hessen.de/>).

118 **2.2 Soil physico-chemical parameters and GHG fluxes**

119 **2.2.1 Point measurements**

120 Soil sampling and GHG flux measurements (CH₄, N₂O, and CO₂) were conducted at spatially distributed
121 sampling sites across the study landscape (see Tab. 1 for a list of observed variables). We used a stratified random
122 sampling approach to distribute 270 sites across different land uses (forest, grassland, and arable), soil types
123 (cambisol, stagnosol/gleysol, and luvisol), and slopes (0–5, 6–11, and >11%) to capture the spatial variability of soil
124 GHG fluxes and the driving parameters (Wangari et al., 2022). Out of the 270 targeted locations, field measurements
125 were conducted at 246 sites in the summer (30th June – 9th July, field measuring campaign 1) and 268 sites in the
126 autumn (8th – 17th September, field measuring campaign 2) of 2020. The estimated number of measured points for
127 the forest, grassland, and arable ecosystems was ~25, 150, and 28 per km² (Table 1). We allocated more grassland
128 sites due to the hypothesis that riparian grasslands are hot spots of GHG fluxes.

129 Soil GHG flux measurements were performed during the day (7.00 am – 5.00 pm) using a fast-box chamber
130 technique (Hensen et al., 2013; Butterbach-Bahl et al., 2020). The CO₂ concentrations in the opaque chamber
131 headspace were measured with an infrared gas analyzer (LI-840A & LI-850, LI-COR Biosciences, Lincoln, NE,
132 USA), while CH₄ and N₂O concentrations were measured with an Off-Axis Integrated Cavity Output Spectroscopy
133 (OA-ICOS) analyzer (Los Gatos Research, Inc., CA, USA). The GHG fluxes were calculated based on the linear
134 changes of gas concentrations in the chamber headspace in the first 5–7 minutes following chamber closure. The soil
135 sampling, analysis, and flux measurement methods are detailed in Wangari et al. (2022).

136 **Table 1:** List of the soil physico-chemical parameters and remotely-sensed data used in this study to upscale the GHG fluxes and
 137 details of the spatial resolutions of the maps.

Category	Predictor variables	Resolution		Source
		Original	Final	
Remotely-sensed data (RS)	Elevation	1 m	1 m	Hessische Verwaltung für Bodenmanagement und
	Slope	1 m	1 m	Calculated from elevation
	Aspect	1 m	1 m	
	Topographic wetness index (TWI)	1 m	1 m	
	Topographic position index (TPI)	1 m	1 m	
	Normalized difference vegetation index (NDVI)	10 m	1 m	Copernicus Sentinel-2 (European Space Agency)
	Green normalized difference vegetation index (GNDVI)	10 m	1 m	
Normalized difference moisture index (NDMI)	20 m	1 m		
Soil physico-chemical parameters (SP)	Soil temperature (°C)		1 m	Interpolated from sampling point data measured in summer and autumn (Wangari et al. 2022)
	Gravimetric soil moisture (%)		1 m	
	pH		1 m	
	Bulk density (g cm ⁻³)		1 m	
	NO ₃ -N (mg kg ⁻¹ dry soil)	~ 25, 150, and 28 sites	1 m	
	NH ₄ -N (mg kg ⁻¹ dry soil)	per km ² in forest,	1 m	
	DOC (mg kg ⁻¹ dry soil)	grassland,	1 m

	Soil TN (%)	land	1 m	
	Soil TOC (%)		1 m	
	CN		1 m	
	Sand content (%)		1 m	
	Silt content (%)		1 m	
Clay content (%)		1 m		

139 2.2.2 Spatial interpolation of soil parameters

140 Upscaling soil GHG fluxes using the RF algorithm required spatial raster maps of the soil physico-chemical
 141 predictor parameters. Thus, we interpolated our measured point data to continuous landscape maps using the inverse
 142 distance weighted (IDW) approach in the System for Automated Geoscientific Analyses software (SAGA: QGIS)
 143 with a distance coefficient power of 1 (Gradka & Kwinta 2018). The spatial interpolations were performed per land
 144 use (forest, grassland, and arable land) and for each season (summer and autumn) due to significant variations in soil
 145 parameters such as soil moisture or inorganic N content across land uses and seasons (see Wangari et al., 2022).

146 2.3 Remote sensing data

147 We retrieved several landscape-scale remote-sensing images with spatial data representing potential drivers
 148 of soil GHG fluxes, such as vegetation cover and vegetation water content. Landscape elevation was acquired from a
 149 high-resolution (1 m) digital elevation model (DEM) retrieved from the Hessische Verwaltung für
 150 Bodenmanagement und Geoinformation on March 1, 2022 (link source). Slope and aspect were calculated from the

151 DEM using the “r.slope.aspect” function in QGIS. We further computed the topographic position index (TPI) and
152 topographic wetness index (TWI) from the DEM using the terrain analysis plugin in QGIS. Vegetation information
153 on chlorophyll and water content was derived from satellite bands of Sentinel-2 images. Satellite images with low
154 (<1%) cloud cover were accessed from the ESA Copernicus Open Access Hub (link source; accessed on March
155 2021) using the Semi-Automatic Classification Plugin (SCP) in QGIS for each field measuring period. The
156 normalized difference vegetation index (NDVI) and the green normalized difference vegetation index (GNDVI) were
157 calculated using the near-infrared (NIR), red, and green bands (Bannari et al. 1995; Gitelson and Merzlyak, 1998;
158 Eq. 1 and 2). Compared to NDVI, GNDVI has a higher ability to detect differences in the chlorophyll content of
159 plants, especially later in the vegetation period, due to the higher chlorophyll sensitivity of the green band in GNDVI
160 than the red band in NDVI. The vegetation water content was estimated using the normalized difference moisture
161 index (NDMI), which was computed using the NIR and short-wave infrared (SWIR) bands (Gao, 1996; Malakhov
162 and Tsyhuyeva, 2020; Eq. 3). We uniformly downscaled the resolutions of these remotely-sensed vegetation indices
163 to match the 1 m spatial resolution of the DEM-derived data files (Table 1).

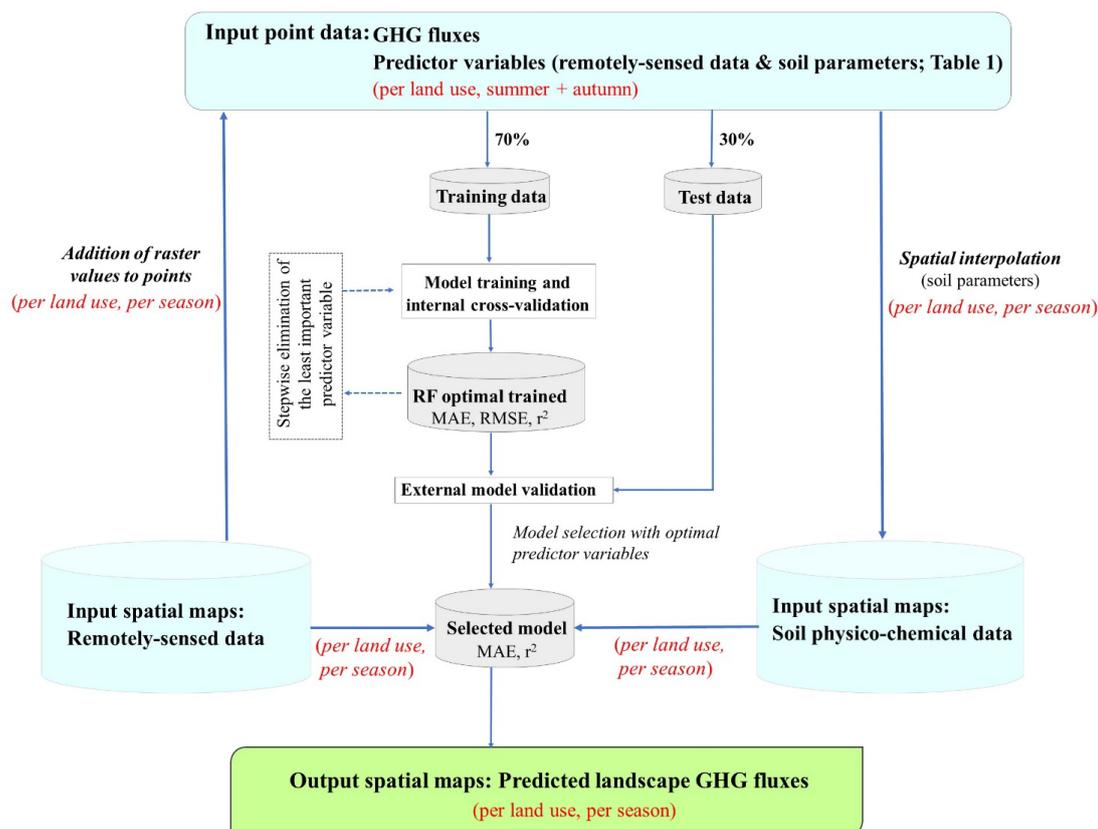

164
$$NDVI = \frac{NIR-RED}{NIR+RED} \quad (\text{Eq. 1})$$

165
$$GNDVI = \frac{NIR-GREEN}{NIR+GREEN} \quad (\text{Eq. 2})$$

166
$$NDMI = \frac{NIR-SWIR}{NIR+SWIR} \quad (\text{Eq. 3})$$

167 **2.4 Random Forest regression model**

168 RF model development and prediction of the GHG fluxes were performed per land use (forest, grassland,
169 and arable) because there were statistically significant differences observed in the measured fluxes and the
170 underlying GHG flux controls of soil parameters for the different land uses (Wangari et al., 2022). For instance, N₂O
171 fluxes and soil nitrate concentrations were up to two-fold higher in arable soils than in forestry or grassland soils.
172 The CH₄ uptake rates of grassland and arable soils were lower than those of forest soils due to general differences in
173 soil structure, nitrogen concentrations, and disturbances (Wangari et al., 2022). We trained models using merged
174 summer and autumn point data to enable larger and temporally representative datasets for training models that could
175 estimate low and high landscape GHG fluxes (Figure 2).

176

177 **Figure 2:** Workflow summary showing the input data (in blue), the approach used for RF model development and prediction of
178 landscape fluxes, and the performance evaluation metrics (MAE, RMSE, and r^2).

179 We used the RF algorithm built in the CARET (classification and regression training) package in R to
180 predict the soil GHG fluxes at a landscape scale (Breiman, 2001; Kuhn, 2008). For model development, the input
181 datasets were split into a training and internal cross-validation set (70%) and an external test set (30%) using a
182 stratified random sampling method. We defined a ten-fold ($K=10$) repeated cross-validation scheme using the
183 ‘trainControl’ function to internally validate our trained models and prevent model overfitting (Berrar, 2018). A seed
184 value of 123 was specified using the ‘set.seed’ function to enable reproducible results each time we ran a specific
185 model. The optimal trained model was automatically selected using the mean absolute error (MAE) metric with the
186 least value. The predictor variables in the optimal trained model were then ranked according to their importance
187 using the RF variable importance measure in the ‘varImp’ function. Subsequently, stepwise elimination of the least
188 essential variable was performed to quantify the predictive power of landscape GHG fluxes using fewer predictor
189 variables (Figure 2).

190 To assess the effectiveness of various types of predictors in modeling landscape fluxes, we defined
191 three categories of datasets, namely remote-sensing (RS), site-measured soil physico-chemical parameters (SP), and
192 combined data (CD) (Table 1). Several RF models were trained following the stepwise elimination of the least

193 important variables in each data category (RS, SP, CD). Since 88% of CH₄ fluxes were negative and 86% of N₂O
194 fluxes were positive (Wangari et al., 2022), we additionally trained models using only the negative CH₄ and positive
195 N₂O flux datasets to compare their performances with the models built with all (positive and negative) fluxes.

196 **2.5 Model performance assessment and prediction of landscape fluxes**

197 The performance assessment metrics of the trained models included MAE, root mean square error (RMSE),
198 and the coefficient of determination (r^2) from the internal cross-validation. The final models for predicting landscape
199 fluxes in each data category (RS, SP, CD) were selected based on the highest possible r^2 with a relatively low MAE.
200 For each season and land use, the surface maps of the respective predictor variables in the final models were merged
201 using the raster brick function in R. The spatial fluxes for each land use were then predicted based on the selected
202 model and the input raster brick using the ‘predict’ function in R. To improve the prediction performance, the non-
203 normal distributed (SR/ER_CO₂ and N₂O) fluxes were log-transformed before model development. After prediction,
204 the transformed fluxes were retransformed using an exponential function.

205 Further evaluation of the model performances was conducted through linear regression and correlation
206 analysis of observed against retransformed predicted fluxes for all sampling sites. An additional external validation
207 step was performed using the measured and predicted fluxes of the sampling sites in the 30% test dataset that was
208 excluded from the model development. For this analysis, we compared the predicted mean fluxes (using RS, SP, and
209 CD datasets) with the observed mean fluxes. Analyses of variances (Type II) from linear mixed-effects models
210 (“nlme” package in R) were used to compare these arithmetic means. The fixed effects in the mixed models were
211 seasons (summer and autumn) and GHG flux type (measured and predicted fluxes from the RS, SP, and CD
212 datasets). Random effects of site variability were also included in the mixed models. The measured and predicted
213 fluxes were log-transformed to the normality assumption. A Tukey post-hoc test (p-value <0.05) of least square
214 means was used on the mixed models to identify statistically significant differences between the measured, RS-
215 predicted, SP-predicted, and CD-predicted fluxes.

216 Since many traditional GHG upscaling approaches rely on aggregated fluxes (area-weighted averages), we
217 also estimated spatial fluxes for the summer and autumn seasons using this technique. GHG fluxes were aggregated
218 on the landscape scale by multiplying the average fluxes measured for each land use by the area of each land use. We
219 compared the total landscape fluxes upscaled using this conventional aggregation technique of average fluxes with
220 the spatial fluxes predicted using the modeling approach.

221 **2.6 Identification of GHG ‘hot’ and ‘cold’ spots from predicted landscape fluxes**

222 Statistical approaches were deployed to identify areas that may have disproportionately contributed to the
223 overall landscape GHG fluxes (e.g., van Kessel et al., 1993; Mason et al., 2017). We defined the threshold for hot
224 spots using the sum of the median (M) flux and the interquartile (Q3-Q1) flux range (Eq. 4). Thus, the hot spots
225 within the landscape were identified as the areas with flux values greater (lower for CH₄ uptake) than the set hot spot
226 threshold. We fixed an inverse threshold (Eq. 5) for cold spots and identified cold spot patches with fluxes below
227 (above for CH₄ uptake) this threshold. Common emission hot spots were defined as the areas with overlapping

228 elevated emissions of the three GHG fluxes (SR/ER-CO₂, CH₄, and N₂O) within the landscape. The average
229 (summer and autumn) landscape fluxes were used to identify the hot and cold spots. We also calculated season-
230 specific thresholds to compare the increase and decrease of hot and cold spot areas between summer and autumn.

231
$$\textit{Hot spot threshold} = M + (Q3 - Q1) \quad (\text{Eq. 4})$$

232
$$\textit{Cold spot threshold} = M - (Q3 - Q1) \quad (\text{Eq. 5})$$

233 3. Results

234 3.1 RF model performance

235 The performance of the final models selected for the prediction of landscape fluxes varied across input
236 datasets (RS, SP, and CD), GHG fluxes (SR/ER_CO₂, CH₄, and N₂O), and land use (forest, grassland, and arable
237 land) (Table 2). The predictive performance (r^2) from the internal cross-validation step was higher in the models
238 using the CD dataset (range: 0.15 – 0.78) than those using the RS (range: 0.13 – 0.73) and SP (range: 0.15 – 0.63)
239 datasets (Table 2). The RF models predicting SR/ER_CO₂ fluxes had much higher r^2 (range: 0.45 – 0.78) than those
240 predicting N₂O and CH₄ fluxes (range: 0.13 – 0.56). Arable ecosystem models resulted in much better predictions of
241 SR/ER_CO₂ (r^2 range: 0.63 – 0.78) and N₂O (r^2 range: 0.45 – 0.56) fluxes compared to those for forest and grassland
242 ecosystems across all data categories (Table 2). The prediction of CH₄ fluxes was also better for arable lands, but
243 only when using the RS data (Table 2). Stepwise elimination of the least important variables had a minimal effect on
244 the performances of the trained models (Table B1-B5 in Appendices). The selected models for the different
245 categories of datasets (RS, SP, and CD) had varying predictor variables across land uses. The forest and grassland
246 models required the most (5 and 6) predictor variables. In contrast, the least number of predictors (2) were mainly
247 observed for models describing GHG fluxes from arable soils, especially in the RS and SP categories (Table 2).

248 Comparing the models (CD) applied to predict the landscape fluxes, the site-measured soil moisture content
249 was a key predictor variable for all three GHG fluxes across land uses. In addition to soil moisture, the measured soil
250 nitrogen content (NH₄ or SN) and remotely sensed vegetation indices (NDVI, GNDVI, or NDMI) were prevalent
251 predictors of landscape SR/ER_CO₂ fluxes. Soil nitrogen content (NO₃ or CN) was also a recurrent predictor of CH₄
252 fluxes across land uses. However, the landscape CH₄ models had other varying predictors, such as aspect and soil
253 temperature in forest models, pH and clay in grassland, and vegetation indices in arable ecosystem models. For N₂O,
254 soil inorganic nitrogen (NH₄ or NO₃) concentrations predicted the fluxes in the forested areas, while vegetation
255 indices were common predictors in grassland and arable ecosystems (Table 2).

256 Further assessment of model performance was performed through an external validation step comparing the
257 mean of observed and predicted fluxes in the test dataset (n=~140 per flux). The mean measured CO₂ and CH₄
258 fluxes were similar to the predicted carbon fluxes across all the data categories (RS, SP, CD). In contrast to the
259 carbon fluxes, the measured N₂O fluxes were significantly lower than the predicted fluxes in autumn (Figure A1 in
260 Appendices).

261 **Table 2:** List of predictor variables and the performance of the selected RF models using either remote sensing (RS), soil physico-
 262 chemical parameters (SP), or combined (remote sensing and soil parameters) data. The model selection was made after a cross-
 263 validation (10-fold) step whereby the model's predictive power was tested based on unseen data to avoid overfitting.

Flux type	Land use	Category	Predictor variables	10-fold cross validation		
				R ²	RMSE	MAE
SR/ER-CO ₂ -C (mg m ⁻² h ⁻¹)	Forest (SR)	Remotely-sensed data (RS)	NDVI, GNDVI, NDMI	0.45	1.76	1.55
	Grassland (ER)		NDVI, GNDVI, NDMI	0.46	1.88	1.61

264

265 3.2 Observed versus predicted GHG fluxes

266 The measured and predicted GHG fluxes for all the sampling points had significant ($p < 0.001$) linear
 267 relationships (Figure 3). The model predictions of SR/ER_CO₂ fluxes were better (r^2 ; 0.49 – 0.67) than for soil CH₄
 268 (r^2 ; 0.39 – 0.46) or N₂O (r^2 ; 0.34 – 0.43) flux predictions across the three input datasets. Based on the estimated
 269 slopes, the predicted values were 35 – 46% lower than the measured values for SR/ER_CO₂ fluxes. Compared to
 270 CO₂, the CH₄ and N₂O predicted fluxes were lower (CH₄ 53 – 58%; N₂O 60 – 65%) than the measured fluxes,

271 primarily due to the underestimation of high fluxes. Based on r^2 values, the performances of the different predictor
 272 datasets were in the order of CD>RS>SP for carbon fluxes and CD>SP>RS for N_2O fluxes (Figure 3).

273

274 **Figure 3:** Linear regressions (with 95% confidence bands) of the measured and predicted GHG fluxes using remotely sensed data
 275 (RS), soil physico-chemical parameters (SP), and combined data (CD). GHG fluxes from all the sampling locations were considered
 276 in this regression analysis. The dotted line represents the 1:1 line.

277 3.3 Spatio-temporal variation in modeled landscape-scale fluxes

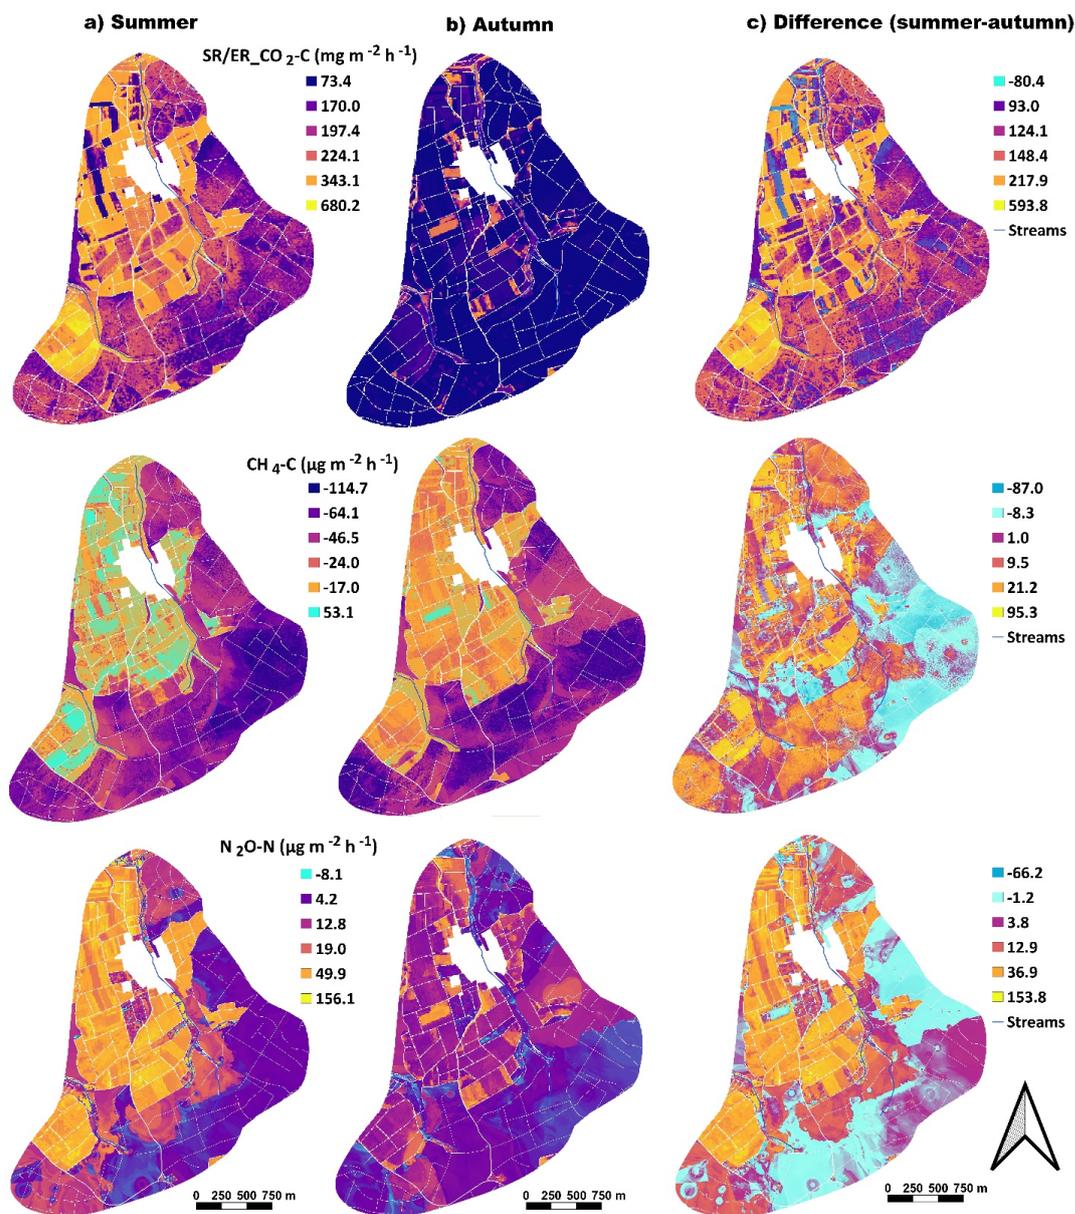

278 Predicted landscape fluxes for the summer and autumn seasons ranged from $+27.7 - +733.3\ mg\ m^{-2}\ h^{-1}$ for
 279 CO_2 -C, $-148.4 - +89.4\ \mu g\ m^{-2}\ h^{-1}$ for CH_4 -C, and from $-8.8 - +189.9\ \mu g\ m^{-2}\ h^{-1}$ for N_2O , and did not differ much in
 280 dependence of the input dataset used (RS, SP, or CD) (Table B6 in Appendices). However, the predicted flux ranges
 281 for the landscape were narrower than the measured fluxes, which ranged from 8.7 to $877.0\ mg\ m^{-2}\ h^{-1}$ for CO_2 -C,
 282 from $-214.1 - +221.2\ \mu g\ m^{-2}\ h^{-1}$ for CH_4 -C and from $-18.1 - +281.8\ \mu g\ m^{-2}\ h^{-1}$ for N_2O -N. Since the CD dataset

283 revealed models with better predictions for all GHG fluxes than the RS and SP datasets, we used GHG fluxes
284 predicted from CD predictors for seasonal and land use comparisons.

285 Most of the landscape area (99.2%) had higher SR/ER_CO₂ fluxes in summer than in autumn, with a small
286 proportion of arable and grassland ecosystems having an opposite trend. Around 76% of the landscape also had
287 higher N₂O fluxes in summer than in autumn. The remaining landscape area (24%) had higher N₂O fluxes in autumn
288 than in summer, particularly in forested areas. CH₄ uptake rates were lower in summer than autumn in most of the
289 landscape (63%), especially in arable and grassland soils. However, an opposite trend was found for about 37% of
290 the landscape area, dominated by forests, where CH₄ uptake rates were lower in autumn than in summer (Figure 4c).

291 High spatial heterogeneities (within short distances of <2 m) of the predicted landscape fluxes were
292 observed in each land use. Overall, spatial variations were more prominent in summer than in autumn (Figure 4;
293 Table B6 in Appendices). The spatial variability of SR/ER_CO₂ fluxes was higher (with a range of up to 2.6-folds)
294 on arable soils than forest and grassland soils, with multiple patches of low fluxes surrounded by high fluxes. CH₄
295 fluxes on arable lands were also heterogenous, with the soils acting as CH₄ sinks and sources within a few meters,
296 especially during summer (Figure 4a). For N₂O fluxes, high spatial heterogeneities were observed on grassland soils
297 in summer, as N₂O uptake and emission of the same or even higher order of magnitude occurred at neighboring
298 pixels. Arable soils in autumn were also highly heterogeneous, with patches of high N₂O fluxes surrounded by low
299 fluxes (Figure 4b).

300

301

302

303

Figure 4: Landscape maps of SR/ER_CO₂, CH₄, and N₂O for (a) summer, (b) autumn seasons, and (c) the difference maps showing the variation of the autumn from the summer fluxes. The surface fluxes were predicted using RF models trained with combined (remote-sensing and site-measured soil parameters) data (CD; Table 2).

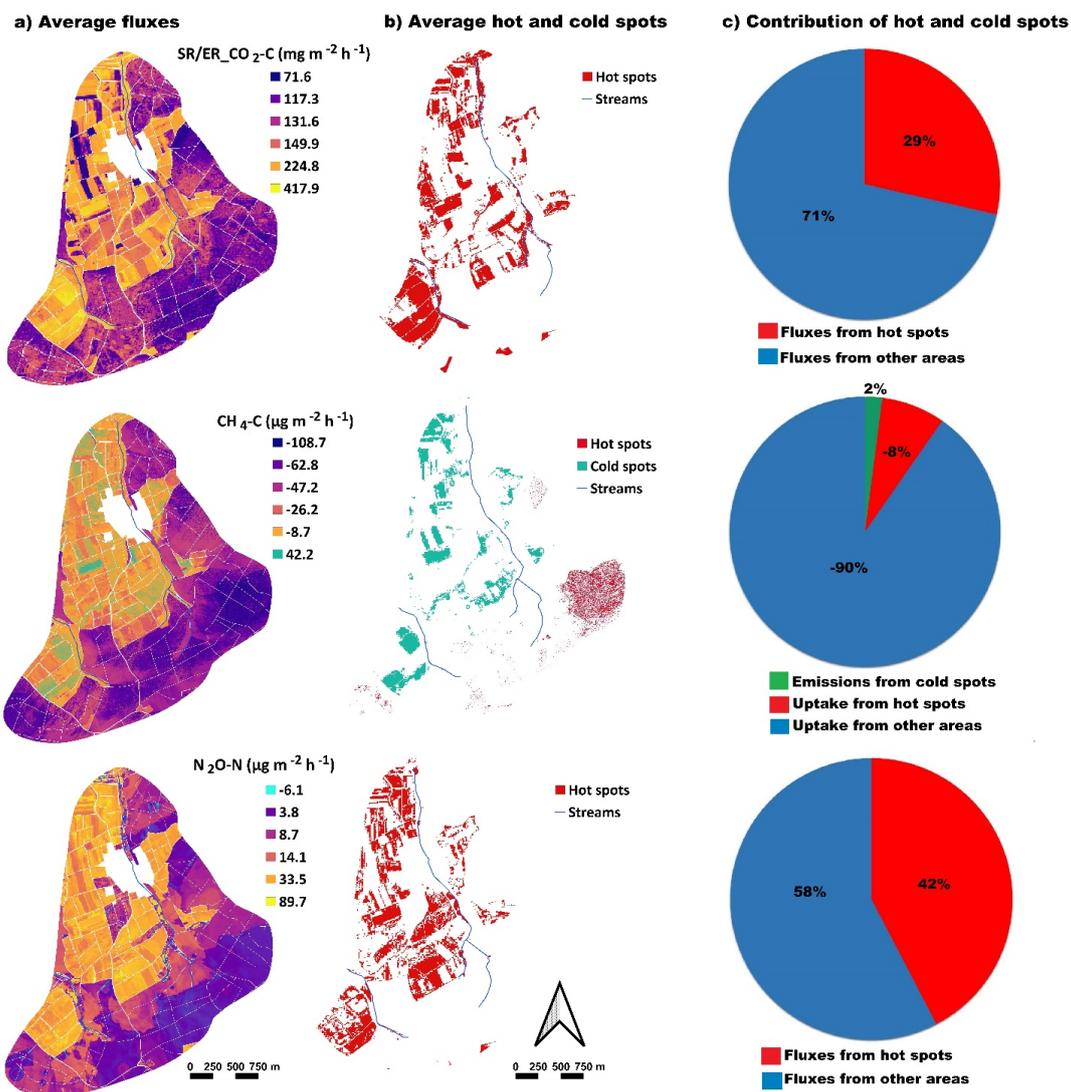

304 3.4 Hot spots and cold spots

305 The hot and cold spots of the GHG fluxes were identified from the average (summer and autumn) upscaled
306 landscape fluxes (Figure 5a). Using equation 4, the SR/ER_CO₂ and N₂O spatial hot spots had threshold values
307 >231.5 mg CO₂-C m⁻² h⁻¹ for CO₂ and >36.8 μg N₂O-N m⁻² h⁻¹ for N₂O. These hot spots covered a relatively small
308 portion (~16.7%) of the landscape, yet they played a significant role, especially the N₂O hot spots which accounted
309 for 42% of the landscape fluxes. Around 29% of the total SR/ER_CO₂ landscape flux emanated from the hot spot
310 areas (Figure 5). Overall, the SR/ER_CO₂ and N₂O hot spots were mainly located on arable lands (77.0% and 94.5%,
311 respectively) and grasslands (22.9% and 5.5%, respectively). Compared to the SR/ER_CO₂ and N₂O hot spots, the
312 hot and cold spots of CH₄ uptake were observed in smaller regions (3.1% and 7.3%) of the landscape with high soil
313 CH₄ uptake rates (>87.3 μg CH₄-C m⁻² h⁻¹) and low soil CH₄ uptake rates (<3.4 μg CH₄-C m⁻² h⁻¹). The CH₄ uptake
314 hot spots, exclusively on the forested soils, offset 8% of the landscape CH₄ fluxes (Figure 5). The cold spots
315 occupied 7% of the landscape and were primarily on arable soils (99.6%), accounting for 2% of the landscape's CH₄
316 emissions.

317 Common hot spots, with overlapping areas with elevated GHG emissions (i.e., SR/ER_CO₂ and N₂O hot
318 spot areas and CH₄ uptake cold spot areas), were mainly on arable soils (99.87%), with few located in grasslands
319 (0.12%) and forests (0.01%). Overall, these patches covered 1.5% of the landscape area and contributed 5%, 1%, and
320 8% of the SR/ER_CO₂, CH₄, and N₂O emissions within the landscape (Figure A2 in Appendices). Based on field
321 observations of the sampling sites (n=14) in the common hot spots, the sites at arable lands were either cropped with
322 barley or wheat. These arable common hot spots also had higher soil moisture content and NO₃ concentrations than
323 the average values recorded at all the other sampling locations. The common hot spots in the forest were found along
324 the riparian zones if either nitrogen-fixing alder trees were present or if grazed by cattle. Soil moisture (%), DOC,
325 NO₃, and NH₄ concentrations at these sites were also higher than mean values across all sampling points. The
326 grassland common hot spot regions were densely covered by nitrogen-fixing clover, with some located along the
327 riparian zones (Figure A3; Table B7 in Appendices).

328 Comparison of the GHG emission hot spots in summer and autumn using season-specific thresholds
329 revealed significant shifts in their geo-locations between the two seasons (Figure A4 in Appendices). SR/ER_CO₂
330 hot spot regions expanded by 46% from summer to autumn, even though the emissions from the former season were
331 higher. Unlike CO₂, N₂O emission hot spots and CH₄ uptake cold spots contracted by 23% and 86%, respectively,
332 from summer to autumn.

333

334

335

336

Figure 5: Maps showing (a) the average GHG fluxes and (b) the average hot spot and cold spot regions on the landscape for the summer and autumn seasons. The pie charts show the contribution (%) of hot and cold spots to total landscape fluxes. For this analysis, landscape fluxes were predicted using the combined data (CD; Table 2; Figure 3).

337

3.5 Comparison of upscaling approaches

338

339

340

341

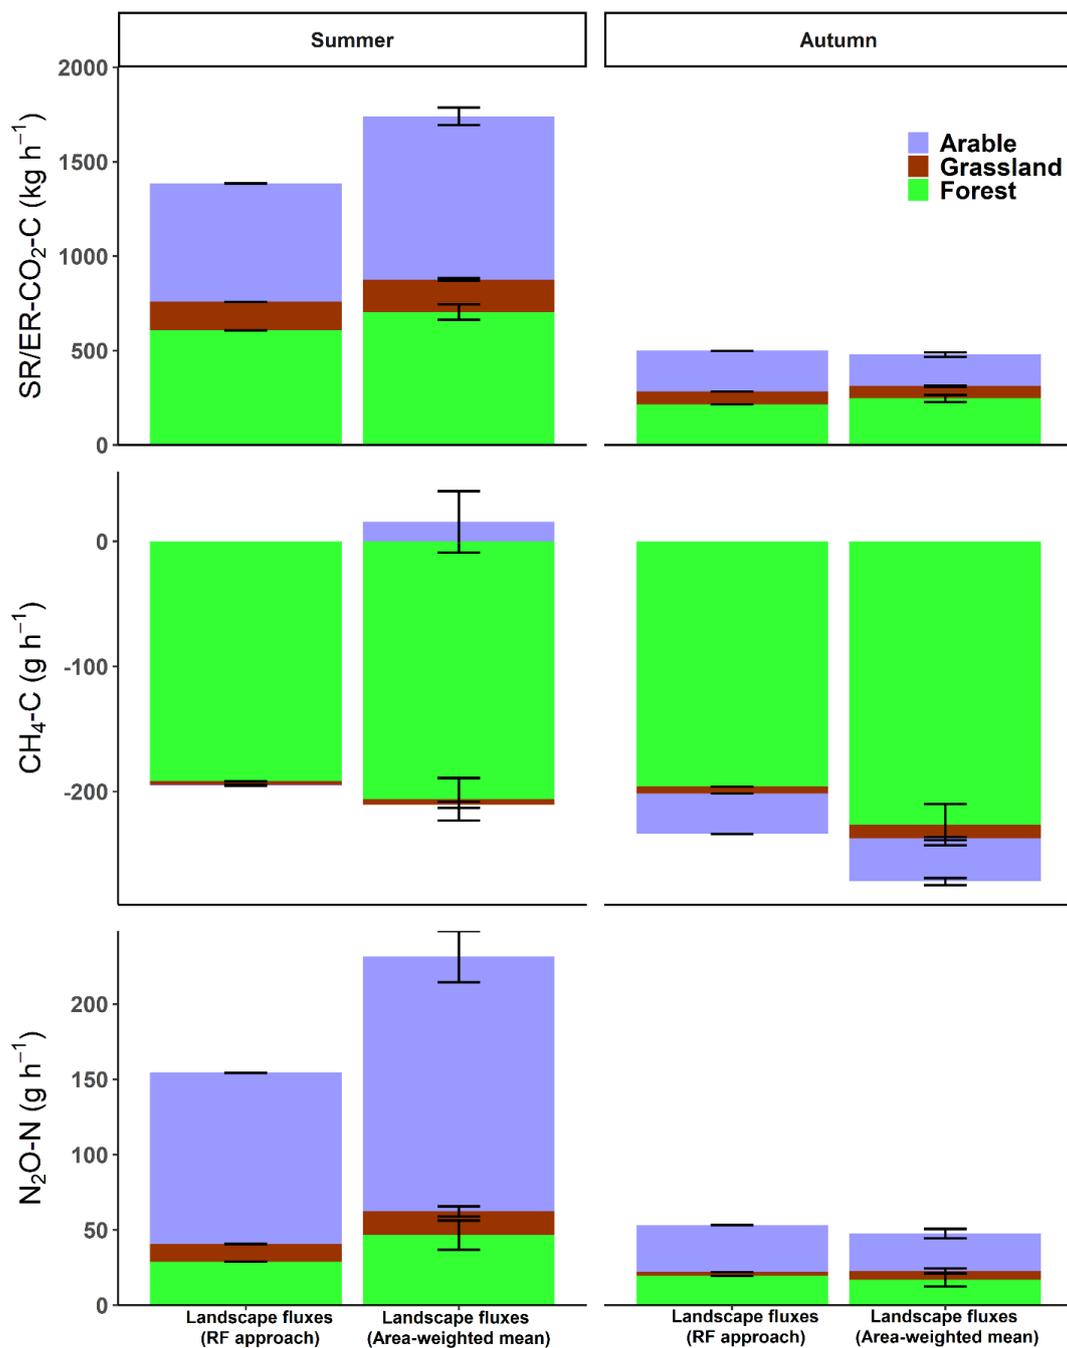

342

Seasonal differences in spatial patterns and magnitudes of GHG fluxes were observed for upscaled fluxes using either RF modeling or mean values of measured fluxes. In both approaches, the SR/ER_CO₂ and N₂O landscape fluxes were an order of magnitude higher in summer than in autumn. The CH₄ uptake rates were higher in autumn than in summer but within the same order of magnitude. In summer, the landscape-scale SR/ER_CO₂ and N₂O fluxes estimated using the area-weighted average approach were 26% and 50% higher than the RF-modelled

343 fluxes. The contrary was observed in autumn, where the later methodology produced slightly (4% and 11%) higher
344 fluxes than the area-weighted mean estimates.

345 The entire landscape CH₄ uptake estimates for autumn using the area-weighted mean were 16% higher than
346 the modeled estimates. Contrary to autumn, the area-weighted mean approach had slightly lower estimates of CH₄
347 uptake than the modeling approach in summer. Additionally, the CH₄ surface flux estimates for the whole arable land
348 in summer were net sinks (-0.9 CH₄-C g h⁻¹) using the RF modeling approach contrary to the net sources (15.5 CH₄-
349 C g h⁻¹) estimated by the area-weighted mean method. Overall, the total landscape fluxes estimated using the area-
350 weighted mean approach had up to two orders of magnitude higher uncertainty (standard error) than the modeled
351 landscape fluxes (Figure 6).

352

353

354

Figure 6: The total landscape fluxes (+SE) predicted using random forest (RF) models (with combined dataset) and the fluxes estimated using the area-weighted mean approach where the average point-measured fluxes were multiplied by the landscape area.

355 4. Discussion

356 4.1 Efficiency of in-situ soil parameters and remote-sensing data in upscaling GHG fluxes

357 Our study showed that remotely-sensed (RS) data and measured soil parameters (SP) could effectively
358 upscale soil-atmosphere CO₂, N₂O, and CH₄ fluxes from point chamber measurements across a heterogenous
359 landscape with mixed land uses. The improved prediction performance of the combined data (CD) sources indicates
360 the importance of incorporating controls of soil GHG fluxes that are remotely sensed and ground-based field
361 observations. The prediction models in this study suggested that the Sentinel-2-derived indices (NDVI, GNDVI, and
362 NDMI) were more effective predictors than the DEM-derived terrain attributes (elevation, slope, aspect, TWI, and
363 TPI). This finding is supported by the appearance of the Sentinel-2-derived indices in the prediction models of the
364 three GHGs, contrary to only one DEM index (aspect) that appeared in the CH₄ flux prediction models for the forest
365 ecosystem. The minor role of DEM indices in this study can be attributed to the relatively flat terrain of our study
366 landscape (Figure 1b) and is further backed by the lack of spatial variation in the measured GHG fluxes with slope,
367 yet slope was considered during site stratification (Wangari et al., 2022). Another possible explanation could be that
368 soil wetness, a common predictor of all the GHG fluxes across the landscape, was better represented by the site-
369 measured soil moisture content and the NDMI index (vegetation water content), than any of the DEM terrain
370 attributes, including the TWI that focuses on moisture conditions, as they lack a temporal dimension.

371 Compared with other studies that have upscaled GHG fluxes using the random forest algorithm, we
372 considered more site-measured data on soil parameters, all three GHG fluxes, and different land uses (Table 3). The
373 prediction accuracies of soil respiration for our mixed forest ecosystem (3.3 km²) were slightly better than those
374 reported for a smaller forested headwater watershed (0.12 km²) in Maryland, USA (Warner et al., 2019). Our CH₄
375 prediction performance for forest soils was comparable to those of a boreal forest landscape (Vainio et al., 2021).
376 However, our CH₄ prediction performance was up to 3.6-folds lower than those of a forested headwater watershed
377 and peatland soils, which can be attributed to higher and more homogenous CH₄ production in such ecosystems
378 (Warner et al., 2019; Räsänen et al., 2021). Our CH₄ and N₂O model prediction accuracies for arable soils were
379 better than those for arable soils in New South Wales, Australia, which only considered input data from ground-
380 based sensors such as soil pH and clay content (McDaniel et al., 2017). Nevertheless, caution has to be taken when
381 interpreting any conclusions from these study comparisons due to the limitations of different model validation
382 techniques, different predictor variables used for modeling, and the different ecosystems and spatial scales of
383 measurement and predictions.

384 4.2 Seasonal variability of landscape fluxes

385 The GHG fluxes predicted by the RF model in this study revealed seasonal trends of up to 3-fold higher
386 CO₂ and N₂O fluxes in summer and 1.2-fold higher CH₄ uptake in autumn, which were also evident in the measured
387 fluxes at the sampling points (Wangari et al., 2022). These trends can be attributed to seasonal changes in soil
388 parameters and vegetation within the landscape that were well captured by the measured soil parameters and
389 Sentinel-2-derived indices in the prediction models. The higher soil moisture, mineral nitrogen, and vegetation cover
390 observed during the summer growing season enhanced the respiration rates (SR/ER_CO₂) and N₂O emissions,

391 particularly in arable ecosystems, which were flux hot spots for both gases. Root respiration of growing plants can
392 also enhance N_2O production through denitrification by creating anaerobic conditions and supplying labile exudates
393 to denitrifying microbes (Butterbach-Bahl & Dannenmann, 2011; Malique et al., 2019). Previous studies have shown
394 that higher mineral nitrogen and soil moisture content can enhance N_2O production in soils through an increased
395 supply of substrates and the creation of anaerobic conditions that enhance denitrification rates (Barton et al., 1999;
396 Ciarlo et al., 2006; Butterbach-Bahl et al., 2013). The lower CH_4 uptake rates in summer can be primarily explained
397 by the observed higher soil moisture content, which has been previously reported to hinder CH_4 oxidation by slowing
398 down gas (atmospheric CH_4) diffusion in soils (Le Mer & Roger, 2001).

399 The high-resolution (1 m pixel size) scaled-up fluxes could also identify detailed temporal patterns of the
400 GHG fluxes across the landscape, thus, revealing trends that were otherwise undetectable in the aggregated measured
401 (point) fluxes. To illustrate, parts of the landscape (24% and 37%) showed even opposite trends of higher N_2O fluxes
402 and lower CH_4 uptake rates in autumn, and these areas were predominantly in the forested ecosystem. Such fine-
403 scale patterns of GHG fluxes result from land use-specific local effects depending on the season. For example,
404 decaying fallen leaves during autumn can favor denitrification in forest soils but not in grassland or arable
405 ecosystems. The higher CH_4 uptake rates in summer could be due to the increased exposure of some forest soils to
406 the sun leading to drier and warmer soils that promote CH_4 oxidation (Steinkamp et al., 2000). This finding is
407 supported by the importance of aspect as a predictor of landscape CH_4 fluxes in the forest ecosystem, which
408 influences the amount of incoming radiation an area receives.

409 **4.3 Importance of hot spots and cold spots of landscape-scale GHG fluxes**

410 The high spatial resolution of our predicted GHG fluxes enabled the identification of areas across the
411 landscape that functioned as hot spots (of soil CH_4 uptake, SR/ER_ CO_2 , and N_2O) or cold spots of soil CH_4 uptake.
412 Based on field observations and analyses of important predictor variables, the existence of these hot and cold spots
413 was primarily driven by human activities such as fertilizer application, crop growing and tillage, and landscape
414 environmental parameters related to seasonality and proximity to riparian areas. This finding is supported by the
415 primary association of the SR/ER_ CO_2 and N_2O hot spots and CH_4 uptake cold spots within arable ecosystems since
416 these systems showed higher soil mineral nitrogen concentrations than grassland and forest soils. The hot spots of
417 SR/ER_ CO_2 and N_2O observed on the grassland ecosystem can be attributed to the primary location of grasslands
418 along the riparian areas. Increased soil moisture values, a key characteristic of the riparian regions, has also been
419 reported to drive elevated soil GHG fluxes (Kaiser et al., 2018; Vainio et al., 2021).

420 Spatial hot spots of SR/ER_ CO_2 and N_2O played a crucial role in determining total landscape fluxes,
421 accounting for up to 42% of the total predicted landscape fluxes, despite their relatively low (~16%) coverage area.
422 Such high contributions suggest that failure to capture these hot spots results in large uncertainties in landscape GHG
423 flux estimates. Overall, the contribution of the hot spot areas (of CO_2 , N_2O , and CH_4 emissions) to the landscape
424 fluxes decreased in the order of $\text{N}_2\text{O} > \text{CO}_2 > \text{CH}_4$. This finding emphasizes the importance of capturing the N_2O hot
425 spots and improving the spatial coverage of N_2O measurements, as it can introduce enormous uncertainty in
426 landscape fluxes. A similar finding emphasizing the importance of N_2O flux heterogeneities has been concluded in a

427 previous study, which recorded more sampling locations required for improved N₂O flux estimates than CO₂ and
428 CH₄ at a landscape scale (Wangari et al., 2022).

429 Identifying common patches with elevated emissions of the three GHGs can inform priority areas for
430 implementing localized mitigation measures within a landscape. These common patches covered only 1.5% of our
431 landscape (~0.2 km²) and had the highest GHG fluxes contributing around 5%, 1%, and 8% of the landscape CO₂,
432 CH₄, and N₂O emissions. The location of these patches primarily (99.9%) on arable land emphasized the significant
433 role of focusing on mitigating GHG fluxes from arable soils. The mitigation strategies may include adjusting the
434 fertilizer application rates, especially in specific areas that hold more water, probably due to topographical or soil
435 conditions (e.g., Hassan et al., 2022). This finding is further supported by the high soil moisture content measured at
436 the sampling sites within the common patches of elevated GHG fluxes. In contrast to hot spot regions of elevated
437 GHG emissions, CH₄ uptake hotspots inform future mechanisms for leveraging the GHG sink ability of soils, such as
438 expanding local forests. This finding is supported by uptake hot spots identified on forest soils in this study,
439 offsetting 8% of the total landscape CH₄ flux. The expansion of forested areas will also likely have a much higher
440 mitigation impact via CO₂ sequestration. Although some of the above strategies are currently applied at broader
441 scales (1 km²), localized mitigation strategies may be required at smaller scales (<100 m²), especially at highly
442 heterogeneous landscapes with a high variability of agricultural practices. We also found significant shifts in the geo-
443 locations of hotspot regions between summer and autumn, suggesting that seasonal changes in land management and
444 soil conditions may also lead to a temporal expansion or contraction of the hot spot regions. This finding further
445 emphasizes the need for time-based mitigation strategies, such as considering fertilizer application times, which not
446 only target the spatial hotspots but also consider the temporal patterns that result in peak emissions (e.g., Wagner-
447 Riddle et al., 2020).

448 **4.4 Comparison of upscaling approaches**

449 Contrary to the area-weighted upscaling approach of spatial aggregation of chamber fluxes (Webster et al.,
450 2008; Molodovskaya et al., 2011; Rosenstock et al., 2016), random forest modeling allowed us to estimate the entire
451 spatial distributions of the fluxes at high spatial resolution (1 m pixel size), capturing both cold spots and hot spots.
452 In agreement with our hypotheses, the landscape fluxes were either over or under-estimated by the area-weighted
453 average approach compared to the RF modeling approach. The overestimated landscape CO₂ and N₂O fluxes by up
454 to 50% during the peak summer season suggest an overrepresentation of the high fluxes measured at most of the
455 sampling points, resulting in elevated mean and upscaled fluxes. Furthermore, landscape CH₄ uptake rates were
456 overestimated during the peak autumn season. Previous studies have also observed a similar trend of elevated mean
457 CH₄ uptake rates at measured sites, which they attributed to the over-representation of high uptake rates during the
458 peak uptake seasons (Warner et al., 2019). Conversely, the underestimation of CO₂, N₂O, and CH₄ uptake, especially
459 on arable soils, coincided with the low flux season, implying reduced mean fluxes due to the overrepresentation of
460 the low fluxes. An alternative explanation of the differences in landscape flux estimates from both approaches could
461 be the underestimation of high fluxes by the RF models, which we also found in our study. However, the landscape
462 means of RF predicted and measured fluxes from 30% of our sampled sites were primarily similar (Figure A1 in

463 Appendices), suggesting that the lack of spatial representation of all hot and cold spots by the area-weighted mean
464 approach rather than the inability of the RF models to reproduce high values accounted for the findings above.

465 Collectively, our results illustrated that the representativeness of landscape fluxes using aggregated chamber
466 fluxes might be influenced by the spatial and temporal heterogeneity of the fluxes. This finding aligns with previous
467 results on the required number of chamber measurement locations for reliable landscape fluxes that varied with land
468 use and season (Warner et al., 2019, Wangari et al., 2022). The high (50%) overestimation of landscape N₂O fluxes
469 suggested the higher sensitivity of reliably estimating N₂O fluxes using the (aggregated means) conventional method.
470 Previous studies have also emphasized the importance of N₂O fluxes in constraining uncertainties in landscape flux
471 quantification (e.g., Wangari et al., 2022). Compared to the suggested way of lowering landscape-scale flux
472 uncertainties in the conventional estimates by increasing the number of chamber measurements within a landscape
473 (Wangari et al., 2022), the modeling approach can be a less resource-intensive alternative.

474 Combining high-resolution remote sensing data and measured soil parameters to upscale the chamber fluxes
475 reduced the biases and the aforementioned landscape-scale flux uncertainties. The reduced uncertainties in the
476 modeled landscape fluxes can be attributed to the relation of multiple underlying controls of soil GHG fluxes, which
477 have high seasonal and spatial variability. Remote sensing datasets have unlimited spatial extents with high spatial
478 resolution and thus allowing reliable prediction of spatially continuous fluxes that can capture the cold and hot spots
479 over different seasons across heterogeneous landscapes (Warner et al., 2019; Räsänen et al., 2021). This study's high
480 spatial resolution upscaling (1 m pixel) enabled capturing small-scale variabilities in GHG fluxes within short
481 distances, which would have been missed out with coarser resolution upscaling. Upscaling at a finer resolution was
482 especially relevant due to the heterogeneous nature of our study landscape, related to different land uses, soil types,
483 and slope positions.

484 5. Conclusions

485 This study demonstrated the potential of improved prediction performance when combining field-based
486 measurements of soil parameters with remotely-sensed data in scaling up flux (chamber) measurements from
487 stratified sites. Among the remotely-sensed predictors, Sentinel-2 indices played a more significant role than DEM-
488 derived attributes in upscaling the GHG fluxes across our relatively flat landscape terrain. The high-resolution (1 m
489 pixel size) scaled-up fluxes effectively revealed fine-scale (within a few meters) hot and cold spots of GHG fluxes
490 across a mixed land use landscape. The N₂O hot spots were more significant sources of GHGs as they contributed
491 42% of the landscape N₂O fluxes compared to SR/ER_CO₂ and CH₄ emission hotspots, which accounted for 29%
492 and 2% of the landscape CO₂ and CH₄ emissions, respectively. Arable soils, which had higher N₂O fluxes, also had
493 patches with elevated emissions of the three GHGs, especially in areas with high soil moisture content. These
494 findings emphasize the importance of targeted local mitigation measures, especially for agricultural soils, in
495 mitigating landscape GHG fluxes. Compared to RF upscaling, the area-weighted average approach lacked detailed
496 spatiotemporal patterns of landscape fluxes, which can prevent targeted mitigation measures to some extent.

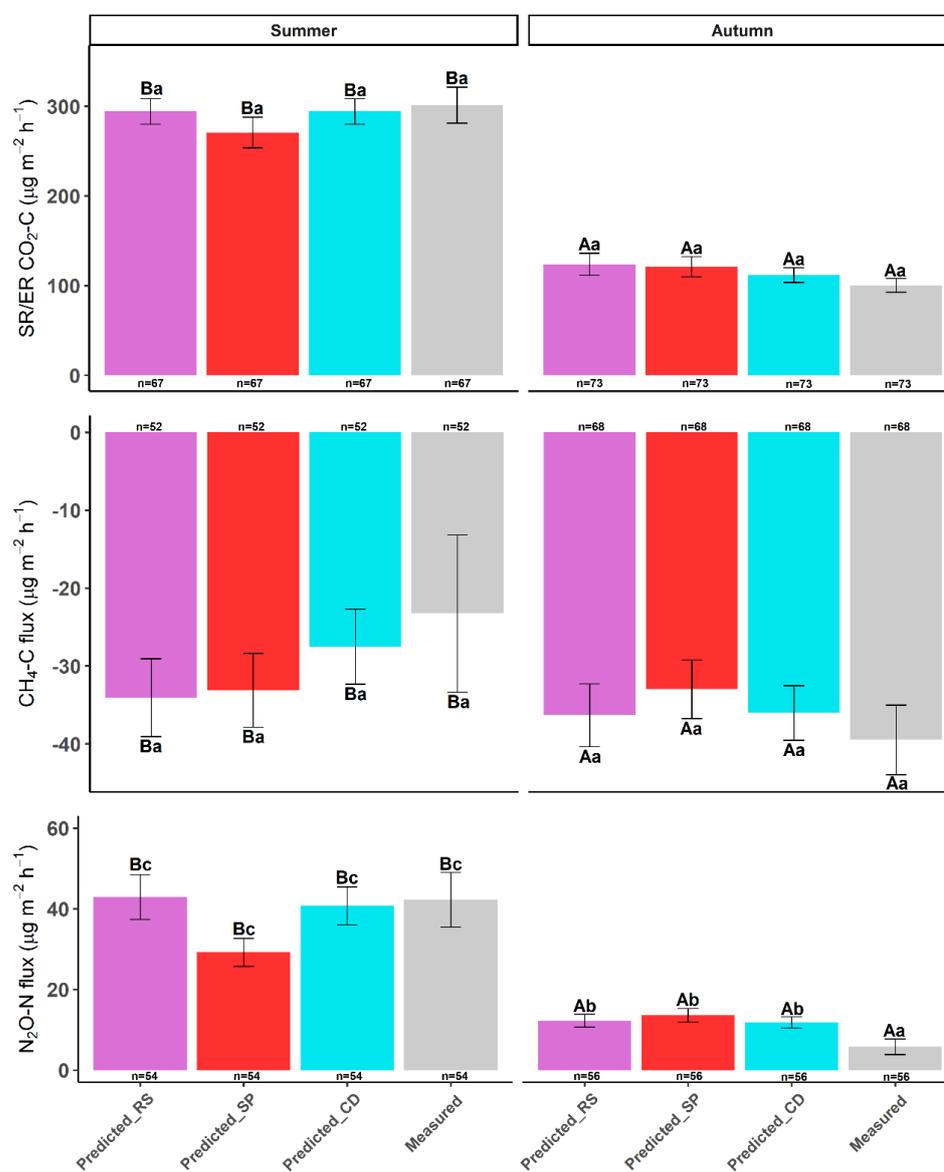

Table 3: Comparison of other that have upscaled landscape fluxes using the random forest algorithm.

499 **Appendix A: Figures**

500

501 **Figure A1:** Bar graphs showing the mean fluxes (\pm SE) predicted using remote sensing (RS), soil properties (SP), and combined
 502 data (CD) and the measured fluxes at the sampling sites in the 30% model test dataset. The upper-case and lower-case letters indicate
 503 significant differences ($p < 0.05$) in the mean fluxes in the different seasons and across the measured and predicted fluxes.

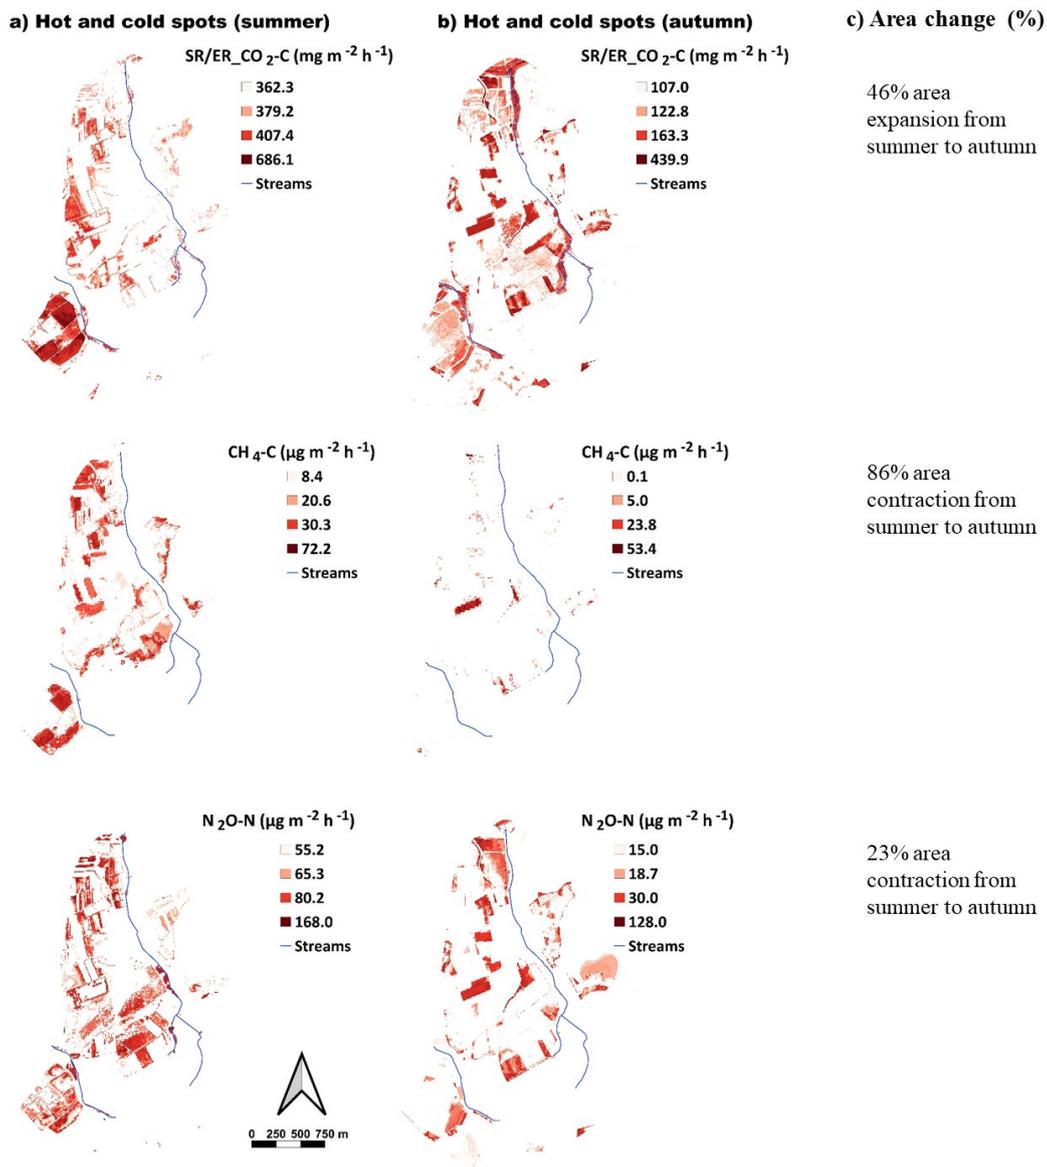

504

505 **Figure A2:** Map showing the common hotspot regions of the three GHG fluxes and the location of the measured sampling points
506 within these recurrent hotspots (Satellite Image downloaded from © Google Maps).

507

508 **Figure A3:** Clover (*Trifolium*) on grassland ecosystems.

509

510 **Figure A4:** Maps showing the hot and cold spots of the (a) summer and (b) autumn seasons. These regions were defined using each
 511 season's specific threshold.

512 **Appendix B: Tables**

513 **Table B1 a, b, c:** Cross-validation results of different models developed for SR/ER-CO₂ fluxes in 1a) forest, 1b) grassland and 1c)
 514 arable land using different predictors in the training dataset. Stepwise elimination of least important predictors was implemented.

543 **Table B7:** Description of the sampling locations within the common hotspot patches of all three GHG fluxes.

Site ID	Land use	Site description and observed soil properties
Q10	Forest	Riparian forest with alder (<i>Alnus</i>) trees, higher soil moisture, nitrate, ammonium and DOC concentrations
Q73	Grassland	Riparian grassland with higher soil moisture, ammonium and DOC concentrations
Q80	Grassland	Riparian grassland with Clover (<i>Trifolium</i>) and higher soil moisture
C23	Grassland	Higher soil moisture, nitrate, ammonium and DOC concentrations
C79	Grassland	Higher ammonium and DOC concentrations
C45	Grassland	A lot of Clover (<i>Trifolium</i>)
C37	Grassland	A lot of Clover (<i>Trifolium</i>)
E7	Grassland	A lot of Clover (<i>Trifolium</i>)
C3	Arable land	Barley crops
C13	Arable land	Barley crops and the soils had higher nitrate concentrations
Q20	Arable land	Barley crops
C12	Arable land	Barley crops and the soils had higher soil moisture
C56	Arable land	Wheat crops and the soils had higher soil moisture
C97	Arable land	Wheat crops and the soils had higher nitrate concentrations

544

545 **Acknowledgments**

This work was part of the MINCA (MIItigation of Nitrogen pollution at CAatchment scale) research project. The authors gratefully acknowledge the German Research Foundation (DFG) for funding the project (HO6420/1-1, KR5265/1-1). KBB additionally received funds via the Pioneer Center for Research in Sustainable Agricultural Futures (Land-CRAFT), DNRG Grant Number P2. Furthermore, Wangari, E. received doctoral funding from the German Academic Exchange Service (DAAD).

546 **Declaration of competing interest**

The authors declare that they have no conflict of interest.

547 **Author contribution**

Conceptualization: KB, LB, GG, TH, RK, DK, EW. Field measurements and laboratory work: EW, RM, TH. Data analysis: EW, RM, KB. Funding acquisition: KB, RK, TH, DK. Writing-original draft preparation: EW, RM, KB. Writing-final draft: EW, KB, RM, LB, RK, TH, DK, GG.

548 **Data availability**

The data will be made freely available via the Zenodo repository after publishing. However, reviewers can request the data anytime during the review process, and the corresponding author will provide it via email.

Plain text summary

Agricultural landscapes act as sinks or sources of the greenhouse gases (GHG) CO₂, CH₄ or N₂O. Fluxes of these GHGs between ecosystems and the atmosphere are controlled by various physico-chemical and biological processes. Therefore, fluxes depend on environmental conditions such as moisture, temperature, or soil parameters, which results in large spatial and temporal variations of GHG fluxes. Here we describe an example how this variation may be studied and analysed.
