Abstract. Transport and cycling of dissolved organic carbon (DOC) are most active in estuaries. However, a comprehensive understanding of the sources, sinks, and transformation processes of DOC throughout the river-estuary-ocean continuum is yet to be derived. Taking the Changjiang Estuary and adjacent shelf sea as a case study area, this study applies a physics-biogeochemistry coupled model to investigate DOC cycling the river-estuary-ocean continuum. DOC is classified into two types depending on the origin, namely terrigenous DOC (tDOC) and marine DOC (mDOC). Simulation results were compared with observation and showed a satisfactory model performance. Our study indicates that in summer, the distribution of DOC in the Changjiang Estuary is driven by both hydrodynamics and biogeochemical processes, while in winter, it is primarily driven by hydrodynamics. The spatial transition from terrigenous-dominated DOC to marine-dominated DOC occurs mainly across the contour line of a salinity of 20 PSU. Additionally, the source-sink patterns in summer and winter are significantly different, and the gradient changes in chlorophyll-a indicate the transition between sources and sinks of DOC. A five-year averaged budget analysis of the model results indicates that the Changjiang Estuary has the capability to export DOC, with tDOC contributing 31% and mDOC accounting for 69%. The larger proportion of mDOC is primarily attributed to local biogeochemical processes. The model offers a novel perspective on the distribution of DOC in the Changjiang Estuary and holds potential for its application in future organic carbon cycling of other estuaries.

1 Introduction

Dissolved organic carbon (DOC), as the largest pool of reduced carbon in the oceans (Benner et al., 1992), is transported from rivers to oceans in the amount of approximately 0.25 Gt each year (Hedges et al., 1997). DOC is defined as the nonliving organic matter in the ocean that can pass a 0.5μm pore size filter, with decomposition time scales varying from hours to years (Sondergaard and Middelboe, 1995; Hedges, 1992).

Estuaries serve as a key interface between the land and ocean, typically displaying pronounced gradients in biogeochemical variables, such as salinity, turbidity, and organic carbon (Bauer et al., 2013; Ma et al., 2023; Zhang et al., 2021). DOC in estuaries is predominantly derived from river inputs and marine production (Hu et al., 2020; Benner and Opsahl, 2001; Mantoura and Woodward, 1983). Terrigenous DOC (tDOC), which originates from terrestrial sources (e.g., soils) and is

30   delivered from rivers, is relatively susceptible to photodegradation but resistant to microbial degradation (Mantoura and
       Woodward, 1983), while marine DOC (mDOC), which is derived mainly from local production, tends to be consumed
       biochemically (Guo et al., 2021; Fellman et al., 2010). DOC of both origins can be transformed through complicated
       biogeochemical processes, including being converted into particulate organic carbon (POC) through heterotrophy and
       flocculation or into dissolved inorganic carbon (DIC) through respiration (Bauer et al., 2013; Medeiros et al., 2015).

35   Therefore, DOC in estuaries is vital in the coastal biogeochemical carbon cycle and marine ecosystem (Romankevich and
       Ljutsarev, 1990; Meng et al., 2022; Tian et al., 2021).

       Estuarine hydrodynamic environment, including the river runoff, tides, and estuarine turbidity maximum region, can
       significantly influence the distribution of DOC and corresponding biogeochemical processes (Aminot et al., 1990; Song et
       al., 2022; Li et al., 2015). In recent years, increasing attention has been paid to understanding the distribution and

40   transformation of DOC in estuaries. Increased concentrations of DOC have been observed in freshwater river plumes in
       several estuaries, which are attributed to elevated primary production and low microbial decomposition (Marcinek et al.,
       2020). Production of DOC in estuaries is promoted in summer by the exudation of surface phytoplankton and the dissolution
       of POC from deeper regions in the water column (Druon et al., 2010). DOC concentration is significantly higher inside
       estuaries than outside (Ji et al., 2021; Guo et al., 2021; Benner and Opsahl, 2001). However, how DOC is retained in

45   estuaries and how much DOC from estuaries is exported to open shelf seas remain unclear. In some estuaries (e.g., the Pearl
       River estuary), existing studies showed that a significant portion of DOC is exported to shelf area; a unitary alteration in
       terrestrial DOC input results in an approximate 0.92-unit response in carbon export flux, whilst studies from other estuaries
       indicated that exported DOC is removed in a short time near the estuary mouth (Guo et al., 2021). A conceptual model
       considering the turnover of DOC in estuary suggested that ~5% tDOC may be exported to the open ocean at a global scale

50   (Anderson et al., 2019). Quantifying the contributions and impacts of individual processes for source-to-sink pathways of
       DOC in estuaries is challenging, and deserves focused attention and analysis (Kumar et al., 2022; Zhao et al., 2023; Sun et
       al., 2022; Martineac et al., 2021).

       The Changjiang River is the world's fifth-largest river in terms of discharge (9.24×10^{11} m^3 year^{-1}) (Tian et al., 1993). Its
       estuary (Changjiang Estuary) receives large amounts of freshwater and nutrients every year (Gu et al., 2012). It has been

55   estimated that the Changjiang River delivers approximately 1.5~1.9 Tg DOC to the East China Sea (Wang et al., 2012; Shi et
       al., 2016). Besides, because of a high sediment discharge and interaction between river runoff and tides, a prominent and
       persistent turbidity maximum zone exists in the estuary (Ge et al., 2015; Sokoletsky et al., 2014). In this highly dynamic
       estuary, intense anthropogenic activities, terrigenous input, and the functioning of the coastal ecosystem jointly control the
       cycling of DOC. Existing observations show that DOC concentration in the Changjiang Estuary is lower in winter than in

60   summer, probably due to higher primary production and elevated input of tDOC through the river runoff (Ji et al., 2021). On
       the other hand, DOC is removed rapidly in this area due to intense photooxidation and microbial degradation (Guo et al.,
       2021). Due to the diverse sources and pathways associated with DOC, a more specific exploration is needed to understand

the source, sink, and transportation through Changjiang Estuary within the context of physical and biogeochemical processes at the estuary.

65 This study combines field observations and high-resolution numerical modeling to investigate the source-to-sink pathways and transformation of DOC in the Changjiang Estuary by distinguishing tDOC and mDOC. In order to derive a process-based understanding of the DOC cycling in the river-estuary-ocean continuum, we quantified the impacts of relevant biogeochemical processes, analyzed key hydrodynamic and biogeochemical factors, and estimated the transport fluxes across different compartments from the estuary to the open ocean.

2 Methods and Data

2.1 Model description

A three-dimensional hydrodynamic model coupled with a biogeochemical model is applied in this study. The physical model is the unstructured grid, Finite-Volume Community Ocean Model (FVCOM) (Chen et al., 2003), providing simulations of physical properties and hydrodynamic processes in the study area. The finite volume method and use of an unstructured grid

75 in FVCOM facilitate the handling of intricate geographic boundaries as estuaries and islands with irregular shorelines (Chen et al., 2013). An integrated model, FVCOM-SWAVE, was incorporated into FVCOM for the simulation of waves and wave-current interactions (Qi et al., 2009). Besides, FVCOM encompasses a sediment transport model to simulate sediment and SPM dynamics (Ge et al., 2015). A complete coupling of current-wave-sediment interactions is implemented in FVCOM (Wu et al., 2011; Ge et al., 2018; Ge et al., 2020).

80 The European Regional Seas Ecosystem Model (ERSEM) is a biogeochemical and ecological model for complex ecosystems in both pelagic and benthic environments of regional seas (Butenschön et al., 2016). It offers a platform for simulating the microbial food web and major biogeochemical cycles, including carbon, nitrogen, phosphorus, silicate, iron cycling, calcification, and a light model based on inherent optical properties. We used the Framework for Aquatic Biogeochemical Models (FABM) (Bruggeman and Bolding, 2014) as a coupler for data exchange between the

85 hydrodynamic model (FVCOM) and the biogeochemical model (ERSEM).

2.2 DOC cycle module

The DOC cycle module in the coupled FVCOM-ERSEM model distinguishes terrigenous and marine components in the river-estuary-shelf continuum (Anderson et al., 2019). A schematic of the DOC module is shown in Fig. 1.

As for terrigenous components, terrigenous dissolved organic matter (DOM) contains a significant portion of aromatic

90 compounds (Verhoeven and Liefveld, 1997), which tends to be photo-oxidized while resistant to decomposition by microorganisms (Opsahl and Benner, 1998; Hudson et al., 2007). Moreover, aromatic compounds are precipitated as a result of metal ions (Vilge-Ritter et al., 1999). Therefore, based on the unified DOM model (UniDOM) (Anderson et al., 2019), tDOC is divided into photolabile (T_1) and non-photolabile (T_2) pools. T_1 undergoes photodegradation and flocculation but is

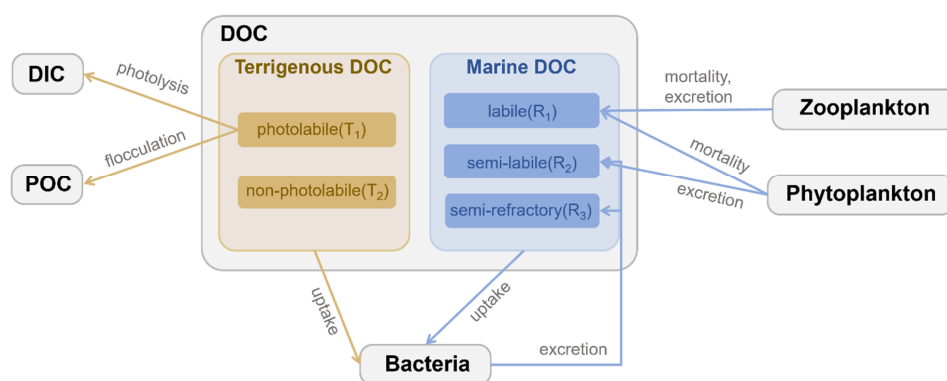
not prone to microbial decomposition, while T_2 does not undergo photodegradation and flocculation but is prone to microbial decomposition. Both T_1 and T_2 are further divided into three components to take into account the decrease of turnover rate over time (Table S1). The three components represent turnover time scales of 30 days, 8 years, and 70 years, respectively, following existing reference studies (Catalán et al., 2016; Evans et al., 2017; Anderson et al., 2019). T_1 comprises T1_30d, T1_8y, and T1_70y, while T_2 comprises T2_30d, T2_8y, and T2_70y. In the model, tDOC cycling is affected by three biogeochemical and physical processes, namely (1) photolysis, (2) bacterial uptake, and (3) flocculation. In the marine components, mDOC is categorized into three pools (R_1, R_2, and R_3) derived from the dynamic decomposition model in ERSEM, labeled explicitly as labile, semi-labile, and semi-refractory mDOC. This classification is determined by considering degradation timescales and production mechanisms (Butenschön et al., 2016; Polimene et al., 2007). mDOC primarily originates from the mortality and excretion of bacteria, as well as the excretion and mortality of phytoplankton and zooplankton. It is subsequently consumed through bacterial uptake. In the model, mDOC cycling is influenced by six biogeochemical processes, namely (1) phytoplankton mortality, (2) phytoplankton excretion, (3) zooplankton mortality, (4) zooplankton excretion, (5) bacterial uptake, and (6) bacterial excretion. A detailed description and equations of the cycling and associated parameterizations are given in Text S1 from the Supplementary Information.


Figure 1. The flow diagram presents the sink and source terms of DOC.

2.3 Model setup for the study area

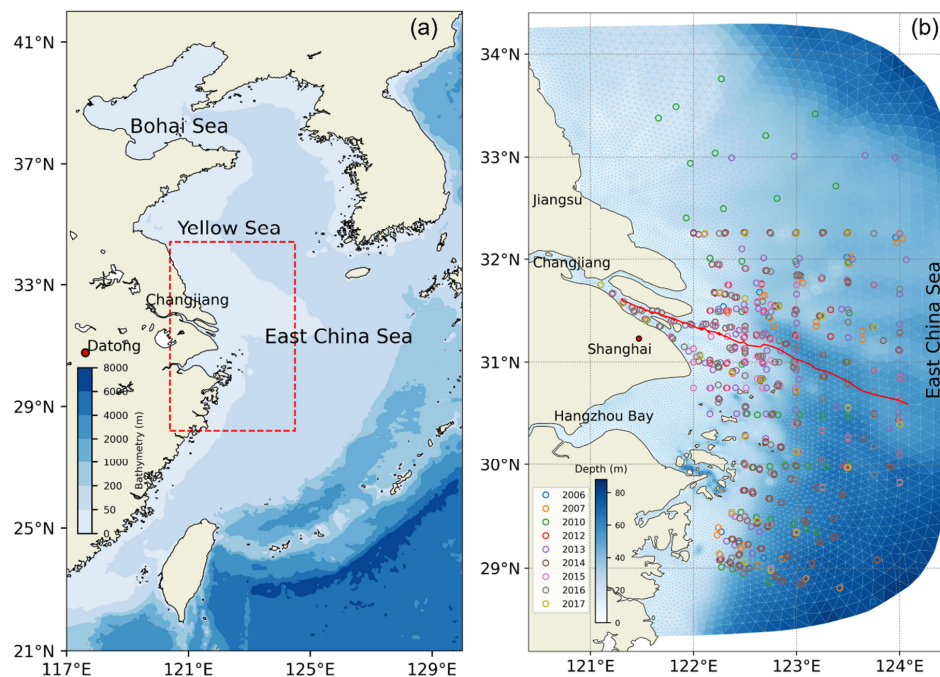
The model domain for the Changjiang Estuary (Fig. 2) extends from the Datong hydrological station as the upstream boundary in the Changjiang River to the inner shelf of the East China Sea (ECS).


Figure 2. Map of the study area. The panel (**a**) shows the location of the Changjiang Estuary, with the red rectangle indicating the study area. The panel (**b**) presents the model domain resolved by a triangular grid. The circles mark the sampling locations of DOC concentration between 2006 and 2017, distinguished by different colored circles. The red solid line is the selected transect from the river channel to the open shelf region for analysis.

The spatial resolution of the model grid is between 1 and 3 km near the river mouth, and between 4 and 15 km at the open boundary. The upstream river boundary at the Datong station is forced by the daily recorded freshwater discharge and SPM flux. Meanwhile, nutrient concentrations, tDOC, and POC concentrations are specified at the river boundary. The organic carbon concentrations based on the climatological average concentration at the river boundary for reference are derived from field observations conducted by multiple origins (Shi et al., 2016; Guo et al., 2014; Wang et al., 2012; Zhang et al., 2014; Liu et al., 2013; Liu et al., 2019). Open boundary conditions are derived from a shelf-scale FVCOM extended to the East China Sea (ECS) to provide astronomical tides and ocean circulations (Ge et al., 2013; Ge et al., 2020). Atmospheric forcing is derived from the global climate and weather reanalysis hourly dataset ERA5 produced by the European Centre for Medium-Range Weather Forecasts (ECMWF). This includes the 10-meter surface wind speed, long waves, short waves, and sensible and latent radiation flux at a spatial resolution of 0.125°. The atmospheric partial pressure of CO_2 (pCO2) is set to a constant value of 385 ppm. The sea surface temperature was assimilated using high-resolution satellite data from GHRSST/JPL (https://podaac.jpl.nasa.gov/GHRSST), with a spatial resolution of 0.011°. Waves and sediment dynamics

130 were incorporated into the model (Ge et al., 2013). The model simulation covers a five-year period from 2013 to 2017, with a computational time step of 6 s.

A key configuration of parameters associated with DOC cycling in the coupled ERSEM model could be referred to Table S1 in the supplementary information. After undergoing univariate verification (chlorophyll-a) and multivariate verification through the application of principal component analysis (involving factors such as temperature, salinity, sediment, and

135 nutrients) in the Changjiang Estuary, this coupled model FVCOM-ERSEM was utilized within the framework developed by Ge et al. (2020) for further simulation and analysis of DOC.

2.4 Model setup for the study area

To enhance our understanding of DOC cycling in the Changjiang Estuary, we have compiled and synthesized historical data of DOC concentration based on observations. The procedure included data retrieval, extraction of image-based data, data

140 cleaning (involving the removal of duplicate and outlier values, exclusion of data outside the research area, and standardization of data units), as well as data visualization. The sites of DOC observation are shown in Fig. 2. A compilation of all data sources is listed in Table 1. In this compiled dataset, 869 data points are for the surface water, and 757 data points are for the bottom water. The dataset encompasses observation in all four seasons from the period of 2006 - 2017 in the region stretching from the south branch of the Changjiang Estuary to the adjacent coastal area.

3 Results

3.1 Model validation

The FVCOM-ERSEM coupled model has been proven to reproduce the distribution of chlorophyll-a, nutrients, and suspended sediment concentration in the Changjiang Estuary effectively (Ge et al., 2020). In this study, we assess the model
150 performance in the DOC concentration. Based on the compiled observational dataset, a comparison was conducted between the model results and the observation data (Fig. 3). Because the observational data include only monthly records, a point-to-point comparison was performed using model monthly-averaged data corresponding to the respective time periods, covering the simulation time from 2013 to 2017. The scatter plots (Fig. 3a, b) show a general agreement between the model results and observations with root mean square deviation (RMSD) of 282 and 249 mg m^{-3} in the surface and bottom water,
155 respectively, and the normalized RMSD is 0.25 for both layers. The statistical results of the DOC concentration comparison are displayed in the Taylor diagram (Fig. 3c), which shows that the centered RMSD for both the surface and bottom water is below 250 mg m^{-3}, with the standard deviation (SD) remaining around 300 mg m^{-3}. The correlation coefficient (CC) is close to 0.7. In addition, the spatial distribution of simulated DOC also shows a similar range with the observation data at a seasonal scale (Fig. S1 in the Supplementary Information). Based on these overall good agreements with observation data,
160 the model proves to be capable of capturing the distribution and variation of DOC in the Changjiang Estuary.
Figure 3. Model comparison with observational data for the period from 2013 to 2017 in the surface and bottom water, respectively. (**a**) and (**b**) represent scatterplot density maps of the model-observation comparison for the surface and bottom water, respectively. Color denotes the density of data points. (**c**) depicts the Taylor diagram, with the orange triangle representing the data in the surface water and the red diamond representing the data in the bottom water.

3.2 Distribution of DOC and its components tDOC and mDOC

To figure out the seasonal distribution characteristics of DOC, the seasonal average of the model results over the years 2013-2017 was calculated for all four seasons. Results indicate two distinct seasonal patterns in summer and winter (Fig. 4).

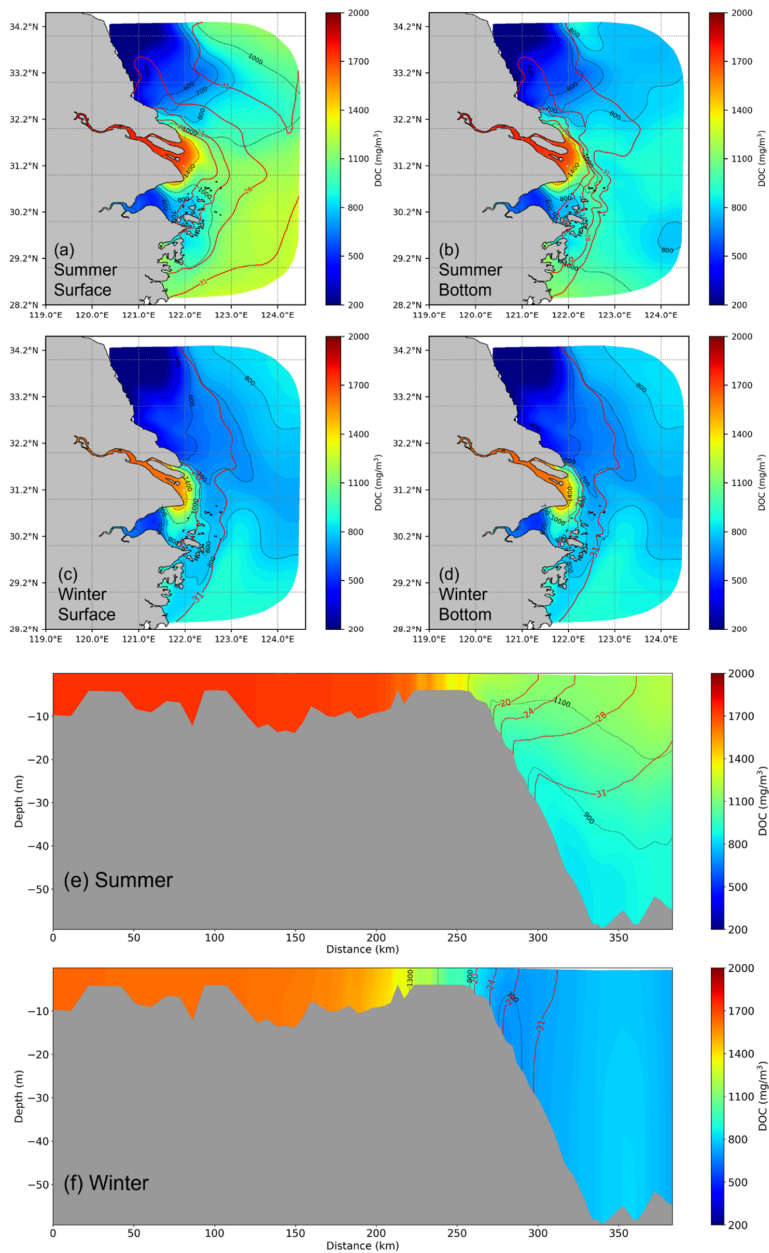
Spatially, there is a declining trend in DOC concentrations from the river to the offshore region. Maximum DOC concentrations are typically found close to the river channel. In general, DOC concentration in the summer season is higher than in the winter season and exhibits a more extensive distribution of high concentration values (> 1400 mg m^{-3}). This phenomenon is attributed to the increased summer runoff and prevailing southerly winds. In winter, driven by the northerly winds, the freshwater plume shifts southward, with a subsequent southward shift of DOC distribution. Meanwhile, because of reduced river runoff and strengthened tidal effects, the dispersion range of DOC is constrained. Furthermore, in summer, there is a significant contrast between the surface and bottom layer, while during the winter, the vertical differences are relatively minor. In the contour maps of DOC and salinity distribution, the nearshore DOC distribution closely resembles the salinity distribution, highlighting that physical mixing predominantly governs the distribution of DOC at the estuary. However, during the summer, at the boundary of transition between plume and saltwater (Salinity=31), the distribution of DOC shows no significant correlation with salinity, whereas, in winter, their distributions exhibit a higher consistency.


Figure 4. DOC spatial distribution is based on a five-year average for both surface and bottom layers and vertical distribution in summer and winter along the selected transect from river to shelf. The red contour lines represent salinity, while the black contour lines indicate DOC concentration.

Spatial distribution of DOC concentration along the pre-defined transect (Fig. 2) provides more details of the change from the estuary towards the offshore region (Fig. 4e-f). In summer, a notable stratification exists in the region where salinity exceeds 20 PSU along the transect. The vertical distribution of DOC is highly similar to the salinity contour within low- and mid-salinity (salinity<20) regions, showing aligning with conservative mixing with salinity, while the inconsistent distribution of DOC in higher salinity may be attributed to the dominance of other signals, such as local biogeochemical process in deep region. In winter, enhanced mixing due to surface cooling leads to a nearly homogeneous DOC concentration in the water column with little vertical gradient. These distribution characteristics suggest that in summer, the distribution patterns of DOC in the low- and mid-salinity area are dominated by physical hydrodynamics, while in the offshore area, there are other factors influencing the distribution of DOC. In winter, it is primarily driven by hydrodynamic factors.

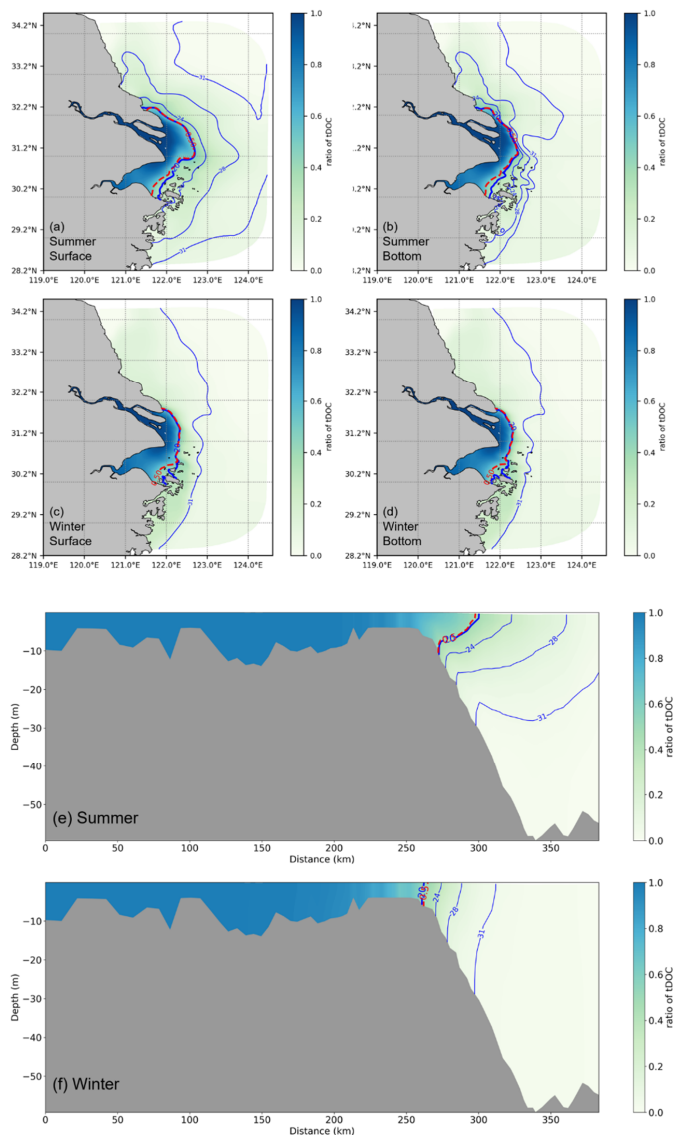
The total DOC concentration is divided into tDOC and mDOC for analysis of the origin. The proportion of tDOC shown in Fig. 5 shows that the isoline of 0.5, which indicates that the proportion of tDOC and mDOC is equal, is located quite close to the contour line of salinity of 20 PSU in both summer and winter seasons. It can be seen that the distribution of tDOC is largely constrained by the transport of diluted water. The extension of tDOC is broader, and differences between the surface and bottom layers are more pronounced in summer than in winter.


Figure 5. The proportion of tDOC in total DOC is calculated based on a five-year average in summer and winter. The proportion of horizontal distribution for both surface and bottom layers and vertical distribution in summer and winter. The blue contour lines represent salinity, with the red contour lines indicating a ratio of 0.5.

3.3 Time series variation of DOC in the estuary

To further figure out the driving mechanisms for the distribution of DOC and its components, the study area is divided into
205   four sub-regions (Fig. 6a, b) based on the distribution of salinity, namely the river channel, the river mouth, the river plume, and the open shelf. Considering the temporal variation of the river plume, delineation of the sub-regions is distinguished between wet (May to October) and dry (November to April) periods.

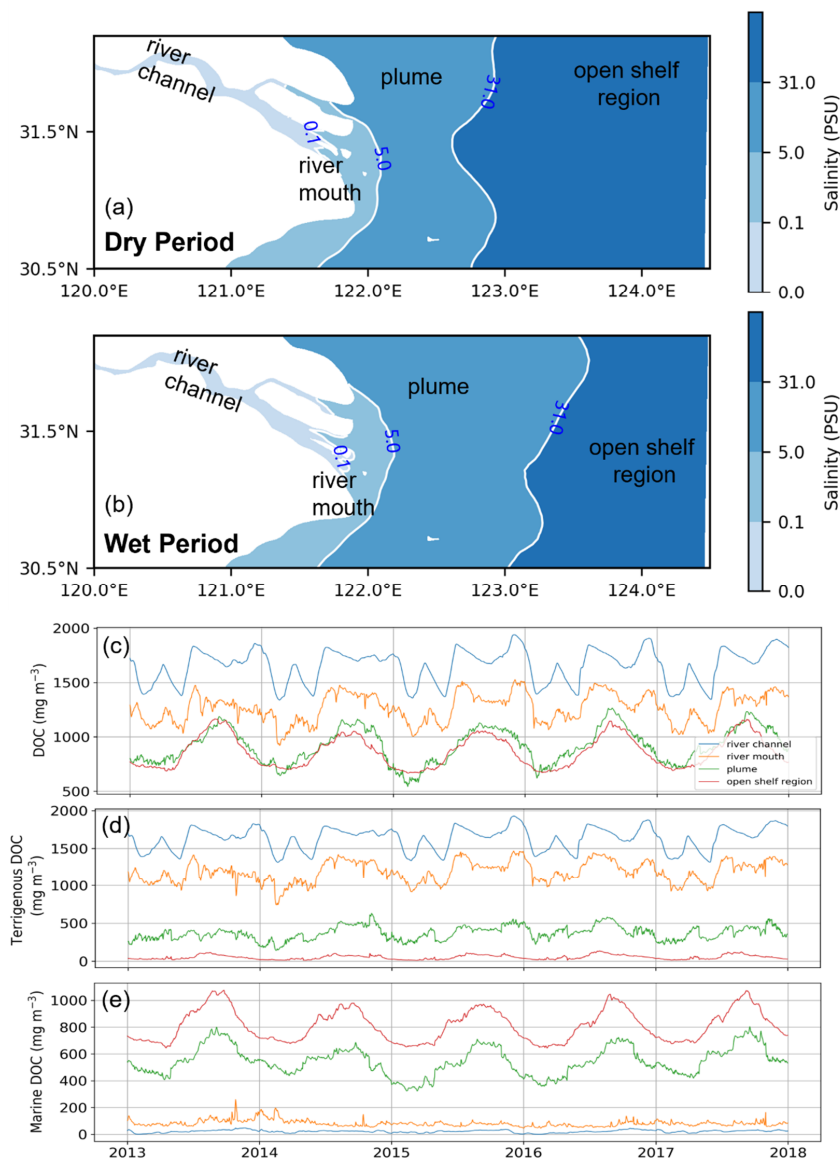
The time series of DOC and its components tDOC and mDOC spatially vertically averaged in each sub-region is shown in Fig. 6c-e. Concentration of the total DOC gradually decreases from the river channel to the continental shelf, and the
210   concentration in the plume area is comparable to that in the open shelf region. The temporal variation of DOC in the river channel is mainly influenced by the climatological average concentration of DOC input from the river boundary, which does not exhibit a distinct summer-high and winter-low single peak pattern. Instead, the temporal variation of the DOC from river discharge shows a generally lower level in the first five months of the year (Jan-May) compared to the following seven months (June-December) but superposed with large monthly fluctuations. Such river discharge-induced variation also
215   significantly affects the DOC concentration in the river mouth sub-region. By contrast, the plume and open shelf region exhibit pronounced summer-high and winter-low pattern with relatively smooth transition in spring and autumn. Our modeled variation of total DOC concentration is consistent with previous observational studies (Liu et al., 2014; Ji et al., 2021; Guo et al., 2021; Han et al., 2021). This variation is associated with the change of terrigenous and marine components (Fig. 6d, e). tDOC decreases gradually from the river to the open shelf region, whilst mDOC shows an opposite trend. The
220   river channel and river mouth sub-regions are dominated by tDOC, which contributes to more than 85% of the total DOC. In the plume area, the concentration of mDOC becomes larger than tDOC, suggesting a shift of dominance in the origin. The open shelf sub-region is dominated by mDOC, which takes up more than 90% of the total DOC.


Figure 6. The partition of the model study area into four sub-regions based on the vertical average of salinity (**a, b**). The region with salinity less than 0.1 PSU is classified as the river channel, 0.1-5 PSU is the river mouth, 5-31 PSU is the plume, and the reminder region with salinity greater than 31 PSU is defined as an open shelf region. Time series of the concentration of total DOC (**c**) and its components

tDOC (**d**) and mDOC (**e**) in the four sub-regions. Blue, orange, green, and red lines represent regions of river, river mouth, plume, and open shelf region, respectively, and all concentrations are regional vertical averages.

The distribution and cycling of DOC are intimately linked with various biogeochemical processes. The daily vertical average

230   rate in different processes that act as source or sink of DOC is calculated respectively in the model and shown in Fig. 7. Since tDOC in the study area derives exclusively from river discharge, only sink terms of tDOC are calculated. The decreasing rate of tDOC in the sink terms from the river to the open shelf region indicates that tDOC is gradually consumed, resulting in a reduction in concentration during its transport towards the open shelf. Among the sink terms of tDOC, photolysis exhibits pronounced fluctuations, while the rate of bacterial uptake shows relatively smooth variation along the

235   river-estuary-ocean continuum. The production (source) and consumption (sink) rates of mDOC both exhibit a gradual increase from the river to the open shelf region. mDOC production and consumption are more active from around January to July. After July, the production and consumption rates of mDOC declined rapidly and remained consistently low until the end of the year. Consequently, DOC concentration accumulates to its maximum during summer and gradually declines to its minimum in the winter (Fig. 6c). Among the production terms of mDOC, in the plume and open shelf region, phytoplankton

240   release exhibits the highest rate, followed by zooplankton release and bacterial release in descending order. mDOC is consumed mainly by bacteria. The bacteria uptake rate (sink) of mDOC is much higher than the bacterial production rate through release (source). The released mDOC from bacteria is converted into semi-refractory mDOC. In summary, bacterial uptake is the major process for the removal of DOC (mostly tDOC) in the river channel and river mouth regions. The plume region serves as a transitional zone, where the bacterial uptake rate of tDOC decreases while the bacterial uptake rate of

245   mDOC increases. Meanwhile, the production of mDOC by processes such as release from phytoplankton, zooplankton, and bacteria also becomes prominent in the plume region and offsets the loss of DOC. In the open shelf region, DOC (mostly mDOC) is mostly produced by phytoplankton release (source) and consumed by bacteria uptake (sink), with secondary contributions from zooplankton release and other processes.
Figure 7. Daily vertical average rate (Units: mg m^{-3} d^{-1}) of production (source) and consumption (sink) of tDOC (dashed lines) and mDOC (solid lines) in the four sub-regions. Positive values indicate sources, while negative values indicate sinks.

3.4 Transformation of DOC in the River-Estuary-Ocean Continuum

After deriving a general understanding of the distribution of DOC and its components, further analysis was conducted focusing on the transformation of DOC in the source-sink dynamics. Our results show that in summer, the transition from a net sink to a net source of DOC occurs gradually through the river-estuary-ocean continuum. The crucial interface for the shift between the net sink and the net source is located at the area characterized by a significant gradient of chlorophyll-a concentration. This interface is influenced by physical mixing and aligns closely with the contours of salinity (Fig. 8a, b). As shown in Fig. 5, tDOC is gradually diluted, mixed, and consumed by biogeochemical processes (photolysis and bacteria uptake) along the river-estuary-ocean continuum, whilst the activities of plankton and bacteria gradually intensify towards the open shelf, leading to a shift from tDOC-dominated to mDOC-dominated DOC. With production rates surpassing consumption rates, DOC accumulates in summer, implying a transformation of the estuary from a sink to a source of DOC. The change in the spatial gradient of Chlorophyll-a concentration serves as a practical indicator for this transformation (Fig. 8c, d).

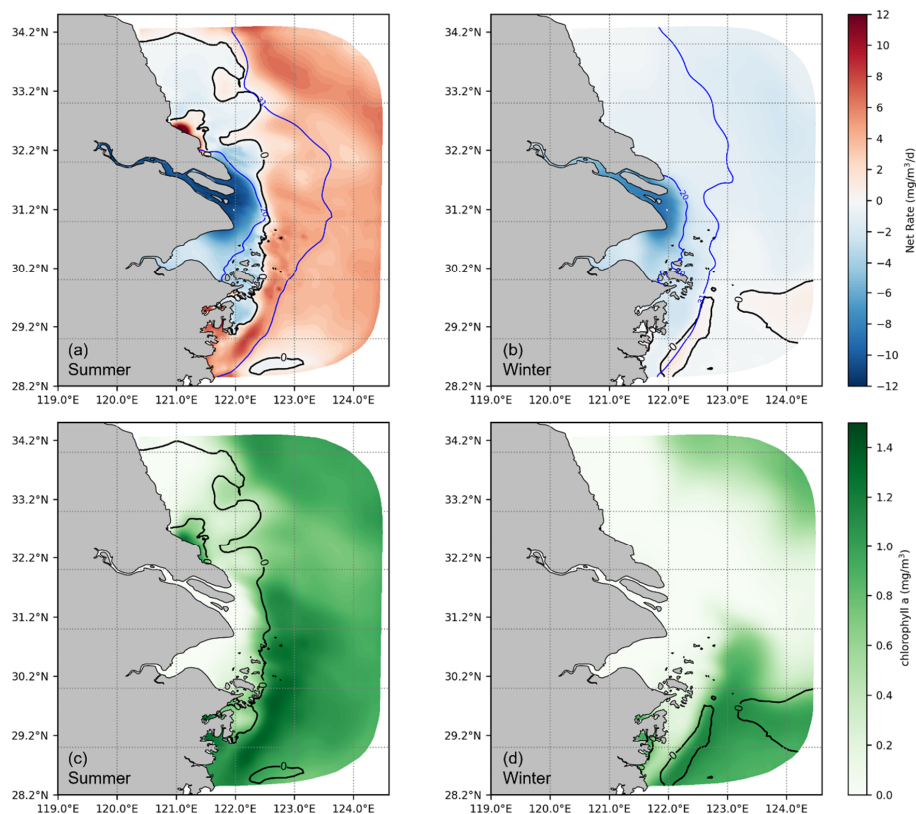
In winter, the majority part of the estuary acts as a DOC sink. During this season, with a low temperature (average
265   around 10 ℃) and limited nutrient fluxes from the river, biological activity rates are much reduced compared to summer.
The interface for the transition from sink to source is shifted offshore and to the southeast corner of the model area.


Figure 8. Vertical average net cycling rate of DOC (**a, b**) and chlorophyll-a (**c, d**). The solid black line indicates a net cycling rate at zero,
and the solid blue line represents the vertical average salinity (units: PSU).

270   Along the transect, starting from the river channel to the shelf, vertical averaged production and consumption rate of DOC
by each relevant process is calculated (Fig. 9). The result shows that in summer, among the production terms, the rate related
to bacteria is relatively stable along the transect. Production by both phytoplankton and zooplankton starts to increase where
salinity exceeds 5 PSU and continues until 30 PSU, where the growth of chlorophyll-a concentration is relatively stable.
Among the consumption terms, the rates of various processes exhibit minimal changes in the river channel and river mouth
275   regions. Upon entering the plume area, the rates of bacterial activity and photolysis of tDOC exhibit a decreasing trend.

Simultaneously, the bacterial consumption rate of mDOC gradually rises, assuming a dominant role before stabilizing. With regard to the change in the net rate (indicated by the solid black line in Fig. 9), the largest gradient is seen in the plume area, marked by a transition from negative values (sink) to positive values (source), and becomes smooth. This indicates a rapid and complex biogeochemical transformation of DOC in the estuary. In winter, the rates of all processes are reduced

280   compared to summer, remaining the significant rate transitions in the plume area. Compared to the summer season, planktonic organism rates reach their peak in the open shelf region, where chlorophyll-a concentration is maximal. The total consumption rate slightly exceeds the total production rate, resulting in an overall negative net rate along the entire transect.
Figure 9. Vertical average production and consumption rates of DOC along the transect from the river channel to the shelf in summer (**a**) and winter (**b**).

3.5 Budget analysis

To further identify the role of the Changjiang Estuary in the source-to-sink pathways of DOC, budget analysis was carried out for the whole model domain. In this study, budget analysis was based on the annual average over the five years (2013-2017). Input and output of DOC at the boundary, as well as production and consumption terms within the model domain, were taken into account. Results shown in Table 2 indicate that the Changjiang Estuary received 1.53±0.13 Tg/yr of DOC from the river, which is consistent with previous studies (Shi et al., 2016; Wang et al., 2012). The export of DOC to adjacent open ocean is 2.26±0.22 Tg/yr, greater than the input value. It should be noted that the export of mDOC refers to the net export (output – input). Therefore, the import of mDOC is indicated as 0. This result indicates that the Changjiang Estuary as a whole acts as a source of DOC. This is partly due to a larger production (28.91±1.07 Tg/yr), which exceeds the consumption (28.52±1.03 Tg/yr) of mDOC in the model domain, and partly due to the export of unconsumed tDOC from the upstream river. In the exported DOC, tDOC accounts for 0.69±0.08 Tg/yr (equivalent to ~31% of the total export), while mDOC contributes 1.57±0.18 Tg/yr. Since there is no local production of tDOC in the model domain, the ratio of the exported tDOC to the imported tDOC indicates that ~55% of imported tDOC from the upstream river is consumed within the Changjiang Estuary (by photolysis and bacterial uptake), and the rest 45% is exported to the open ocean. By contrast, mDOC is mostly (~96%) recycled within the model domain, despite that it accounts for a major portion (~69%) of the exported DOC.

Table 2. Budgets of annual mean input, output, and internal production and consumption of DOC with standard deviations in the Changjiang Estuary (units: Tg/yr, $1Tg=10^{12}g$).

Component	Import	Export	Production	Consumption
Total DOC	1.53±0.13	2.26±0.22	28.91±1.07	28.52±1.03
tDOC	1.53±0.13	0.69±0.08	0.00	0.92±0.05
mDOC	0.00	1.57±0.18	28.91±1.07	27.60±1.01

Table 3. Annual budget (mean ± standard deviations) of relevant biogeochemical processes and proportion of their contribution to the source and sink of DOC in the Changjiang Estuary.

Source and sink	Terms	Bulk (Tg/yr)	Proportion
Production	Bacteria	6.48±0.24	22.42%±0.11%
	Phytoplankton	15.29±0.62	52.91%±0.10%
	Zooplankton	7.13±0.32	24.67%±0.16%
Consumption	Bacteria (Marine)	27.60±1.10	96.79%±0.17%
	Bacteria (Terrigenous)	0.86±0.05	3.01%±0.17%
	Photolysis (Terrigenous)	0.060±0.005	0.20%±0.01%

To figure out the relative contribution of each biogeochemical process in the source and sink of DOC, the annual production and consumption of these processes are calculated. Results shown in Table 3 indicate that the ranks of the processes contributing to the production of DOC are phytoplankton excretion, zooplankton excretion, and bacterial excretion, with

310 respective proportions of 52.91%, 24.67%, and 22.42%, respectively. In the consumption category, the processes ranked from highest to lowest contribution are bacterial uptake of mDOC, bacterial uptake of tDOC, and photolysis, with respective proportions of 96.79%, 3.01%, and 0.20%. Based on the data above, it is evident that bacteria play a predominant role as the primary consumers in the degradation of tDOC, while the contribution of photolysis consumption is relatively minor in the whole estuary.

315 **4 Discussion**

4.1 The role of estuaries in mediating DOC flux between land and ocean

Our results reveal that the Changjiang Estuary plays a vital role in mediating the DOC flux between the land-ocean interface, not only as an important transport route for export of terrigenous DOC to open ocean but also as a reactor for biogeochemical cycling of DOC from both terrigenous and marine origins.

320 Existing literature reveals that a significant part of tDOC delivered from rivers worldwide is depleted before entering the open ocean (Hedges et al., 1997; Opsahl and Benner, 1997; Looman et al., 2019). This signifies that tDOC is removed (mineralized) by biological or abiotic processes within the estuary. A study of the Mississippi-Atchafalaya River system by Fichot and Benner (2014) suggested that biomineralization is the main process for the removal of tDOC in the system, and around ~40% of tDOC is removed during the transport towards the continental shelf within the estuary. Similar results

325 estimated that the removal of tDOC in the Mississippi River estuary is no less than 30-50% within high-salinity (>25 PSU) water mixing (Wang et al., 2004). In the York River estuary, Raymond and Bauer (2000) report the proportion of tDOC removed by bacteria is ~10%. Additional studies have also substantiated that estuaries serve as a reactor and filter for DOC cycling. A study of the Pearl River estuary by He et al. (2010) suggested microbial degradation as the primary bioprocess for the removal of DOC (~31% in the mixing zone). Another study reveals the loss of DOC in the Lena River estuary can reach

330 ~10-20% (Alling et al., 2010). Dai et al. (2012) estimated the removal of DOC in the Artic estuaries to be approximately 20%. Kumar et al. (2022) suggested that during the dry season, the Godavari estuary could remove ~33% DOC by photodegradation and microbial respiration. In the Changjiang Estuary, a series of 12-day incubation experiments showed that ~17% of estuarine DOC were removed after biodegradation (Guo et al., 2021). Surface microbial incubations showed that the deletion of DOC varied between 5% and 39% (Ji et al., 2021). In our simulations, results indicate that the removal of

335 tDOC can reach ~60% at an annual scale.

Our results (Fig. 9) show that fluctuations of the net cycling rate of DOC, especially between negative and positive values, mainly occur off the estuarine river mouth, namely the plume region and adjacent coastal waters, whilst within the river channel and around the river mouth the net cycling rate remains relatively stable and persistently negative throughout the

year. Raymond and Bauer (2001) estimated that, despite around half of tDOC being depleted, the York River Estuary acts as
340 a net source of DOC due to the supplementation of autochthonous mDOC. Our result showing the main contribution of
phytoplankton to the export of estuarine DOC is consistent with this study. In addition, a slight loss of DOC at low salinity
and a primary source at mid salinity found in the plume of the Changjiang Estuary found in our results also show similarity
with the study from the Mississippi River by Fichot and Benner (2014).

4.2 Future research needs

345 The considerations of our model regarding sediment flocculation and adsorption are relatively simple by assuming a constant
rate (Table S1) and may require further development and improvement. The quantitative impact of flocculation on DOC in
the Changjiang Estuary remains unknown. We assume that the simplifications have a limited effect on the cycling of DOC in
the estuary, as indicated by studies from other estuaries. For example, Søndergaard et al. (2003) found that the flocculation
of DOC with a salinity gradient ranging from 0 to 25 ppt was not a primary removal process, resulting in only a marginal
350 decrease of 2-5%. In another study by (Khoo et al., 2022), the flocculation removal of DOC within a salinity range of 12-25
PSU was also found to constitute a minor proportion (~3.5%).
Research on the cycling of DOC in the river-estuary-ocean continuum is essential for understanding carbon dynamics and
coastal ecosystems, particularly in the context of intensified human activities on land and ocean, as well as global warming-
induced change in the occurrence of extreme climate events. With increased extreme climatic events, estuaries are
355 susceptible to changes in nutrient and organic matter transport and transformations, which impact the structure and function
of estuarine ecosystems (Wetz and Yoskowitz, 2013; Leal Filho et al., 2022). As a key component of ecosystems, the
transformation, variation, and potential ecological effects of DOC in estuaries require further investigation. Ongoing human
activities are causing continuous changes in many estuarine and coastal ecosystems (Cloern et al., 2016). The long-term
trends and potential shifts in DOC cycling in estuaries under human influence also need further investigation.

360 **5 Conclusions**

A physical-biogeochemical coupled model FVCOM-ERSEM was employed to simulate the sources and sink of DOC in the
Changjiang Estuary. Through an analysis of variation, transformation, and budget estimation of DOC in the river-estuary-
ocean continuum, we derived insights into the influencing factors of DOC from both terrigenous and marine origins in the
Changjiang Estuary. Additionally, we identified patterns of source-sink variations in the DOC dynamics. The primary
365 conclusions drawn from our study are as follows:
During summer, the distribution of DOC is jointly governed by hydrodynamic and biogeochemical processes, whereas in
winter, it is mainly controlled by hydrodynamics. Within the Changjiang Estuary, the river channel and river mouth are
primarily dominated by tDOC, while the plume and open shelf region are dominated by mDOC.

In summer, the plume region serves as a transitional zone where the dominated source of DOC shifts from terrigenous to
370   marine origin, as well as a shift from a sink to a source along the river-estuary-ocean continuum. The transition from
terrigenous-dominated to marine-dominated DOC occurs primarily around a salinity contour line of 20 PSU. Furthermore,
the offshore coastal region predominantly acts as a source, characterized by a higher DOC production rate. In winter, a vast
part (>90%) of the estuary functions as a sink.

Analysis of the budget of terrigenous and marine components suggests that the majority of tDOC (~55%) undergoes
375   depletion within the Changjiang Estuary at an annual scale. DOC exported to the open ocean mainly originates from mDOC.
The proportions of tDOC and mDOC export are approximately 31% and 69%, respectively. Based on our results, it can be
inferred that the biogeochemical processes within the Changjiang Estuary play a crucial role in supporting the production
and export of DOC to the open ocean. Overall, phytoplankton emerges as the primary contributor to the generation and
export of estuarine DOC, and the gradient variations of chlorophyll-a serve as practical indicators of the source-sink
380   transitions.
